Introduction: Acute respiratory distress syndrome (ARDS) due to Coronavirus disease 2019 (COVID-19) causes high mortality. The objective of this study is to determine whether the arterial pressure of oxygen/inspiratory fraction of oxygen (PaO₂/FiO₂) 24 hours after invasive mechanical ventilation (IMV) and the difference between PaO₂/FiO₂ at 24 hours after IMV and PaO₂/FiO₂ before admission to IMV (ΔPaO₂/FiO₂ 24h) are predictors of survival in patients with ARDS due to COVID-19. **Methods:** A retrospective cohort study was conducted that included patients with ARDS due to COVID-19 in IMV admitted to the intensive care unit (ICU) of a hospital in southern Peru from April 2020 to April 2021. The ROC curves and the Youden index were used to establish the cut-off point for PaO₂/FiO₂ at 24h of IMV and ΔPaO₂/FiO₂ at 24h associated with mortality. The association with mortality was determined by Cox regression, calculating the crude (cHR) and adjusted (aHR) risk ratios, with their respective 95% confidence intervals (95%CI). **Results:** Two hundred patients were analyzed. The average age was 54.29 years, 79% were men, and 25.5% (n=51) died. The cut-off point calculated for PaO₂/FiO₂ 24h after IMV and ΔPaO₂/FiO₂ 24h was 222.5 and 109.5, respectively. Those participants with a value below the cut-off point of ΔPaO₂/FiO₂ 24h and PaO₂/FiO₂ 24h after IMV had higher mortality, aHR=3.32 (CI95%: 1.82-6.07) and aHR=2.87 (CI95%: 1.48-5.57) respectively. **Conclusion:** PaO₂/FiO₂ 24 hours after IMV and ΔPaO₂/FiO₂ 24h in patients diagnosed with ARDS due to COVID-19 on IMV were associated with higher hospital mortality. These findings are helpful

to identify those patients with a higher risk of dying on admission to the ICU.

Determination of PaO₂/FiO₂ after 24 hours of invasive mechanical ventilation and ΔPaO₂/FiO₂ at 24 hours as predictors of survival in patients diagnosed with ards due to COVID-19

ABSTRACT

Introduction: Acute respiratory distress syndrome (ARDS) due to Coronavirus disease 2019 (COVID-19) causes high mortality. The objective of this study is to determine whether the arterial pressure of oxygen/inspiratory fraction of oxygen (PaO₂/FiO₂) 24 hours after invasive mechanical ventilation (IMV) and the difference between PaO₂/FiO₂ at 24 hours after IMV and PaO₂/FiO₂ before admission to IMV (Δ PaO₂/FiO₂ 24h) are predictors of survival in patients with ARDS due to COVID-19.

Methods: A retrospective cohort study was conducted that included patients with ARDS due to COVID-19 in IMV admitted to the intensive care unit (ICU) of a hospital in southern Peru from April 2020 to April 2021. The ROC curves and the Youden index were used to establish the cut-off point for PaO₂/FiO₂ at 24h of IMV and Δ PaO₂/FiO₂ at 24h associated with mortality. The association with mortality was determined by Cox regression, calculating the crude (cHR) and adjusted (aHR) risk ratios, with their respective 95% confidence intervals (95%CI).

Results: Two hundred patients were analyzed. The average age was 54.29 years, 79% were men, and 25.5% (n=51) died. The cut-off point calculated for PaO₂/FiO₂ 24h after IMV and Δ PaO₂/FiO₂ 24h was 222.5 and 109.5, respectively. Those participants with a value below the cut-off point of Δ PaO₂/FiO₂ 24h and PaO₂/FiO₂ 24h after IMV had higher mortality, aHR=3.32 (CI95%: 1.82-6.07) and aHR=2.87 (CI95%: 1.48-5.57) respectively.

Conclusion: PaO₂/FiO₂ 24 hours after IMV and Δ PaO₂/FiO₂ 24h in patients diagnosed with ARDS due to COVID-19 on IMV were associated with higher hospital mortality. These findings are helpful to identify those patients with a higher risk of dying on admission to the ICU.

INTRODUCTION

A significant percentage of patients with Coronavirus disease 2019 (COVID-19) develop severe disease with respiratory failure, and some of the progress to acute respiratory distress syndrome (ARDS), requiring admission to invasive mechanical ventilation (IMV) in an intensive care unit (ICU) (1,2). The lethality in these patients can vary from 28.6% to 60.4% (3–5)

ARDS is characterized by severe hypoxemia, reduced lung compliance, and bilateral pulmonary infiltrates on chest radiography (6). Because the diagnosis is based on different parameters, in 2012, the Berlin criteria were proposed (7), which use the relationship arterial oxygen partial pressure/inspired oxygen fraction ($\text{PaO}_2/\text{FiO}_2$) to classify the severity of the condition.

Currently, there is evidence that hypoxemia is associated with an increase in mortality in patients diagnosed with COVID-19; multiple studies have determined an association between a lower $\text{PaO}_2/\text{FiO}_2$ or oxygen pulse oximetry at hospital admission with an increase in-hospital mortality in patients with COVID-19, which can be up to 7 times higher than in patients without hypoxemia. (8–10). However, the variation in $\text{PaO}_2/\text{FiO}_2$ that would impact after 24 hours of admission to IMV on hospital outcomes is still unknown. In this context, we aimed to know if the difference between $\text{PaO}_2/\text{FiO}_2$ at 24 hours after IMV and $\text{PaO}_2/\text{FiO}_2$ before admission to IMV ($\Delta\text{PaO}_2/\text{FiO}_2$ 24h) is associated with mortality. In addition, we evaluate whether the increase or decrease of the $\text{PaO}_2/\text{FiO}_2$ 24 hours after the VMI was associated with greater or lesser mortality in patients diagnosed with ARDS by COVID-19.

MATERIALS AND METHODS

Study design and site

A retrospective cohort study was conducted using physical and electronic medical records of patients diagnosed with ARDS due to COVID-19. The study was carried out at Hospital III Daniel Alcides Carrión, located in the district of Calana in Tacna, in southern Peru. This third-level referral hospital belongs to the Tacna Social Security Health Care Network (EsSalud). It has a capacity of 28 beds in intensive care units (ICU) (11). The study period

was from April 2020 to April 2021. The writing of the manuscript was carried out following the recommendations of STROBE to inform observational studies. (12)

Study population

The study population included critically ill adult patients (≥ 18 years) diagnosed with ARDS due to COVID-19 on IMV and hospitalized in the ICU. Diagnosis of COVID-19 was made by real-time polymerase chain reaction (RT-PCR) or positive nasopharyngeal swab antigenic rapid test. The diagnosis of ARDS was made according to what was proposed in the Berlin criteria (13). The patients who could not confirm the diagnosis of COVID-19, who were still in the ICU during data collection, and in whom complete data were not available in their medical record records were excluded. The sample included all patients who met the eligibility criteria within the study period.

Hospital management

As part of the institutional protocol for critical patient ventilatory management in our hospital, all patients admitted to IMV underwent initial programming with the following parameters in pressure-controlled mode: a) tidal volume 6-8ml/kg of ideal weight, b) Positive end-expiratory pressure (PEEP): 8-12 cmH₂O, c) Respiratory rate (RR) for Carbon dioxide arterial pressure (PaCO₂) between 35 and 50 mmHg and or pH >7.2 and d) FiO₂ for pulse oximetry saturation (SatO₂) between 92-96%. Additionally, all patients were placed in the prone position for 48 to 72 continuous hours, which was suspended when PaO₂/FiO₂ was ≥ 200 mmHg with PEEP ≤ 10 and FiO₂ $\leq 40\%$. Likewise, all patients received sufficient analgesia to allow the coupling to the IMV, associated with neuromuscular blockade during the prone period. On the other hand, those patients who, after coming out of pronation, presented a PaO₂/FiO₂ <150 or a 20% decrease in PaO₂/FiO₂ with respect to PaO₂/FiO₂ in prone (with or without posterior dense pulmonary infiltrates evidenced in the multicut computerized tomography) were subjected again to another cycle of prone.

We decided to evaluate all the patients who underwent MV and were admitted to the ICU and met the inclusion criteria. We calculated the statistical power of the collected sample (200 patients) based on the study by Michiel T.U. Schuijt et al. (5), who reported mortality at 28 days in patients with severe ARDS on the second day after admission to IMV of 44.3% and 28.6% in patients with mild ARDS, also reported a ratio of unexposed to exposed of

6.21 (764/123). With a confidence level of 95% and 200 participants in the study sample and a non-exposed/exposed ratio of 3, calculated the statistical power was at 53.5%.

Data collection

After reviewing all physical and digital medical records, patients were evaluated from hospital admission to outcome (medical discharge or death). Sociodemographic, clinical, ventilatory (before access to the IMV and 24 hours later), laboratory and imaging characteristics that the radiologists reported at the time of admission to the IMV were collected, the calculation of the extent of parenchymal involvement was performed by a semi-quantitative scoring used in previous studies (33,34). To calculate lung damage, the average percentage of lung damage reported for each lobe was used (from 0 to 100%). Complications and therapies administered during the ICU stay were also evaluated.

Two researchers conducted data collection; Each one entered the data independently; A third researcher supervised and compared the data collected; when he found any error, the third researcher reviewed the medical history and corrected the error. The coded data collection forms were entered into the Microsoft Excel v.2016 program and performed the statistical analysis with the STATA V17.0 (Stata Corp. 2019) and Prism 9 (GraphPad corporation, 2021) software.

Analyzed variables

Result variable

The outcome variable was hospital mortality, this data was collected from the medical records of the patients included in the study, and the data were compared with the national death registry of Peru.

Exposure variables

Clinical characteristics and treatment

The clinical characteristics were sex, age, comorbidities (obesity, DM2, hypertension, heart failure, asthma, chronic kidney disease, and immunosuppression), the number of comorbidities and date you entered the emergency room (2020/2021). The treatment administered was antibiotics, corticosteroids, colchicine, tocilizumab, and renal replacement therapy; these data were obtained from digital medical records.

Ventilatory and laboratory characteristics

The ventilatory characteristics were obtained from the analysis of arterial gases that were brought before the patient entered mechanical ventilation; the rest of the parameters were obtained from the report given by the mechanical ventilator and collected by the ICU nursing staff.

The laboratory characteristics were obtained from the record given in the digital medical records.

Complications during ICU stay

The most important complication was ARDS, defined according to the Berlin criteria (13). The rest of the complications were: nosocomial infection, sepsis, septic shock, acute kidney injury, and arrhythmias. All were diagnosed according to international criteria (2,14-16).

Statistical analysis

Categorical variables were described as absolute and relative frequency, and quantitative variables as mean/standard deviation or median/interquartile range depending on whether their distribution was normal or not. The Chi-square or Fisher's exact statistical tests were used for the bivariate analysis between the categorical variables and the results. For the quantitative variables, the Student's t-test was used if the assumptions were fulfilled or, failing that, the Mann–Whitney U test. For the comparison with the degrees of severity of ARDS, the ANOVA or Kruskal Wallis statistical tests were used according to the normality of the variables.

We investigated the predictive capacity of $\Delta\text{PaO}_2/\text{FiO}_2$ 24h and $\text{PaO}_2/\text{FiO}_2$ 24 hours after IMV as a predictor of survival in patients with ARDS due to COVID-19. First, we calculated the ROC (Receiver Operating Characteristic) curves, the ROC curve (AUC) area, and the corresponding Youden indices. The highest Youden index identified the optimal cut-off point. Next, the 95% CI was calculated by bootstrapping a thousand repetitions, thereby generating dichotomous exposure variables for $\Delta\text{PaO}_2/\text{FiO}_2$ 24h and $\text{PaO}_2/\text{FiO}_2$ 24 hours after IMV. Then, we calculated the sensitivity, specificity, and odds ratio with their respective 95% CI of the established cut-off points to predict survival. In addition, the differences between the ROC curves were tested using the Chi-square test (17).

Finally, to answer our hypothesis, we used Cox proportional hazards models to find the crude and adjusted hazard ratios (aHR) and their respective 95% confidence intervals (95%CI). The variables $\Delta\text{PaO}_2/\text{FiO}_2$ 24h, $\text{PaO}_2/\text{FiO}_2$ 24h of IMV, and ARDS severity

before IMV and after 24 h of IMV, as they were not independent of each other, were analyzed individually in different adjusted regressions (one for each variable). In the adjusted model, we included the variables: age, sex, number of comorbidities, septic shock, acute renal failure, positive end-expiratory pressure, plateau pressure, driving pressure, and date of admission. These variables were selected for clinical plausibility as they could influence the outcome. The proportionality of the multivariate model had a value of $p=0.452$.

Ethical aspects

This research followed the international guidelines of the Declaration of Helsinki. The research protocol was evaluated and approved by the ethics committee of the Faculty of Health Sciences of the Private University of Tacna (Identification code: N391-2021-UPT/FACSA-D). Due to the retrospective observational nature of the study, they did not request informed consent. All information was coded to maintain the anonymity of the participants, and only the researchers had access to the data.

RESULTS

Characteristics of the study population

Of the 235 medical records examined, 35 did not meet our inclusion criteria (25 were still hospitalized and 10 had incomplete data), so a total of 200 medical records of patients with ARDS secondary to COVID-19 undergoing IMV and who were admitted to the ICU; of these the 79% ($n=158$) were male, and the mean age was 54.29 (SD: 12.19) years. 78% ($n=159$) of those admitted had at least one comorbidity, and the most frequent were obesity (59%), hypertension (26.5%), and diabetes mellitus type 2 (21.50%). The median length of hospital stays, time in the ICU, and time in IMV was 20 (IQR: 14-28) days, 10 (IQR: 5.5-16) days, and 10 (IQR: 6-16) days, respectively (**Table 1**).

At the time of hospital admission, the median SatO₂ and PaO₂/FiO₂ were 88% (IQR: 84.5-90) and 245.5 (IQR: 165.5-297), respectively, and the mean extent of pulmonary involvement on chest tomography was 61.34% (SD: 14.02). At the time of admission to IMV, the median PaO₂/FiO₂ was 91.5 (IQR: 70-129.5); likewise, 58.5% of patients were

admitted to IMV with a diagnosis of severe ARDS, and the median SOFA score at admission was 4 (IQR: 3-5) points. Regarding the laboratory data, the median of lymphocytes, procalcitonin, and lactate dehydrogenase were 675.65 (IQR: 480-1070.4) cells/mm³, 0.14 (IQR: 0.06-0.37) ng/mL, and 757.5 (IQR: 587.5-990.5) IU/L, respectively (**Table 1**).

At 24 hours after admission to IMV, the median PaO₂/FiO₂ was 240 (IQR: 200-301.5), and the 24h Δ PaO₂/FiO₂ was 141 (105-193). Concerning ventilatory parameters, the median values for PEEP, plateau pressure, and driving pressure were 12 (IQR: 10.5-14), 28 (IQR: 26-31), and 16 (IQR: 15-18), respectively. Likewise, 74.5% of patients admitted to IMV were classified as having mild ARDS at 24 hours (**Table 1**).

During the ICU stay, 29% (n= 58) of the patients presented a nosocomial infection, with pneumonia associated with IMV being the most frequent (75.86%); however, 98.5% of the patients' received antibiotics. Furthermore, 14.5% of the patients developed acute renal failure, and 51% required renal replacement therapy. Finally, 51 patients (25.5%) of those admitted to IMV died (**Table 2**).

Bivariate analysis according to the severity of ARDS

Significant differences were observed concerning greater severity of ARDS after 24 hours in IMV in elderly patients, a greater number of comorbidities. The most frequent in this group were heart failure, chronic kidney disease, and immunosuppression. The clinical and ventilatory characteristics associated with greater severity of ARDS were, entering the emergency room with minor oxygen saturation, requiring vasopressors, a higher percentage of lung damage, and a higher SOFA score (**Supplementary Table 1**).

Bivariate analysis according to death

In the bivariate analysis, statistically significant differences were observed concerning mortality in patients with older age, with the presence of 1 or more comorbidities, and among them, mainly type 2 diabetes mellitus, heart failure, and chronic kidney disease. It was also observed that those who died had a more extended stay in the ICU (median: 14

days vs nine days) and IMV (median: 15 days vs eight days), lower SatO₂, lower PaO₂/FiO₂ at hospital admission, a greater pulmonary involvement in the chest tomography and a higher score in the SOFA score. Likewise, the patients who died presented a lower PaO₂/FiO₂ before entering IMV (median: 68 vs 95; $p < 0.001$) and in the same way, at 24 hours after IMV, PaO₂/FiO₂ and Δ PaO₂/FiO₂ 24h were lower in the deceased with a median of 190 vs 260 ($p < 0.001$) and a median of 106 vs. 152.2 ($p < 0.001$), respectively, than in the survivors (Figure 1). At 24 hours, the proportion of patients with mild ARDS was 84.56% in the survivors and 45% in the deceased ($p < 0.001$). (Table 1). It was also observed that deceased patients presented higher plateau pressure, driving pressure, and higher PEEP values at 24 hours of IMV and a higher incidence of ventilator-associated pneumonia, septic shock, arrhythmias, and acute renal failure (**Table 2**).

Determination of predictive value of PaO₂/FiO₂ 24h after IMV and Δ PaO₂/FiO₂ 24h

PaO₂/FiO₂ 24h after IMV has an AUC ROC of 0.75 (95% CI: 0.66 – 0.83), with 222.5 (95% CI: 175.85 – 269.14) being the best cut-off point to determine survival, with a sensitivity and specificity of 74.5% (IC95% 66.7-81.3) and 68.6% (IC95% 54.1-80.9), respectively. Similarly, the AUC ROC of Δ PaO₂/FiO₂ 24h was 0.70 (95% CI: 0.61 – 0.78), with a cut-off point of 109.5 (95% CI: 85.43–133.56), whose sensitivity and specificity were 81.2% (IC95% 74-87.1) and 56.9% (42.2-70.7), respectively. Although the AUC ROC of PaO₂/FiO₂ 24h after IMV was higher than Δ PaO₂/FiO₂ 24h, no statistically significant differences were observed between both curves ($p = 0.054$). (**Figure 2, Table 3**).

Multivariable model

In the crude Cox regression analysis, the variables associated with mortality were moderate ARDS (cHR: 2.68, 95% CI: 1.49-4.83) and severe ARDS (cHR: 13.98, 95% CI: 5.59-34-93) at 24 hours of IMV, Δ PaO₂/FiO₂ 24h < 109.5 (HRc: 3.70, CI95%: 2.12-6.46), PaO₂/FiO₂ 24h after IMV < 222.5 (HRc: 3.41, CI95%: 1.88-6.19).

In the adjusted model, an aHR 3.32 (95% CI 1.87-6.07) was obtained for Δ PaO₂/FiO₂ 24h < 109.5 , an aHR 2.87 (95% CI: 1.48-5.57) for PaO₂/FiO₂ 24h < 222.5 after IMV and an

aHR: 2.18 (CI95%: 1.13-4.12) and aHR: 9.81 (CI95%: 3.43-28.04) for moderate and severe ARDS after 24 hours of IMV, respectively. **(Table 4).**

DISCUSSION

In the present retrospective cohort study in patients diagnosed with ARDS and critical COVID-19 undergoing IMV and admitted to the ICU, overall hospital mortality of 25.5% was observed. Our findings show that those patients who responded with a significant increase in oxygenation and classified as having mild ARDS after 24 hours of IMV had lower hospital mortality than those with moderate ARDS and severe ARDS. Likewise, we identified the capacity of $\Delta\text{PaO}_2/\text{FiO}_2$ 24h and $\text{PaO}_2/\text{FiO}_2$ 24h after IMV as predictors of survival in patients with ARDS and critical COVID-19.

In our study, the proportion of patients admitted to IMV with severe ARDS was approximately double that reported in other cohorts in France (18), the Netherlands (5.19), the United Kingdom (20), and Spain (21). However, hospital mortality in our cohort was like that observed in these studies. Non-invasive ventilation and high-flow oxygen are used in many hospitals to reduce the number of patients who ultimately require admission to IMV; Unfortunately, in our hospital, we did not have these therapeutic measures, which could have influenced the high number of patients who were finally admitted to IMV.

We also observed that VMI entry with a diagnosis of severe ARDS was not a factor associated with statistically significant mortality in the adjusted model of our study. These findings could suggest that the severity of the ARDS would not be a determining forecast factor in mortality, especially compared to the seriousness of the ARDS 24 hours after entering VMI. But more similar studies are necessary to support these results.

Those patients who suffered from severe ARDS after 24 hours of IMV had a higher risk of death. These findings are like those reported by the PRoVENT study in patients with ARDS due to COVID-19, where they observed that patients with severe ARDS on day 2 had higher mortality than patients with mild or moderate ARDS (5). Similar findings were observed in the pre-COVID-19 era in the LUNG SAFE study (22). In this study, they reported that patients with severe ARDS at day 2 had a substantially higher risk of death than those with

mild and moderate ARDS and "resolved ARDS," a term that refers to those patients who no longer met the definition of ARDS. The ARDS at 24 hours of IMV occurred in up to 24% of those admitted to this study. Some authors propose that these patients could constitute false positives for ARDS (23), who initially met the diagnostic criteria without presenting the pathophysiological processes seen in classic ARDS. It is unknown if this phenomenon also occurs in patients with COVID-19.

In our study, $\text{PaO}_2/\text{FiO}_2$ 24 hours after IMV and $\Delta\text{PaO}_2/\text{FiO}_2$ 24h were independent factors associated with mortality, not observed with $\text{PaO}_2/\text{FiO}_2$ before intubation. This coincides with previous studies in the pre-COVID-19 era, where determined that oxygenation indices after 24 hours of IMV are better predictors of results in patients with ARDS (24,25). However, other studies in patients with critical COVID-19 observed that a lower $\text{PaO}_2/\text{FiO}_2$ ratio on admission to the ICU was a factor associated with higher mortality (26,27), which disagrees with our findings. Although in none of these studies, it is clear what cut-off point was used for this conclusion, nor the moment of its determination with respect to intubation.

We also found that $\text{PaO}_2/\text{FiO}_2$ 24h after IMV has a higher AUC than $\Delta\text{PaO}_2/\text{FiO}_2$ 24h in predicting survival, although at the expense of lower sensitivity. The AUC ROC of $\text{PaO}_2/\text{FiO}_2$ 24h after IMV observed in our study was higher than those described by other authors in the pre-COVID-19 era. Lai C, et al. (28) reported that $\text{PaO}_2/\text{FiO}_2$ 24h after IMV presented an AUC ROC of 0.657 and was higher than that observed on day 0 of IMV (AUC ROC: 0.556). Similarly, Huber W, et al. (24) reported that the AUC ROC of the Berlin definition at 24 hours was 0.664 and 0.644 at 48 hours. To our knowledge, there are no studies that have evaluated the AUC of $\text{PaO}_2/\text{FiO}_2$ at 24 hours after IMV or $\Delta\text{PaO}_2/\text{FiO}_2$ at 24 hours in patients diagnosed with ARDS due to COVID-19 in IMV. An investigation in patients with ARDS due to COVID-19 in IMV evaluated the mortality prognostic capacity of pulse oximetry saturation/ FiO_2 ($\text{SatO}_2/\text{FiO}_2$) on days 1, 2, and 3 of IMV, whose AUC was 0.53, 0.62, and 0.62 respectively (29), which makes it inferior as a predictive metric than $\text{PaO}_2/\text{FiO}_2$ 24h after IMV and $\Delta\text{PaO}_2/\text{FiO}_2$ 24h observed in our study. Likewise, we must highlight that all the patients in our study were placed in the prone position. It is likely that this intervention increased $\text{PaO}_2/\text{FiO}_2$ after IMV, as reported by

previous observational studies in intubated patients with COVID-19 (30,31) and should be considered in future research.

On the other hand, in our environment, as in most countries with limited resources, we do not have advanced strategies for the management of refractory hypoxemia such as extracorporeal circulation membrane (ECMO), high-frequency oscillatory ventilation (HFOV), or mechanical ventilators (32) with advanced modes of mechanical ventilation, which could be considered as an early alternative tool for patients with $\text{PaO}_2/\text{FiO}_2$ less than 222.5 at 24 hours of IMV and/or with $\Delta\text{PaO}_2/\text{FiO}_2$ less than 109.5, in order to guarantee MV protective and prevent hypoxemia.

This research presented some limitations, including the observational and retrospective nature of the study, which did not allow the exclusion of selection bias, nor did it allow the examination of other parameters (such as mechanical power, compliance, oxygenation index, more inflammatory markers or harmful habits). Another limitation was that the study was conducted in a single health institution with a limited number of patients. Therefore, these results could not be extrapolated to the general population. Finally, it is possible that the different measures of ventilatory therapy, such as changes in PEEP and FiO_2 , may have influenced $\text{PaO}_2/\text{FiO}_2$ at 24 hours of IMV; even so, it was a factor associated with mortality in the adjusted model. Therefore, prospective, multicenter studies and external validation of our findings in other populations are required.

CONCLUSIONS

$\text{PaO}_2/\text{FiO}_2$ 24 hours after IMV and $\Delta\text{PaO}_2/\text{FiO}_2$ 24h in patients diagnosed with ARDS due to COVID-19 on IMV were factors associated with higher hospital mortality. Therefore, $\text{PaO}_2/\text{FiO}_2$, 24h after IMV, and $\Delta\text{PaO}_2/\text{FiO}_2$ 24h are useful variables to identify those patients with a higher risk of dying in patients with ARDS due to COVID-19 in IMV.

ICU: Intensive Care Unit, MV: Mechanical Ventilation, UTI: Urinary Tract Infection.

Table 3 (on next page)

Cox regression analysis to assess predictors of death in patients hospitalized for critically ill COVID-19

cHR: crude Hazard ratio, aHR: adjusted Hazard ratio, IMV: invasive mechanical ventilation, PaO₂/FiO₂: fraction between arterial oxygen pressure over the inspired fraction of oxygen, ΔPaO₂/FiO₂ 24h: the difference between PaO₂/FiO₂ at 24 hours after IMV and PaO₂/FiO₂ before admission to IMV, ARDS: Acute respiratory distress syndrome.

The variables ΔPaO₂/FiO₂ 24h, PaO₂/FiO₂ 24h of IMV, and severity of ARDS at admission to IMV and 24 hours later, as they were not independent of each other, were analyzed individually. The variables adjusted each one: Age, sex, number of comorbidities, septic shock, acute renal failure, positive end-expiratory pressure, plateau pressure, driving pressure and date of admission.

Table 3: Cox regression analysis to assess predictors of death in patients hospitalized for critically ill COVID-19

cHR: crude Hazard ratio, aHR: adjusted Hazard ratio, IMV: invasive mechanical ventilation, PaO2/FiO2: fraction between arterial oxygen pressure over the inspired fraction of oxygen, Δ PaO2/FiO2 24h: the difference between PaO2/FiO2 at 24 hours after IMV and PaO2/FiO2 before admission to IMV, ARDS: Acute respiratory distress syndrome.

Variable	cHR (95% CI)	p-Value	aHR (95% CI)	p-Value
Δ PaO2/FiO2 24h <109.5	3.70 (2.12-6.46)	<0.001	3.3201 (1.8260-65.0765)	\leq 0.001
PaO2/FiO2 24h IMV <222.5	3.41 (1.88-6.19)	<0.001	2.8756 (1.4832-5.57496)	0.0025
ARDS upon admission to IMV				
Moderate	Ref		Ref	
Severe	1.40 (0.75-2.61)	0.280	0.942 (0.47-1.793)	0.806781
ARDS at 24 hours of IMV				
Mild	Ref		Ref	
Moderate	2.68 (1.49-4.83)	0.001	2.18495 (1.13403-4.12366)	0.02038
Severe	13.98 (5.59-34.93)	<0.001	9.8143.64 (3.43495-28.0437.60)	<0.001

PaO2/FiO2 24h of IMV, and severity of ARDS at admission to IMV and 24 hours later, as they were not independent of each other, were analyzed individually. The variables were adjusted by: Age, sex, number of comorbidities, septic shock, acute renal failure, positive end-expiratory pressure, plateau pressure, driving pressure, and date of admission. ~~The variables adjusted each one: Age, sex, number of comorbidities, septic shock, acute renal failure, positive end-expiratory pressure, plateau pressure, driving pressure.~~

Table 4(on next page)

Area under the ROC curve and cut-off points with the highest AUC ROC of the variables PaO₂/FiO₂ 24h after MV and ΔPaO₂/FiO₂ 24h to predict survival in patients hospitalized for critically ill COVID-19

AUC: area under the curve, ROC: receptor operating characteristic, PaO₂/FiO₂: fraction of arterial oxygen pressure over the inspired fraction of oxygen, MV: Mechanical ventilation, ΔPaO₂/FiO₂ 24h: the difference between PaO₂/FiO₂ at 24 hours after MV and PaO₂/FiO₂ before entering MV * p=0.054

Table 4: Area under the ROC curve and cut-off points with the highest AUC ROC of the variables PaO₂/FiO₂ 24h after MV and ΔPaO₂/FiO₂ 24h to predict survival in patients hospitalized for critically ill COVID-19

	PaO ₂ /FiO ₂ 24h after MV (IC 95%)	ΔPaO ₂ /FiO ₂ 24h (IC 95%)	AUC: area under the curve, ROC: receptor operating characteristic, PaO ₂ /Fi
AUC ROC *	0.75 (0.66 – 0.83)	0.70 (0.61 – 0.78)	
Cutpoint	222.5 (175.85 – 269.14)	109.5 (85.43 – 133.56)	
- Sensitivity at cutpoint %	74.5 (66.7-81.3)	81.2 (74.0-87.1)	
- Specificity at cutpoint %	68.6 (54.1-80.9)	56.9 (42.2-70.7)	
- AUC ROC at cutpoint	0.72 (0.64-0.79)	0.69 (0.65-76.58)	
- Odds ratio at cutpoint	6.39 (3.20-12.75)	5.70 (2.87-11.31)	
- Youden index	0.431	0.381	

O₂: fraction of arterial oxygen pressure over the inspired fraction of oxygen, MV: Mechanical ventilation, ΔPaO₂/FiO₂ 24h: the difference between PaO₂/FiO₂ at 24 hours after MV and PaO₂/FiO₂ before entering MV

* p=0.054

Figure 1

Difference between a) $\Delta\text{PaO}_2/\text{FiO}_2$ 24 hours and b) $\text{PaO}_2/\text{FiO}_2$ 24 hours after IMV in patients diagnosed with ARDS due to COVID-19 between deceased and survivors

$\text{PaO}_2/\text{FiO}_2$: fraction between the arterial pressure of oxygen over the inspired fraction of oxygen, $\Delta\text{PaO}_2/\text{FiO}_2$ 24h: the difference between $\text{PaO}_2/\text{FiO}_2$ at 24 hours after IMV and $\text{PaO}_2/\text{FiO}_2$ before admission to IMV

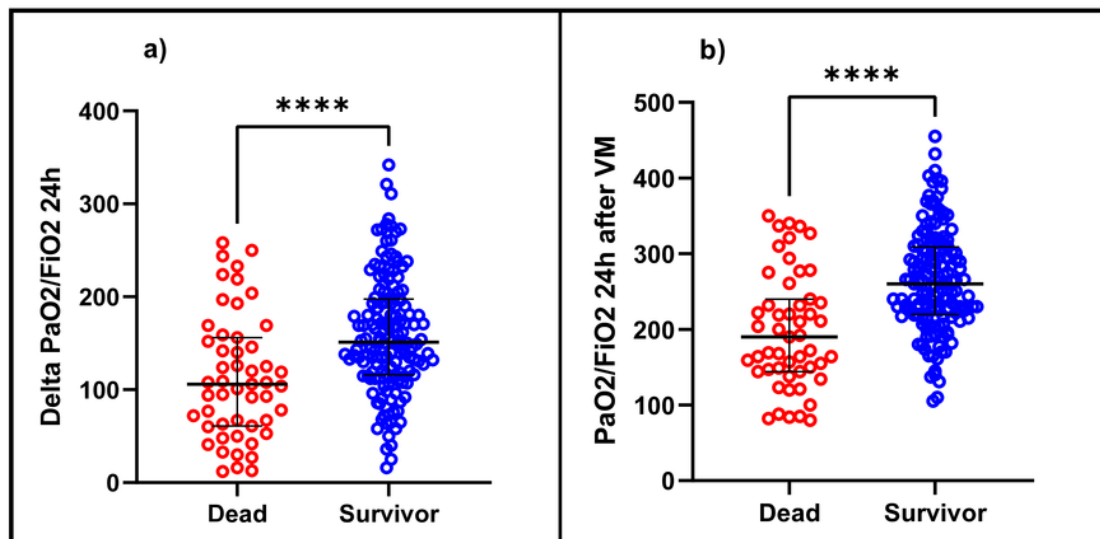

Figure 2

ROC curve and AUC ROC of PaO₂/FiO₂ 24 hours after IMV and Δ PaO₂/FiO₂ 24 hours to predict survival

AUC: area under the curve, ROC: receptor operating characteristic, PaO₂/FiO₂: fraction of arterial oxygen pressure over inspired fraction of oxygen, Δ PaO₂/FiO₂ 24h: difference between PaO₂/FiO₂ at 24 hours after IMV and PaO₂/FiO₂ before entering IMV
