

Poeciliid male mate preference is influenced by female size but not by fecundity.

While female mate preference is very well studied, male preference has only recently begun to receive significant attention. Its existence is found in numerous taxa, but empirical research has mostly been limited to a descriptive level and does not fully address the factors influencing its evolution. We attempted to address this issue using preference functions by comparing the strength of male preference for females of different sizes in nine populations of four poeciliid species. Due to environmental constraints (water toxicity and surface versus cave habitat), females from these populations vary in the degree to which their size is correlated to their fecundity. Hence, they vary in how their size signals their quality as mates. Since female size is strongly correlated with fecundity in this subfamily, males were sequentially presented with conspecific females of three different size categories and the strength of their preference for each was measured. Males preferred larger females in all populations, as predicted. However, the degree to which males preferred each size category, as measured by association time, was not correlated with its fecundity. In addition, cave males discriminated against smaller females more than surface males. These results suggest that factors other than fecundity have a stronger influence on female fitness in these species.

8 **Introduction:**

10 The existence and evolution of female mate choice has received substantial attention in
12 both theoretical and empirical grounds. However, male mate choice has been comparatively
14 neglected until recently. This is because females typically have a larger a priori investment in any
16 given mating event, and they are also inherently limited in the number of offspring they are able
18 to produce (Trivers 1972). The selective pressures giving rise to female mate choice are therefore
20 obvious. However, while these pressures are often stronger in females, similar pressures are also
22 experienced by males in many species. Males are limited in the proportion and quality of females
24 they are able to fertilize, and can therefore maximize their fitness by selectively allocating their
resources towards certain females. Theory thus predicts that male mate choice can be selected for
under the following circumstances: 1) There is substantial male effort in terms of searching,
courtship, mating, and mate guarding (Pomiankowski 1987); 2) Females are scarce due to a
biased operational sex ratio (van den Berghe & Warner 1989); 3) Female quality varies
(Johnstone et al. 1996); 4) Males invest in parental care (Sargent et al. 1986); and 5) Males'
mating opportunities are limited and/or insemination success varies between different females
(Nakatsuru & Kramer 1982; Verrell 1985; also see reviews of Bonduriansky 2001; and Edward &
Chapman 2011).

26 There is some evidence that these factors have indeed resulted in male preference in
28 species ranging from sexually cannibalistic arthropods, fish and birds with heavy parental
investment, and polygynous species without parental care (see reviews by Amundsen 2000;
30 Bonduriansky 2001; Edward & Chapman 2011). However, it difficult to determine the specific
factors driving the evolution of male choice in these systems since multiple factors predicted to
32 drive male mate choice evolution are present in these species. Previous empirical research has
often been limited to demonstrating the existence of male mate choice and describing its
34 manifestation in particular species. We are not aware of research examining the evolution of male
preference in response to specific selective pressures. We attempted to address this by comparing
poeciliid populations in which variation in female quality is likely to be the main driving force
behind male choice evolution.

36 Poeciliids are a family of internally-fertilizing, promiscuous fish that form mixed-sex
shoals and give birth to live young. Previous studies have demonstrated male preference for
38 larger females in many species (Abrahams 1993; Bisazza et al. 1989; Dosen & Montgomerie

2004a; Gumm & Gabor 2005; Herdman et al. 2004; Hoysak & Godin 2007; Jeswiet & Godin
40 2011; Plath et al. 2006; Ptacek & Travis 1997b). This is likely a result of the strong correlation
between female size and fecundity (Herdman et al. 2004; Hughes 1985; Marsh-Matthews et al.
42 2005; Milton & Arthington 1983; Reznick & Endler 1982; Riesch et al. 2009b), suggesting that
size is used as a signal of female quality and has played a role in the evolution of male mate
44 choice.

While previous studies have shown that males prefer more fecund females, how the
46 strength of this preference changes as female fecundity evolves has not been investigated. To
address this, we selected a number of populations from four poeciliid species (*Poecilia mexicana*,
48 *Limia sulphurophila*, *Gambusia sexradiata*, and *Gambusia eurystoma*) that exhibit different
relationships between female size and fecundity. These different relationships evolved as a
50 response to living in different habitats (Fig 1). Living in a toxic habitat or living in a cave
independently led to larger and fewer offspring; in other words, larger and fewer offspring are
52 found in toxic habitats (whether on the surface or in a cave), as well as cave habitats (whether
toxic or nontoxic); smaller and more numerous offspring are found in nontoxic surface habitats
54 (Riesch et al. 2009b; Riesch et al. 2010b; Riesch et al. 2010c). Because female size and fecundity
decoupled from each other in this system, it is possible to comparatively determine how female
56 fecundity affects the evolution of male preference.

Mate preference is most commonly studied using dichotomous choice tests, where focal
58 individuals are given a choice between two stimuli (Ritchie 1996). While this is a powerful
approach to assess mate preferences within populations, this approach makes it difficult to
60 compare between populations. Absolute preference functions are an alternative method that
allows the preferences between populations to be compared (Wagner 1998). Absolute preference
62 functions measure the preference of individual males for females varying in a continuous trait.
This is done by sequentially presenting individual females to each male, allowing the shape of a
64 male's preference for that trait to be quantified. The resulting correlation can thus be thought as
being the probability that a given male will accept a particular female trait (Ritchie 1996). Such
66 association preferences are commonly used to study male mating preferences in poeciliids and
have been shown to correlate well with actual mating preferences (Dosen & Montgomerie 2004b;
68 Plath et al. 2006; Schlupp & Ryan 1997; Wong et al. 2005).

The present study had two goals; 1) to test whether male preferences can be detected using preference functions, and 2) to see if male preference tracks changes in female fecundity in these populations. Our prediction was that male choice would be more acute in populations from toxic environments, where the relative increase in female fecundity is higher as compared to surface populations.

74 **Materials & Methods**

Species and populations:

76 Nine populations of four poeciliid species representing different habitat types were used (summarized in Table 1). *Gambusia eurystoma* is a surface species endemic to the sulfidic Baños del Azufre in Tabasco, Mexico (Tobler et al. 2008c). *Limia sulphurophila* is another surface fish living in a sulfidic habitat, but it is endemic to a small pool in the island of Hispaniola (Rivas 80 1984). The population of *G. sexradiata* used lives in non-sulfidic surface waters. The six populations of *P. mexicana* used in this study live in different habitats. The Oxolotan population 82 is named after the non-sulfidic, surface river it originates from. The PS0 population also lives in a surface creek, but whose water is sulfidic. The water from this creek, named El Azufre, originates 84 from Cueva del Azufre, a sulfidic cave from which three of the other populations originated. These populations, inhabiting a dark and toxic environment, are the PSV, PSX, and PSXIII 86 populations (For a schematic map of the region and of the cave, see Plath et al. 2010, and Tobler et al. 2006). They are named after the chamber of the cave in which they live. The sixth 88 population is the Luna population, which originates from a non-toxic cave of the same name (Tobler et al. 2008c).

90 Fish from all of the populations are maintained in flow-through stock tanks in the Aquatic Research Facility at the University of Oklahoma, and have been in captivity for varying lengths 92 of time (Table 1). These tanks were the immediate source of the fish used in this study. All are maintained in nonsulfidic, common garden conditions inside a greenhouse that receives natural 94 light.

Fish from the stock tanks were caught with a small seine and segregated by sex. Mature 96 females were then selected using minimum standard length (tip of the snout to the end of the vertebral column) as the criterion for sexual maturity. Due to natural size differences between 98 species, the exact criterion used varied (*P. mexicana*: 29mm for the Luna population, and 30mm for all others; *G. eurystoma*: 22mm; *G. sexradiata*: 18mm; and *L. sulphurophila*: 21mm). The

100 mature females were then sorted into roughly equally sized groups according to size (small,
medium, and large), and were then placed in different 38L stock tanks. Males were randomly
102 assigned an ID number that determined the order in which they would be tested, and they were
housed in individual 5L tanks that were out of sight of the females.

104

Experimental Setup:

106 Preference functions are established by measuring the amount of time a focus individual
spends in association with different stimulus fish. These stimulus fish are presented sequentially
108 and differ in the variable in question. In this case, females of different sizes were sequentially
presented to a male, and the time that the male spent with each female was recorded. To do this, a
110 76L aquarium, with gravel spread evenly to reduce potential bias from fish being distracted by
uneven gravel, was divided lengthwise into three equal sections with two vertical lines drawn on
112 the glass (Fig 2). The outer two sections were considered the "preference zones", while the
central section was considered a "neutral zone".

114 Three hollow square prisms (or "cylinder") made out of clear plexiglass were located in
the center of each section of the tank. The cylinder in the center of the tank had solid walls, while
116 the two outer cylinders were perforated with seven circular holes 6mm in diameter to allow for
chemical and mechanosensory signals. Chemical and mechanosensory signals have been found to
118 be important factors in poeciliid mating behavior, influencing the repeatability of individual
preferences as well as the overall preference (Coleman 2011; Hoysak & Godin, 2007; Plath et al.
120 2006; Rüschenbaum & Schlupp 2013). All three cylinders were 8.5cm long by 8.5cm wide, and
tall enough to stick through the water. To reduce visual distractions, three sides of the tank were
122 covered. The observer sat in a chair 2m from the tank and observed the fish through the front
pane of the tank. A light with a 60W, "soft white" light bulb was placed 30cm above the center of
124 the tank for illumination.

126 Testing Procedure:

A randomly selected female from the predetermined size category (small, medium, or
128 large) was placed in the cylinder in one of the outer preference zones. The order of the females
which each male would be presented with, as well as the side in which each female would be
130 placed, were randomly determined. A male was then placed in the central cylinder for 5 minutes.

132 After the 5 minutes of acclimation, the cylinder around the male was gently removed. Using two
stopwatches, the amount of time the male spent in the preference zone containing the female was
measured by the observer. This was done for 5 minutes, after which the fish were removed from
134 the tank. The water was then stirred to homogenize any lingering chemical signals from affecting
the results of future trials. Another pair of fish was then placed in their corresponding cylinders to
136 acclimate. Every three pairs, a partial water change was also made previous to the acclimation
period of the next fish. Male weight and standard length were also measured and used as
138 covariates, but were not included in the final model because neither was significant.

140 Statistical analysis:

After checking the assumptions, a mixed between-within subjects ANOVA was performed
142 to determine the effect of two habitat variables on male preference for small, medium, and large
females. The two habitat variables used were "cave habitat", whether the population originated
144 from a cave or from a surface stream, and "toxicity", whether the population originated from a
toxic or non-toxic stream. Because the raw results were not normally distributed, the male
146 preference variables were reflected and square root transformed to meet the normality
assumption.

148 Experiments were approved by the University of Oklahoma IACUC (R09-030).

Results:

150 All statistical assumptions were met after the data transformation, with the exception of
homogeneity of variances for the time males spent with medium females ($p = 0.026$). However,
152 this violation was not deemed to be severe enough to invalidate the ANOVA. As expected, there
was a significant main effect for time spent with larger females, regardless of the habitat of origin
154 (Wilks' Lambda = 0.911, $F_{(2, 123)} = 5.99$, $p = 0.003$, $h_p^2 = 0.089$). The main between-subjects effect
comparing toxicity was not significant ($F_{(1, 124)} = 0.047$, $p = 0.829$, $h_p^2 = 0.000$), nor was the main
156 effect for cave habitat ($F_{(1, 124)} = 1.043$, $p = 0.309$, $h_p^2 = 0.008$), or the interaction between cave
habitat and toxicity ($F_{(1, 124)} = 0.011$, $p = 0.917$, $h_p^2 = 0.000$). These results suggest that, correcting
158 for the effect of female size, habitat type does not affect male preference values.

There was also a significant interaction between cave habitat and the time males spent
160 with females (Wilks' Lambda = 0.934, $F_{(2, 123)} = 4.36$, $p = 0.015$, $h_p^2 = 0.066$; Fig 3). However, there

was no significant interaction between the time males spent with females and the toxicity of the
162 habitat from which they originated (Wilks' Lambda = 0.996, $F_{(2, 123)} = 0.26$, $p = 0.77$, $h^2_p = 0.004$;
Fig 4). There was also no significant interaction between time, cave habitat, and toxicity together
164 (Wilks' Lambda = 0.956, $F_{(2, 123)} = 8.86$, $p = 0.06$, $h^2_p = 0.044$). These results suggest that the
presence or absence of hydrogen sulfide in the population's habitat of origin does not influence
166 males' preference for female size, but the cave habitat does. Descriptive statistics are summarized
in Table 2.

168 **Discussion:**

As predicted, males did exhibit a general preference for larger females when all
170 populations were considered in aggregate. This result is consistent with previous
dichotomous-test studies finding preference for larger females in poeciliids (Bisazza et al. 1989;
172 Herdman et al. 2004; Hoysak & Godin 2007; Jeswiet & Godin 2011; Plath et al. 2006) and
indicates that absolute preference functions are an accurate tool to study individual preferences.
174 Because preference functions can be used to compare preferences between individuals, they can
also be used to address a more specific and broader range of questions than is possible using only
176 dichotomous choice tests.

In addition to an overall preference for larger females, the strength of male preference
178 should reflect how tightly correlated female size is with female fecundity. The populations tested
originated from habitats with different combinations of two variables- water toxicity as a result of
180 the presence or absence of H₂S ("toxicity"), and epigeal or hypogean habitat ("cave habitat").
Previous studies have shown that in *P. mexicana* (Riesch et al. 2009b; Riesch et al. 2010c), as
182 well as in *G. sexradiata* and *G. eurystoma* (Riesch et al. 2010b), female fecundity is strongly
correlated with toxicity. Females from toxic habitats have much larger, but fewer, offspring.
184 Because of this, there is a larger change in fecundity from small to large females in nontoxic
habitats. The main hypothesis was therefore that the preference function of males from toxic
186 habitats would be less steep than that of males from nontoxic habitats. The results did not support
our hypothesis, as there was no significant interaction between time spent with a female and the
188 toxicity of the habitat the male originated from.

This result suggests that the change in female fecundity experienced from benign to toxic
190 habitats is only weakly correlated with the change female quality. The reason for this is unclear
and could be due to a combination of factors. It is possible that female size in nontoxic habitats is

192 correlated with increased female mortality and/or with a decrease in offspring quality. An
alternative possibility is that female size and quality are highly correlated, but that there has been
194 insufficient time for male preference to change as a response to female adaptation. It is currently
unknown how long the populations in toxic habitats have been adapting to their environments,
196 and how recently the changes in female fecundity have evolved. Since male preference is likely
under weaker selection than other traits, it is possible that males from toxic populations have
198 either not had a sufficient amount of time to adapt, or that the amount of gene flow from nontoxic
populations has been able to counteract the effects of selection. It is currently unknown how
200 much gene flow there is between toxic (*P. mexicana*: PS0, *G. sexradiata*: populations not used in
the present study) and nontoxic (*P. mexicana*: Oxolotan, *G. sexradiata*) surface populations.

202 While the amount of gene flow between toxic and non-toxic populations still needs to be
determined, it is known that there is very little gene flow between *P. mexicana* populations from
204 the Cueva del Azufre (PSV, PSX, and PSXIII) and those in the surface (Plath et al., 2010). The
genetic isolation of cave fish from surface fish might be an important reason why cave habitat did
206 have a significant effect on male preference. This difference seems to be mainly derived from
cave males' relatively low preference for small females (Fig 3), as the change in preference for
208 medium to large females is nearly identical in males from both habitats. This suggests that males
are not responding to fecundity or offspring size per se, since one would expect that the change of
210 preference from medium to large females would differ between the two environments. This same
logic also suggests that the difference is not due to cave males being choosier than surface males.
212 If males preferred larger females due to the cave habitat leading to a greater cost in male effort,
males would disproportionately prefer large females over medium females as well. Instead, these
214 results indicate that there is a relative disadvantage for cave males to mate with smaller females,
which could result if small cave females have a lower fitness than small surface females.

216 A fitness difference could occur if mortality rates for small cave female are higher than
those of medium or large females, perhaps as a result of differential predation pressures. No
218 direct evidence exists on the relative predation pressures between the two habitats, but there is
reason to believe that this possibility might be true. Cave populations of *P. mexicana* are known
220 to be preyed upon by predators which hunt by sensing tactile and/or chemical signals from fish in
close proximity (Horstkotte et al. 2010; Tobler et al. 2008a; Tobler et al. 2009), and may prey
222 disproportionately upon smaller females. At the same time, surface populations experience very

different predation pressures: surface fish are preyed upon by large visual predators (Riesch et al. 2009a, 2010a; Tobler et al. 2006) that target larger fish (Trexler et al. 1994). Thus, medium and large surface females are likely to experience greater predation pressure than small females.

In summary, we have shown that (1) male preference for larger female size exists. This is consistent with previous research, indicating that absolute preference functions are a valid approach in this system. (2) Hydrogen sulphide does not affect the shape of male's preference function for female size in this system. Since H₂S greatly affects female fecundity, this suggests that inter-population differences of fecundity are not very highly correlated with inter-population differences in fitness. Alternatively, there has not been enough time or enough selection pressure to allow male preference to evolve as a response to changes in female fecundity, or gene flow has been large enough to negate the effects of these pressures. (3) Cave habitat, independent of water toxicity, does affect male preference. Cave males had a relative lack of preference for small females. We suggest that this could be a result of differences in predation pressure which could lead to relatively increased mortality for small females in the caves, relatively increased mortality for medium and large females in the surface, or both. If true, this would highlight the role that predators play in the evolution of male mate choice.

Figure 1

Effect of habitat toxicity on the size/fecundity relationship

Figure 1: Schematic illustration of the previously-established relationship between female poeciliid size and her fecundity in toxic and non-toxic habitats.

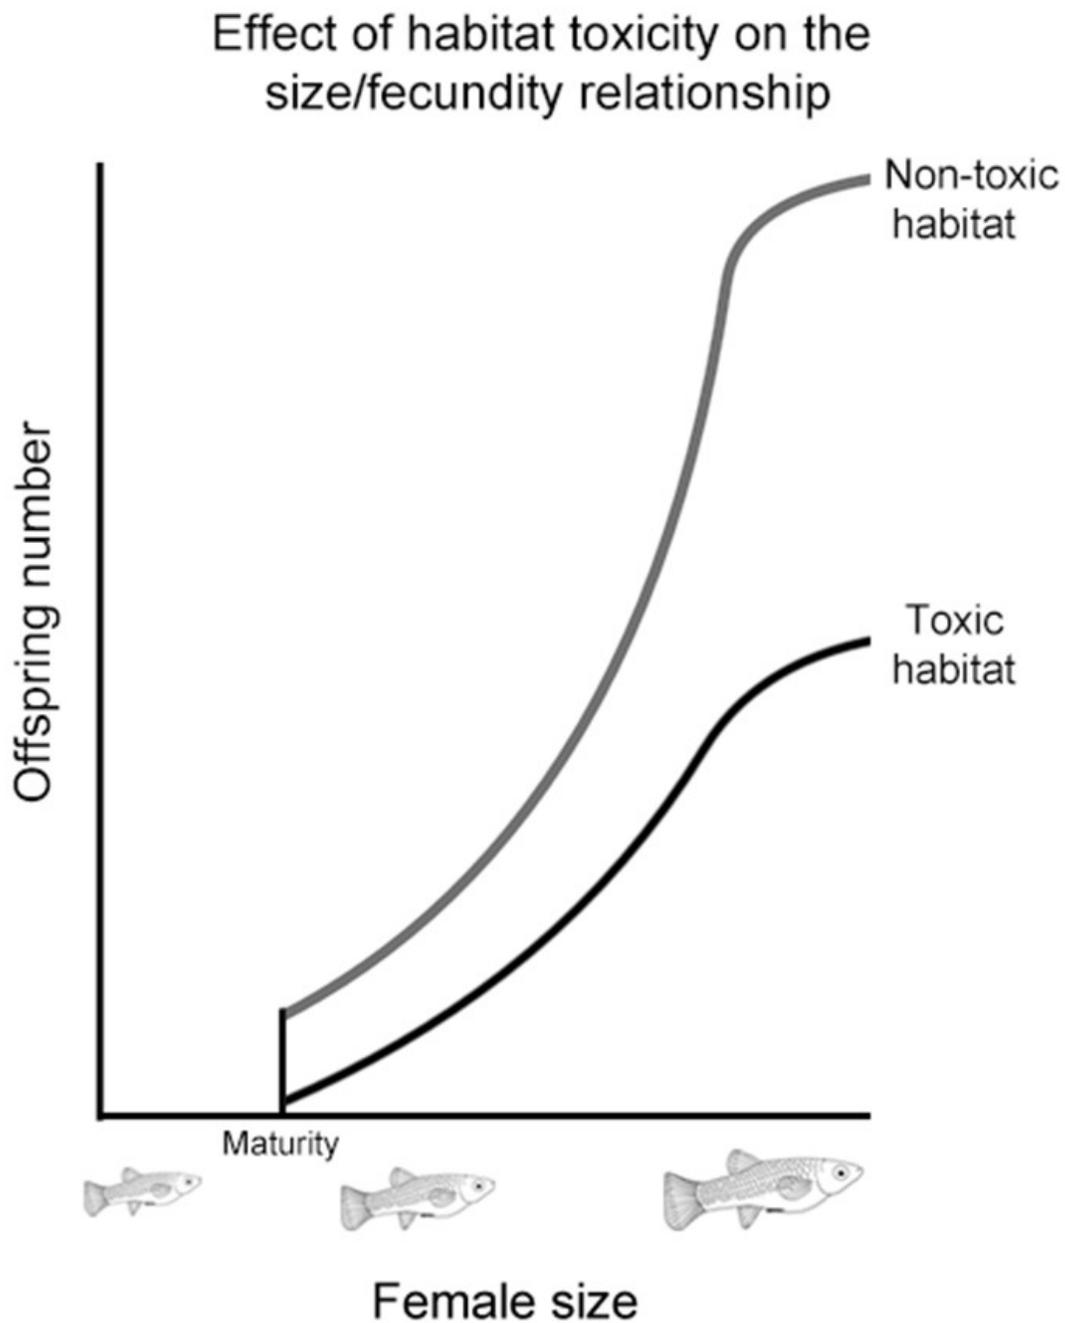

Table 1 (on next page)

Populations used

Table 1: Collection details and habitats characteristics of the populations from which the individuals used originated. All individuals were descendants of these original populations, and were raised in common garden conditions.

Population	Source location	Year	Toxic/non-toxic	Cave/Surface
<i>P. mexicana</i> -Oxolotan	17°26'55"N 92°45'55"W	2005	non-toxic	Surface
<i>P. mexicana</i> -PS0	17°26'30"N 92°46'30"W	2005	Toxic	Surface
<i>P. mexicana</i> -Luna	17°26'35"N 92°46'39"W	2006	non-toxic	Cave
<i>P. mexicana</i> -PSV	17°26'30"N 92°46'30"W	2005	Toxic	Cave
<i>P. mexicana</i> -PSX	17°26'30"N 92°46'30"W	2005	Toxic	Cave
<i>P. mexicana</i> -PSXIII	17°26'30"N 92°46'30"W	2005	Toxic	Cave
<i>G. eurystoma</i>	17°33'10"N 92°59'51"W	2006	Toxic	Surface
<i>G. sexradiata</i>	17°59'56"N 93° 8'11"W	2006	non-toxic	Surface
<i>L. sulphurophila</i>	18°23'52"N 71°34'12"W	2006	Toxic	Surface

Figure 2

Experimental setup.

Figure 2: Schematic representation of the experimental setup during acclimation period. Gravel and cylinder perforations were omitted for clarity.

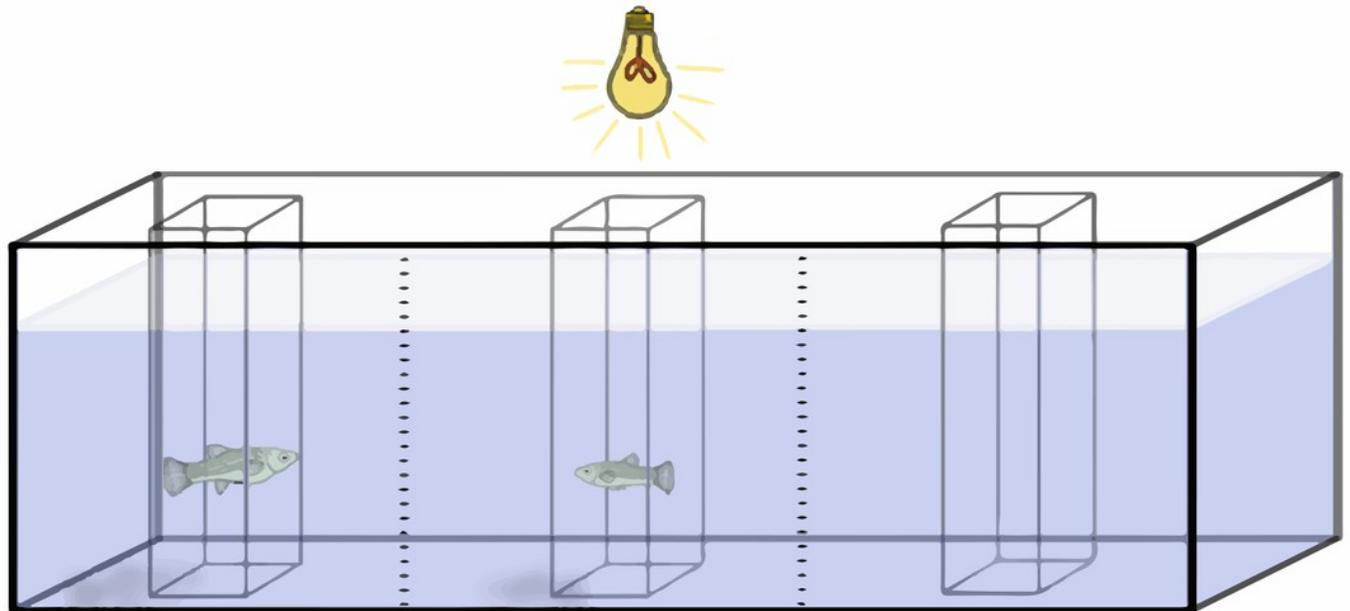

Figure 3

Male preference for female size (cave vs. surface)

Figure 3: Average transformed male preference for female size in cave vs. surface habitats. There is a significant difference between the two preference functions.

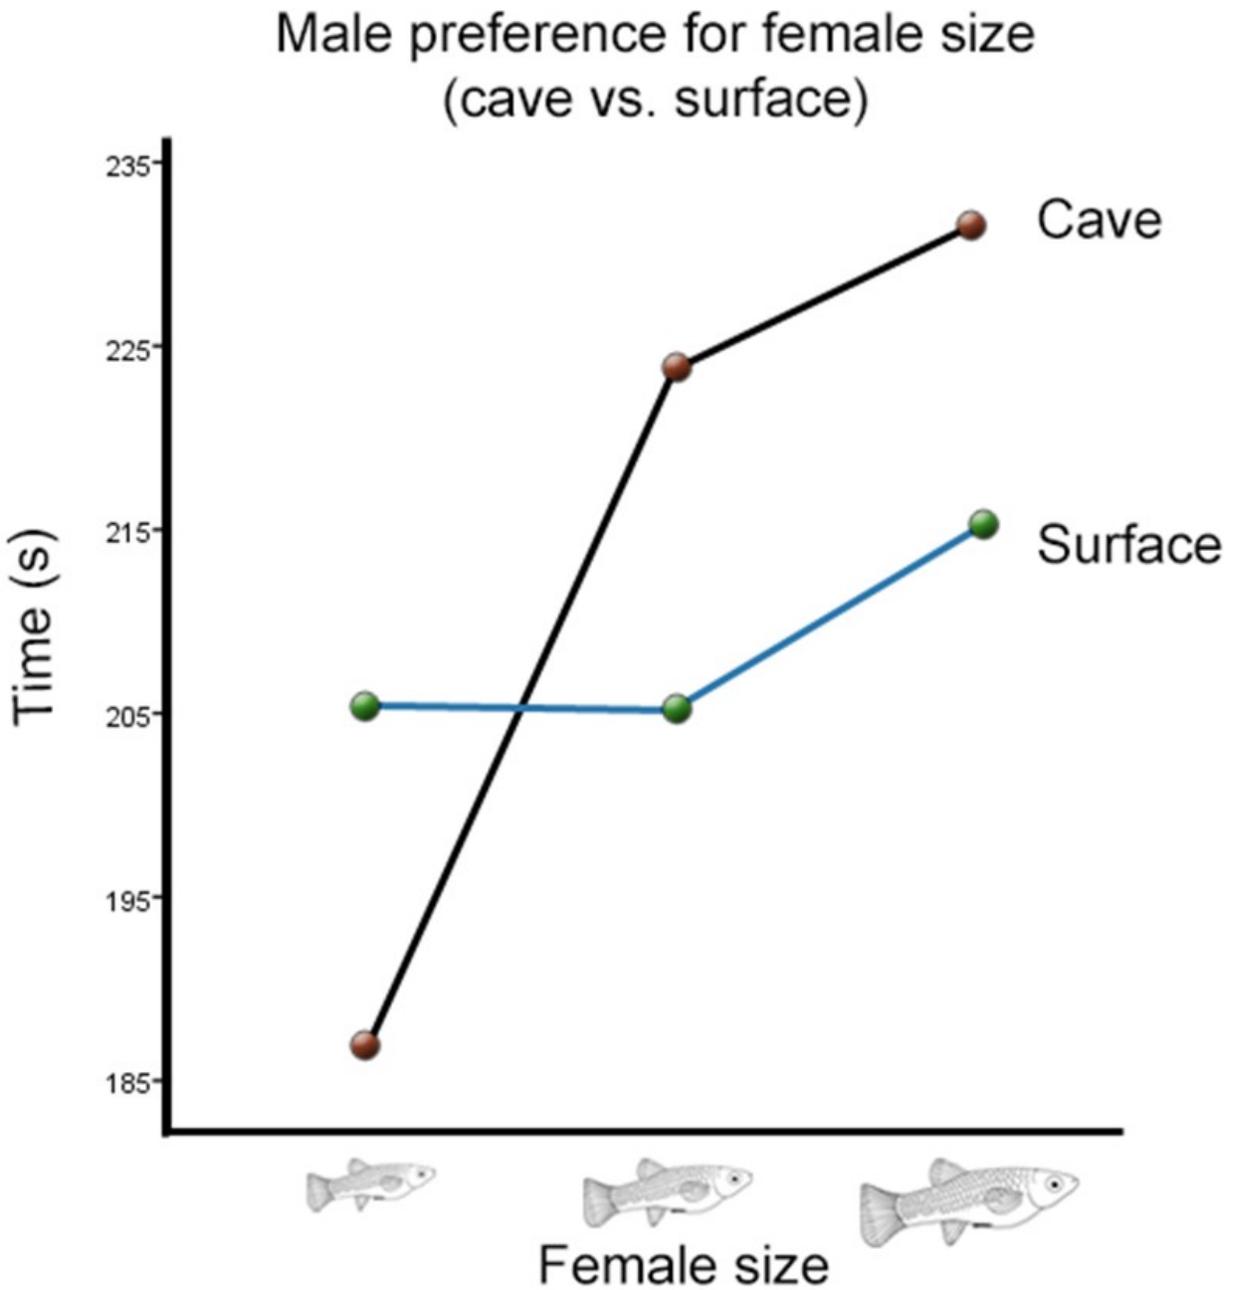

Figure 4

Male preference for female size (toxic vs. non-toxic)

Figure 4: Average transformed male preference for female size in toxic vs. benign habitats. Preference functions are not significantly different from each other.

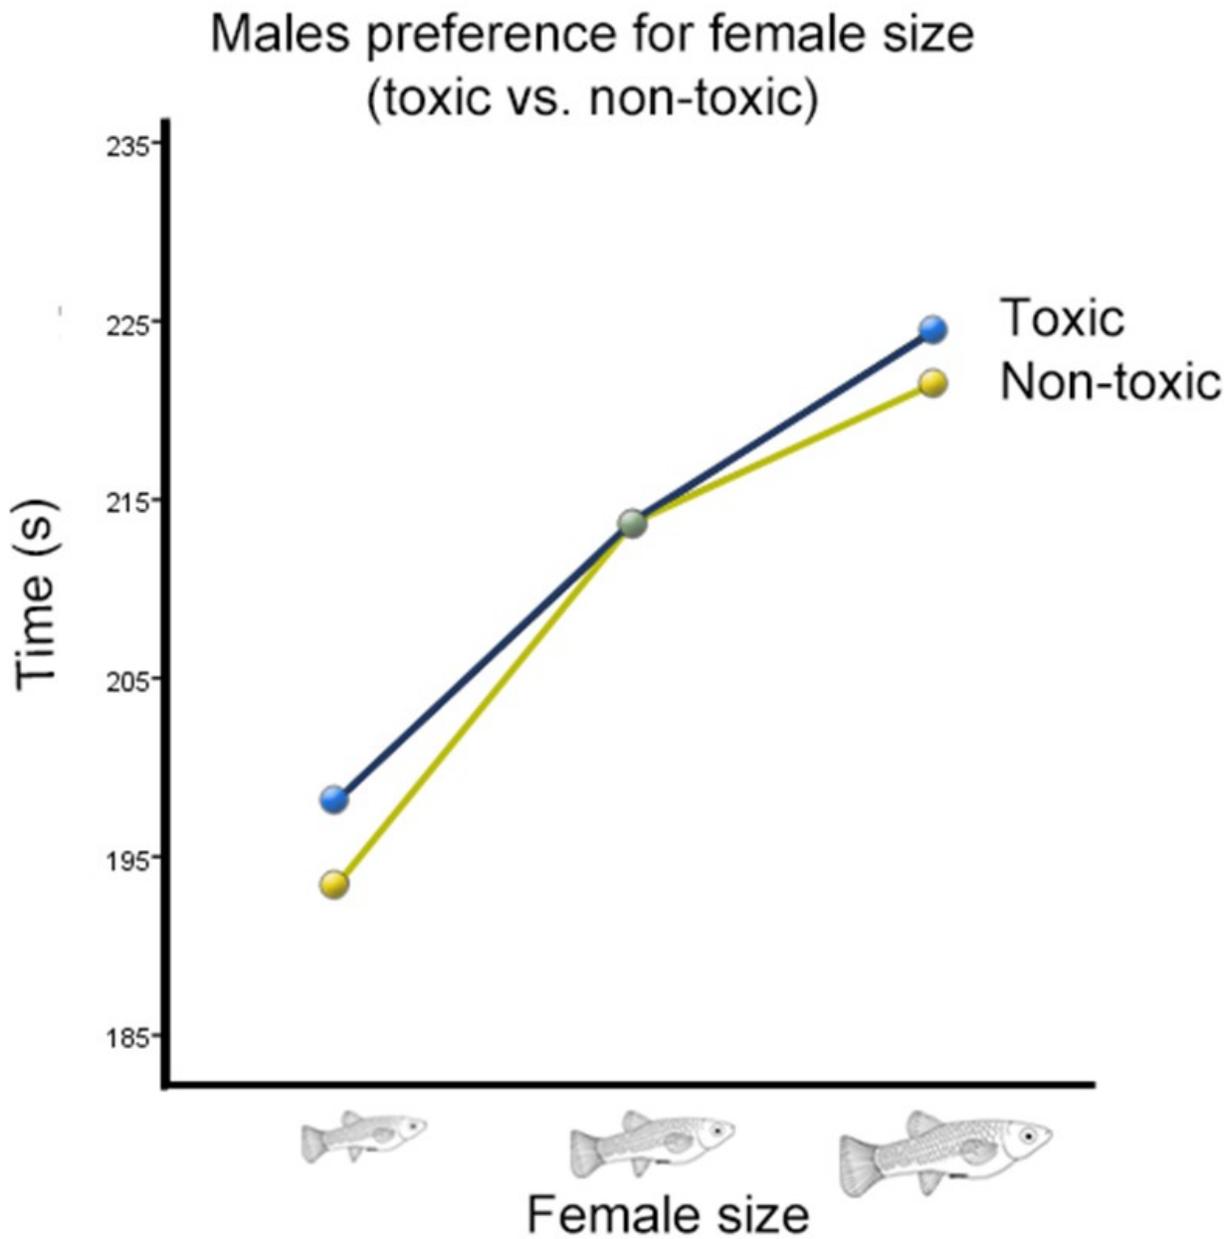

Table 2(on next page)

Descriptive statistics

Table 2: Sample size, average time, and standard deviation that males from each of the populations spent with each female size category.

		N	Mean association time (s)	Std. Deviation
Small Female	Cave	56	191.4	74.9
	Surface	72	205.1	59.1
	Nontoxic	43	199.5	75.7
	Toxic	85	198.8	61.9
Medium Female	Cave	56	218.1	59.4
	Surface	72	206.9	50.9
	Nontoxic	43	206.8	62.4
	Toxic	85	214.3	50.8
Large Female	Cave	56	233.2	62.2
	Surface	72	215.1	62.2
	Nontoxic	43	219.1	56.4
	Toxic	85	225.0	65.7
