24 **Abstract**

25 Roads have considerable ecological effects that threaten the survival of some species,
 26 including many terrestrial carnivores. The western polecat is a small-medium sized
 27 mustelid native to Asia and Europe, including Britain where its historical stronghold is in
 28 Wales. Polecats are frequently killed on roads and road casualties represent the most
 29 common source of data on the species in the UK. However, little is known about the
 30 factors that increase the risk of collision. We used Generalized Linear Mixed Models to
 31 explore seasonal patterns in collisions as well as using Principal Component Analysis
 32 and regression modelling to identify landscape characteristics associated with polecat
 33 road casualties in Wales. Polecat road casualties had a bimodal distribution, occurring
 34 most frequently in March and October. Casualties were more frequently associated with
 35 road density, traffic volume, presence of rabbits, habitat patchiness and the abundance
 36 of proximal improved grassland habitat. Casualties were negatively associated with
 37 elevation and the abundance of semi-natural grassland habitat. The results of this study
 38 provide a framework for understanding and mitigating the impacts of roads on polecats
 39 in their historic stronghold, hence has considerable value to polecat conservation as
 40 well as broader applicability to ecologically similar species.

Introduction

There are currently almost 500,000 kilometres of road in the United Kingdom, over 3,000 kilometres of which has been built in the last 10 years (Department for Transport 2020). As road networks continue to expand, it is critical to understand the impact that they have on wildlife populations (Schwartz, Shilling and Perkins 2020). Roadways pose a serious risk to wildlife and can have a substantial impact on populations (Department for Transport, 2019; Hill, DeVault and Belant, 2019; Schwartz, Shilling and Perkins, 2020). For example, barrier effects caused by linear features in the environment - such as roads – can restrict animal movements (Forman and Alexander, 1998; Schwartz, Shilling and Perkins, 2020), potentially fragmenting populations into smaller, isolated subpopulations that may be more vulnerable to stochastic events (Trombulak and Frissel, 2000; Jaeger and Fahrig, 2004; Riley *et al.*, 2006; Klar *et al.*, 2009).

Roads also have more direct effects in the form of injury and mortalities associated with wildlife-vehicle collisions (WVC). WVCs have been subject to increasing scrutiny in the last 20 years (e.g. Gomes *et al.* 2009; Langen, Ogden and Schwarting 2009; Patrick, Gibbs and Popescu 2012; Schwartz, Shilling and Perkins 2020; Wright *et al.* 2020) and are acknowledged as one of the most important sources of anthropogenic mortality of terrestrial vertebrates worldwide (Hill, DeVault and Belant 2019). Road characteristics such as road class (Clevenger, Chruszcz and Gunson, 2002), traffic volume (Jaarsma, van Langevelde and Botma, 2006) and speed limit (Barrientos and Bolonio, 2009), as well as surrounding land cover (Wright *et al.*, 2020), roadside topography (Clevenger, Chruszcz and Gunson, 2002), species ecology and behaviour (Grilo, Bissonette and

Santos-Reis, 2009; Jacobson et al., 2016) and resource abundance (e.g. prey in roadside verges, Planillo *et al.* 2013) affect the frequency of WVCs. WVC ‘hotspots’ (i.e. areas with high numbers of collisions) are often identified and used to target mitigation measures aimed at reducing the frequency and severity of WVCs (Langen, Ogden and Schwarting, 2009; Patrick, Gibbs and Popescu, 2012; Schwartz, Shilling and Perkins, 2020; Wright *et al.*, 2020). The efficacy of this approach may be dependent on road age, however (Zimmermann Teixeira *et al.* 2017). Road mortality data can also further our understanding of species distributions and movements (Schwartz, Shilling and Perkins, 2020). Threatened mammal taxa include felids (Parchizadeh *et al.* 2018; Blackburn *et al.* 2021), ursids (Ha 2021), ungulates (Putman 1997; Riginos *et al.* 2022), and mustelids (Clarke, White and Harris 1998; Russo *et al.* 2020). Carnivore populations may be particularly susceptible to the negative effects of roads due to their unique life-history traits. For example, predators tend to be highly mobile, occur at low densities and have low reproductive rates (Grilo, Smith and Klar 2015; Ceia-Hasse *et al.* 2017). Hence, they are and more likely to interact with a road network and a single mortality will have a greater impact on the population than would be the case for a more fecund species.

Western polecats (*Mustela putorius*) are small-medium (600 – 1,500 g) mustelids native to Europe and Asia. They are considered generalists in both diet and habitat, although in the UK and Mediterranean regions they rely heavily on European rabbits (*Oryctolagus cuniculus*) and their burrows for both food and shelter (Birks and Kitchener 1999; Barrientos and Bolonio 2009). Polecats were once abundant in Britain but were

hunted to extinction in Scotland and much of England in the 19th century, leaving remnant populations in some English counties and a stronghold in mid-Wales (Langley and Yalden 1977; Blandford 1987; Birks and Kitchener 1999; Packer and Birks 1999; Birks 2008; Croose 2016). Aided by the start of the first World War and the associated decrease in hunting and gamekeeping pressure, along with the recovery of the rabbit population post-myxomatosis (Costa *et al.* 2013), the Welsh polecat population rebounded (Langley and Yalden 1977). Polecats have been listed on schedule 6 of the Wildlife and Countryside Act since 1981 (Wildlife and Countryside Act 1981, 2020), which protects listed species from being killed or taken by certain methods, such as self-locking snares. They are also a priority species on the UK Biodiversity Action Plan (BAP) since 2007 (BRIG 2007). Polecats have now successfully repopulated every county in Wales and much of southern England (Croose 2016). There is the threat, though, of hybridisation with feral ferrets in England which may mask their true distribution, making the Welsh population critical to maintaining the genetic legacy of the species (Costa *et al.* 2013).

Polecats exhibit several of the life-history traits that make many carnivores vulnerable to the impacts of roads (Grilo, Bissonette and Santos-Reis 2009; Ceia-Hasse *et al.* 2017). They are also known to commonly consume carrion, which may put them at particularly high risk of WVC as roads and roadsides provide ample opportunities for scavenging (Forman and Alexander 1998; Grilo, Bissonette and Santos-Reis 2009; Barrientos and de Dios Miranda 2012). Conversely, Grilo *et al.* (2008, 2009) suggest that polecats may be less susceptible to WVC than other carnivores due to an observed tendency to

actively avoid roads. This type of discrepancy demonstrates the need for further, focused research on the topic.

Little is known about landscape characteristics that might increase the likelihood of WVCs involving polecats. The few studies that have been conducted thus far suggest that relevant factors include the speed and density of traffic (Barrientos and de Dios Miranda 2012), proximity to rabbit burrows (Barrientos and Bolonio 2009), presence of arable land and human settlements, and proximity to water courses or other linear features (Červinka *et al.* 2015). Here, we aimed to describe the temporal and spatial distribution of polecat WVC in Wales and to identify landscape characteristics associated with increased risk.

Materials and Methods

Study area

Wales is a small country (20,782 km²) of varied geography, with coastal plains in the south and west giving way to a largely mountainous interior dissected by deep rivers and valleys (Smith, Carter and Gruffudd 2020). Elevation ranges from 200 meters above sea level on the coast to 1,085 meters at the tallest peak. The landscape is primarily a matrix of natural and improved grasslands and pastures, with the exception of the mountainous areas in the centre and north of the country that are characterised by a mosaic of woodland, heathland and wetlands. It has a maritime climate; rainfall is common throughout the year, with an average of 1000 millimetres annually (Mayes

2013). The average daytime temperature ranges from 4°C in the winter to 16°C in the summer (Smith, Carter and Gruffudd 2020), though there is substantial spatial variation.

WVC data

Observations of polecat road mortalities in Wales were provided by the Vincent Wildlife Trust (VWT). Records were collected via a national monitoring survey carried out from December 2013 to December 2015 (Croose 2016). The survey used a community science framework to obtain reports of polecat casualties from members of the public, volunteers, and VWT members. Where possible, reports were verified by professionals with sufficient experience and expertise as polecats, feral ferrets or ferret-polecat hybrids via photo, video, or evaluation of the carcass (Croose 2016). During the survey period there were 85 observations in Wales verified as true polecats, no confirmed records of hybrids or feral ferrets, and 86 unverified records. Both phenotypic and genetic studies suggest that most polecats in Wales are true polecats, while hybridisation is more common in England (Costa *et al.* 2013; Croose 2016). We did not have access to carcass materials, hence further verification was not possible. Therefore, unverified records were retained in analysis and assumed to be true polecats, giving a total of 171 observations. Due to the lack of true absence data a total of 1200 pseudo-absence points (Barbet-Massin *et al.* 2012) were generated across the Welsh road network and at least 3 kilometres (i.e. the average home range size of polecats in Britain (Birks and Kitchener 1999) distant from the nearest presence point (Fig. 1).

Environmental parameters

Species abundance is an important driver of road-kill patterns (Barrientos and de dios Miranda 2012; Husby 2016). While the range and overall, population-level abundance and distribution of polecats in the UK has increased, suitable abundance or density data are unavailable for polecats in Wales (Matthews *et al.* 2018). Simple population-occurrence relationships, where changes in habitat quality and/or quantity impacted the populations of associated species (Freckleton, Noble and Webb 2006) offer a potential proxy for abundance. However, such models have never been applied to polecats in the UK and the extent to which they may be (un)suitable is unknown. Hence, our models did not capture local abundance or a proxy thereof.

Explanatory environmental variables were selected *a-priori*, based on previously published literature and knowledge of the species' ecology. These included proportional land cover, habitat patchiness, elevation, waterway density, road density, presence of rabbits and traffic volume (Table 1). The percentage of each land class and the total number of patches (where more patches = more fragmentation) were extracted from the 25m resolution Land Cover Map 2015 (UK Centre for Ecology & Hydrology 2017) within a 1.5 kilometre buffer of each presence and pseudo-absence point, based on average polecat home range size (Birks and Kitchener 1999). In order to evaluate the effect of many land classes in fewer variables, classes of interest were combined using Principal Component Analysis (PCA) with Box-Cox transformation, prior to analysis. Three principal components (PCs) with eigenvalues >1 were retained for use in models. Elevation was extracted in R using the *elevatr* package (Hollister *et al.* 2021). We attempted to capture spatial autocorrelation using the *glmmPQL* function in the *MASS*

package (Venables, 2002), using a correlation structure (Dormann *et al.*, 2007). However, all models returned zero-distance errors that resisted resolution. We also explored the use of GAMMs via the *mgcv* package (Wood, 2003, 2011, 2017), where spatial coordinates were included in a bivariate spline with a Markov random field smoother. These models performed very poorly. Hence, spatial autocorrelation in the data was captured by calculating Moran's I scores for each presence and pseudo-absence point using the Anselin's Local Moran's I tool within the Spatial Analyst toolbox in ArcGIS Desktop (ESRI 2011). All numeric variables were rescaled so that $\bar{x} = 0$, $\sigma = 1$ to facilitate direct comparison between covariates.

Prey abundance and availability are a key consideration when evaluating predator occurrence (e.g. Šálek *et al.* 2010; Mougeot *et al.* 2019). Indeed, the proximity of rabbits to roads may be a reliable indicator of polecat collision risk (Barrientos and Bolonio 2009). However, accurate, landscape-scale data on the presence or absence of many UK mammals – including European rabbits - are sparse (Mathews *et al.* 2018b). We therefore captured the potential influence of rabbits on polecat WVC using National Biodiversity Network (NBN; <https://nbn.org.uk/>) rabbit data between 2010-2019 inclusive and calculating the minimum distance between mortalities/pseudo-absences and rabbit locations. The selected date range ensured national coverage and assumes that a rabbit observation in a given year represents a population that was present during the period 2013 – 2015 (i.e. when polecat data were collected).

Modelling seasonal trends

Seasonal trends in polecat WVC were analysed using a Generalized Additive Model (GAM), following Wright *et al.* (2020). Five candidate models were created with the number of roadkill observations as the response variable and month as the predictor. Models used a Poisson family error distribution with a log-link function, and a cyclic cubic spline with 12 knots applied to the month variable. Temporal non-independence in the data was accounted for by including a correlation argument in four of the models where the autoregressive order, p varied between 1-4. The fifth model assumed independence between observations. Residuals of each model were evaluated using the Auto-Correlation Function (ACF) and Partial Auto-Correlation Function, and the best-approximating model was identified using Akaike's Information Criterion (AIC).

Modelling environmental relationships

The relationship between polecat road WVC and percent land cover classification ('habitat model', hereafter), was explored using a Generalized Linear Model (GLM) using a binomial error distribution with logit link function. Presence/pseudo-absence of polecats was the dependent variable and the proportional land cover, patchiness, elevation, road density, road class, distance to rabbits, and Moran's I were fixed explanatory variables. All variables had Variance Inflation Factors (VIF) ≤ 2 and were retained (Zuur *et al.* 2010). All possible model permutations of the resulting GLM were generated using the *MuMIn* package (Barton 2020) and Akaike weights were calculated for each model within the top subset of models ($\Delta AIC \leq 2$). Both the best-approximating model ($\Delta AIC = 0$) and the full average model (i.e. averaged across the top subset of n models) were subsequently identified. Using both approaches accounts for uncertainty

in model selection and produces more robust results than using the best-approximating model alone (Grueber *et al.* 2011).

A second GLM was produced using the same method and based on the subset of the data that included traffic volume ('traffic models', from hereon). Traffic volume data for 2015 (point locations) were obtained from the Department for Transport (Department for Transport 2019), but data was not available for every road and, by extension, every presence/pseudo-absence location. However, traffic volume has frequently been reported as an important factor in determining risk of WVC (Forman and Alexander 1998; Jaarsma, van Langevelde and Botma 2006; Jacobson *et al.* 2016). Therefore, a second set of models was constructed using a reduced dataset (n = 150 presence; 1,058 pseudo-absence) containing only presence/pseudo-absence points on roads that were also associated with traffic volume data. WVC data did not necessarily directly overlap roads due to imprecision in location information, hence presence data were aligned with the nearest road, according to a 1.5-kilometer threshold. Code are available at <https://zenodo.org/record/7025191> (Barg *et al.*, 2022).

All analyses were conducted in R (v.3.6.3; R Core Team 2019).

Results

Of the 171 road mortalities identified and included in these analyses, 85 were considered to be true polecats and 86 were unverified (i.e. plausible but not confirmed). WVC were most frequently recorded on trunk roads (28%), followed by unclassified roads (18%), primary roads (15%), and secondary roads (15%). Only one carcass was recorded on a motorway (Fig. 2).

244

245 Out of five candidate seasonal models, the model that performed best was the one that
246 did not include a correlation argument. This model showed significant temporal variation
247 across months (Intercept $\beta = 1.90 \pm 0.16$; $s(\text{month}) F = 2.78$, $p = 0.006$). WVC had a
248 bimodal distribution, peaking in March and October. Winter WVC was substantially
249 lower than summer WVC (Fig. 3).

250

251 PC1 accounted for 24% of total variance in the data and was positively associated with
252 semi-natural grassland, and negatively associated with improved grassland. The
253 loadings of PC2 (14%) described a negative association with improved grassland and a
254 positive association with urban cover. PC3 (13%) was associated positively with
255 wetland and heathland, and negatively with broadleaf and coniferous forest (Table 2).

256

257 The best-approximating habitat model suggested that polecat WVC occurred with
258 greater frequency in landscapes that were more fragmented (habitat patchiness; $\beta =$
259 11.57 ± 1.84 [95% Confidence Interval]) and had greater road densities ($\beta = 0.4.20 \pm$
260 1.63) than areas where WVC were not recorded. Polecat WVC were also more likely
261 where rabbits occur (distance to rabbits; $\beta = 3.63 \pm 1.31$), at lower elevations ($\beta = -2.09$
262 ± 1.03) and in areas with more semi-natural grassland and less improved grassland
263 (PC1; $\beta = -1.17 \pm 0.31$). Polecat WVC also exhibited spatial autocorrelation; carcasses
264 were found nearer to other polecat carcasses than would have been expected by
265 chance (Moran's I; $\beta = 4.92 \pm 4.19$). The top subset of models within $\leq 2 \Delta AIC$ used to
266 create the average model consisted of six models. Six variables occurred across all six

models (weight = 1.00): road density; habitat patchiness; distance to rabbits; PC1; elevation; and Moran's I. PC2 occurred in three models (weight = 0.57), and waterway density and PC3 both occurred in two models (weight = 0.37 and 0.19, respectively; Table 3).

Traffic models behaved similarly to habitat models. Polecat WVC were again associated with a more fragmented landscape ($\beta = 1.14 \pm 0.19$); greater road densities ($\beta = 4.585 \pm 1.70$), proximity to rabbits ($\beta = 3.80 \pm 1.39$), lower elevations ($\beta = -2.42 \pm 1.13$), and semi-natural grassland and less improved grassland ($\beta = -1.12 \pm 0.32$). There was a positive association between traffic volume and WVC, with more carcasses being recorded on more active roads ($\beta = 2.77 \pm 1.99$). Similar results were observed in the average model, in which six variables - distance to rabbits, elevation, habitat patchiness, road density, traffic volume, and PC1 - occurred in all 14 models (i.e. importance = 1) across the top subset of models. Waterway density (weight = 0.43), Moran's I (weight = 0.38) and PC3 (weight = 0.33) each occurred in six models (Table 4). It should be noted that our thinned traffic dataset was biased towards trunk road and primary roads, both meant for high volumes of traffic. Almost all records associated with these road classes were retained, compared to only 10% of records from unclassified roads, 15% from service roads and 30% from tertiary roads.

Discussion

Polecat WVC occurred most frequently in March and October, coinciding with the seasons that polecats are most mobile (Birks 2012). Prior research suggests that

carnivores are particularly vulnerable during specific life-history stages (Grilo *et al.*, 2009). Polecats typically occupy fixed home ranges throughout the year, with two exceptions - the breeding season (March and April) and during the period of kit dispersal in autumn (Birks 2012). Polecats are polygynous (Lodé 2001) and males travel outside of their home-range to find and mate with several females each year, likely increasing their interactions with roads. Moreover, juveniles leaving their natal home range may be particularly susceptible to WVC as they are likely naïve to the variable dangers of roads (Grilo, Smith and Klar 2015; Carvalho *et al.* 2018). High juvenile WVC in the autumn has the potential to negatively impact recruitment and perturb population age- and genetic structure (Holderegger and Di Giulio 2010). We recommend that future WVC studies aim to collect age and sex information whenever possible with the goal of exploring potential population-level impacts.

There was a strong relationship between polecat WVC and the presence of European rabbits adjacent to the road. In Wales, as well as other countries with large rabbit populations, rabbits make up the majority of polecat diet, and polecats frequently use rabbit warrens as daytime resting sites (Birks and Kitchener 1999; Barrientos and Bolonio 2009; Birks 2012). Prey availability in roadside verges has been linked to increases in predator roadkill, especially in heavily agricultural or developed areas where verges may provide refuge for small and medium sized mammals (Barrientos and Bolonio 2009; Silva *et al.* 2019). The presence of rabbits near roads may also lead to higher rabbit road mortality, offering scavenging opportunities which may prove dangerous (Silva *et al.* 2019).

313

314 Habitat analysis showed that WVC was positively associated with areas of improved
 315 grassland, and negatively with semi-natural grassland. Grassland is the most prominent
 316 land classification in Wales, and is the preferred habitat for European rabbits (Birks
 317 2012; Mathews *et al.* 2018b). The split between improved and semi-natural grassland is
 318 likely an effect of elevation, as semi-natural grassland is found primarily in upland areas
 319 and improved grassland in lowland areas. The negative relationship with elevation also
 320 appeared in the models. Several past distribution surveys have reported that polecats in
 321 the UK are less common in upland areas than lowlands, potentially due to a reduction in
 322 available resources at higher elevations (Birks and Kitchener 1999; Croose 2016). Birks
 323 and Kitchener (1999) made the connection that roadways tend to follow valley bottoms
 324 and suggested the increased road density in lowland areas as a potential reason that
 325 polecats have been slow to recolonise parts of the South Wales valleys, the most
 326 densely populated part of the country. The lack of density estimates for polecats, or a
 327 reliable proxy, meant that this variable was not included in the model. However, polecat
 328 densities are thought to be uniform across habitats in Wales, with the exception of
 329 urban areas (Mathews *et al.* 2018; Mathews *et al.* 2020) so the trends observed here
 330 are unlikely to be due to differing densities across habitat types. Still, we recommend
 331 further surveys focused on determining polecat population metrics to inform future
 332 models.

333

334 The influence of habitat patchiness evident herein suggests that polecats are at greater
 335 risk in heavily fragmented landscapes. Several studies on polecat habitat use have

shown a preference for heterogeneous landscapes with a high number of habitat patches (Zabala *et al.* 2005; Mestre *et al.* 2007). Indeed, fragmentation to some degree can be beneficial for a generalist predator such as the polecat as it may provide a higher variety of food resources and a large amount of edge habitat, which can increase landscape-scale connectivity (Zabala *et al.* 2005). However, fragmentation and interactions that increase WVC risk can create barriers to movement and impede functional connectivity (Forman and Alexander 1998; Grilo *et al.* 2011). Further, the influence of road density on polecat WVC risk is clear. It has been suggested that polecats actively avoid roads (Grilo *et al.* 2008, 2009). However, roadside vegetation may provide cover for polecats as well as ample opportunities for scavenging roadkill (Schwartz *et al.* 2018). Polecat population density may also play a role, as high densities of impacted wildlife species have been shown to be important predictors of WVCs in some studies (e.g. Rolley and Lehman, 1992; Mayer *et al.* 2021). Thus, active avoidance is unlikely to be possible where roads or polecats occur at sufficient densities that interactions are inevitable.

We found that higher traffic densities were associated with increased frequencies of polecat WVC. This corresponds with previously published literature on WVC in polecats and other species (Grilo, Bissonette and Santos-Reis 2009; Červinka *et al.* 2015; Jacobson *et al.* 2016). The relationship between WVC and traffic volume (traffic flow theory) suggests that collisions will increase in accordance with traffic volume to a certain threshold, after which high traffic activity causes animals to avoid roads entirely (van Langevelde and Jaarsma 2004; Moore *et al.* 2020). Jacobson *et al.* (2016)

expanded on the traffic flow model using species-specific behavioural responses to traffic to better predict the effect of WVC and barrier effects on populations. Within their framework species are categorized into four categories: nonresponsive, pausers, speeders and avoiders. Polecats most likely fit into the pauser category along with skunks and porcupines. This group tends to respond to perceived risk using by reducing their speed or freezing, increasing the time spent on the roadway and increasing risk of WVC especially in high traffic areas (Jacobson *et al.* 2016).

WVC were most often reported on trunk roads and primary roads, both road classes meant for long-distance travel and associated with high traffic volume and high speed limits (Department for Transport 2012). There is likely an element of observational frequency bias in these results, where a greater number of people using a road leads to a greater number of roadkill reports. However, the relationship between WVC and roads with high traffic volume and speeds is well documented (van Langevelde and Jaarsma, 2004; Jaarsma, van Langevelde and Botma, 2006; Pagany and Dorner, 2016; Canal *et al.*, 2019; Russo *et al.*, 2020). Second to trunk roads, the greatest number of observations came from unclassified roads, which are small roads connecting rural and suburban areas that make up approximately 60% of the roads in the UK (Department for Transport 2012). While this may appear to contradict the result that WVCs increase with traffic volume, the sheer number of unclassified roads likely contributed to the comparatively high number of recorded collisions. Reports may also be somewhat biased towards unclassified roads as, although WVC are less frequent, they may be more likely to be reported when they do occur. Unclassified roads generally have slow

speed limits and little traffic, making it easier to spot roadkill while driving and more convenient to stop, examine, and report the carcass than it would be on a busy road.

Conclusion

This paper is the first to describe factors influencing polecat WVC in Wales, the historic stronghold for the species in Britain. As polecat populations continue to recover after near extirpation, addressing potential risks to their survival is crucial. The Welsh polecat population is important to maintaining the genetic legacy of polecats in Britain, as it has been shown that they have higher rates of hybridisation with feral ferrets elsewhere in their range. Further research on this topic should look at population-level effects of WVC and spatial variation thereof and seek to identify appropriate mitigation measures. This research has implications for polecat protection in Wales as well as applicability to the rest of Britain, and throughout their European range, where they are thought to be in decline in several countries.

Acknowledgements

The authors would like to thank the Vincent Wildlife Trust for providing data on polecat WVC, as well as the many volunteers who submitted observations to make this work possible.

Table 1 (on next page)

Summary of the environmental covariates used for modelling polecat road mortality. TC = Land Class Map 2015 target class.

1

Description	Type	Source	Reference
Broadleaf woodland (% cover)	Raster, non-composite; TC 1	Land Cover Map 2015	Baghli <i>et al.</i> , 2005
Coniferous woodland (% cover)	Raster, non-composite; TC 2	Land Cover Map 2015	Zabala <i>et al.</i> , 2005
Arable (% cover)	Raster, non-composite; TC 3	Land Cover Map 2015	Birks, 2008
Improved grassland (% cover)	Raster, non-composite; TC 4	Land Cover Map 2015	Baghli <i>et al.</i> , 1005
Semi-natural grassland (% cover)	Raster, composite; TC 5, 6, 7	Land Cover Map 2015	Baghli <i>et al.</i> , 2005
Heathland (% cover)	Raster, composite; TC 9, 10	Land Cover Map 2015	Fournier <i>et al.</i> , 2007
Wetland (% cover)	Raster, composite; TC 8, 11	Land Cover Map 2015	Birks, 2008
Urban (% cover)	Raster, composite; TC 20, 21	Land Cover Map 2015	Baghli <i>et al.</i> , 2005
Number of habitat patches	Raster, non-composite	Land Cover Map 2015	Zabala <i>et al.</i> , 2005
Density of roads	Spatial line	Open Street Map	Forman and Alexander, 1998
Density of water features	Spatial line	Open Street Map	Bahgli <i>et al.</i> , 2005
Distance to rabbits	Spatial point	National Biodiversity Network	Barrientos and Bolonio, 2009
Road type	Spatial line	Open Street Map	Barrientos and de Dios Miranda, 2012
Traffic volume	Spatial point	Department for Transport	van Langevelde and Jaarsma, 2004
Elevation	Spatial point	Calculated with Elevatr in R	Birks, 2012

2

Table 2 (on next page)

Principal Component Axes loadings showing variation in the habitat classes used in roadkill models and retained within the top subset of models ($\Delta AIC \leq 2$; see Supplementary Information for PCs 4-8).

The percentage of total variation explained by each component is given in parentheses. Loadings that explain the largest proportion of each PC are in bold.

1

Habitat type	Principal Component Axes		
	PC1 (24%)	PC2 (14%)	PC3 (13%)
Arable	-0.297	0.012	-0.360
Broadleaf woodland	-0.277	0.392	0.427
Coniferous woodland	0.351	0.126	0.496
Heathland	0.263	0.070	-0.467
Improved grassland	-0.566	-0.411	0.054
Semi-natural grassland	0.540	-0.186	0.051
Urban	-0.115	0.787	-0.173
Wetland	0.129	0.057	-0.435

2

Table 3 (on next page)

Results of habitat models (n = 171 presence, 1200 pseudo-absence) investigating habitat and road characteristics in relation to polecat road mortality.

The conditional average model was created from the top subset ($\Delta AIC \leq 2$) of six models. Regression coefficients (β) and 95% confidence intervals (+/- 95% CI) are given as well as the significance of each variable where *P < 0.05, ** P < 0.01, and *** P < 0.001. The weight of variables included in conditional average model is also given, with the importance (number of candidate models that contain the variable) in parentheses.

1

Variable	Best-approximating model		Full average model		
	β	+/- 95% CI	β	95% CI	Weight
Habitat patchiness	11.57	1.84***	11.47	1.83***	1.00 (6)
Elevation	-2.09	1.03***	-2.09	1.06***	1.00 (6)
Moran's I	4.92	4.19*	4.89	4.16*	1.00 (6)
Road density	4.20	1.63***	4.19	1.63***	1.00 (6)
Distance to rabbits	3.63	1.31***	3.66	1.33***	1.00 (6)
PC1	-1.17	0.31***	-1.17	0.31***	1.00 (6)
PC2	-0.18	0.22	-0.10	0.23	0.57 (3)
Waterway density	-	-	0.47	1.67	0.37 (2)
PC3	-	-	-0.02	0.03	0.19 (2)

2

Table 4(on next page)

Results of traffic models analyzing habitat and road characteristics related to polecat road casualties using only data points associated with traffic counts (n = 150 presence, 1,058 pseudo-absence).

The conditional average model was created from the top subset ($\Delta AIC \leq 2$) of fourteen models. Regression coefficients (β) and 95% confidence intervals (+/- 95% CI) are given as well as the significance of each variable where *P < 0.05, ** P < 0.01, and *** P < 0.001. The weight of variables included in conditional average model is also given, with the importance (number of candidate models that contain the variable) in parentheses.

1

Variable	Best-approximating model		Full average model		
	β	95% CI	β	95% CI	Weight
Road density	4.58	1.70***	4.05	0.83***	1.00 (14)
Distance to rabbits	3.80	1.39***	3.86	1.39***	1.00 (14)
Elevation	-2.42	1.13***	-2.41	1.13***	1.00 (14)
Traffic volume	2.77	1.99**	2.49	2.02*	1.00 (14)
Patches	1.14	0.19***	1.13	0.19***	1.00 (14)
PC1	-1.12	0.32**	-1.13	0.32***	1.00 (14)
PC2	-0.20	0.26	-0.11	0.28	0.55 (7)
Waterway density	-	-	0.56	0.90	0.43 (6)
Moran's I	-	-	1.12	4.11	0.38 (6)
PC3	-	-	-0.05	0.20	0.33 (6)

Figure 1

Maps of Wales showing locations of (a) mortalities ($n = 171$) and (b) pseudo-absences ($n = 1200$).

Country shapefiles were extracted using the *maps* (Becker and Wilks, 2021) and *mapdata* (Becker and Wilks, 2018) packages in R.

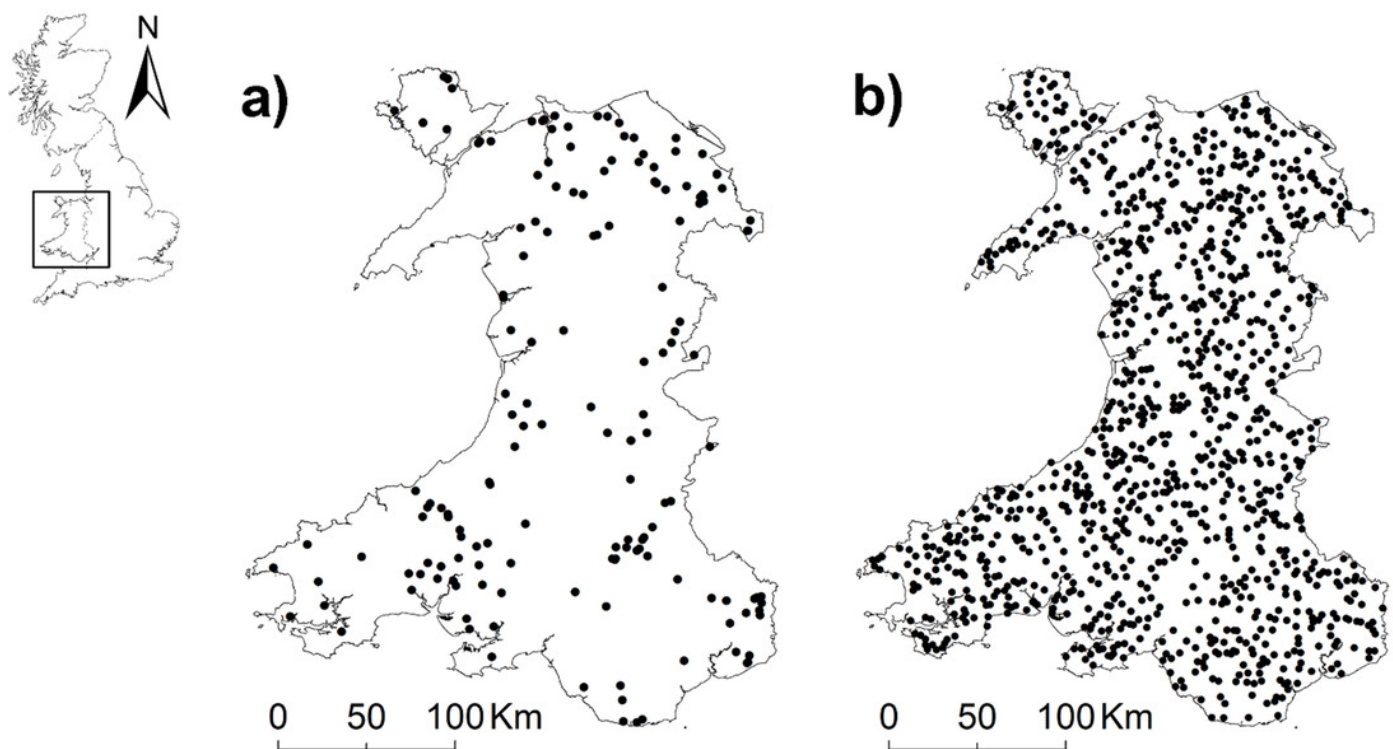

Figure 2

Total numbers of polecat road casualties associated with certain road types in Wales.

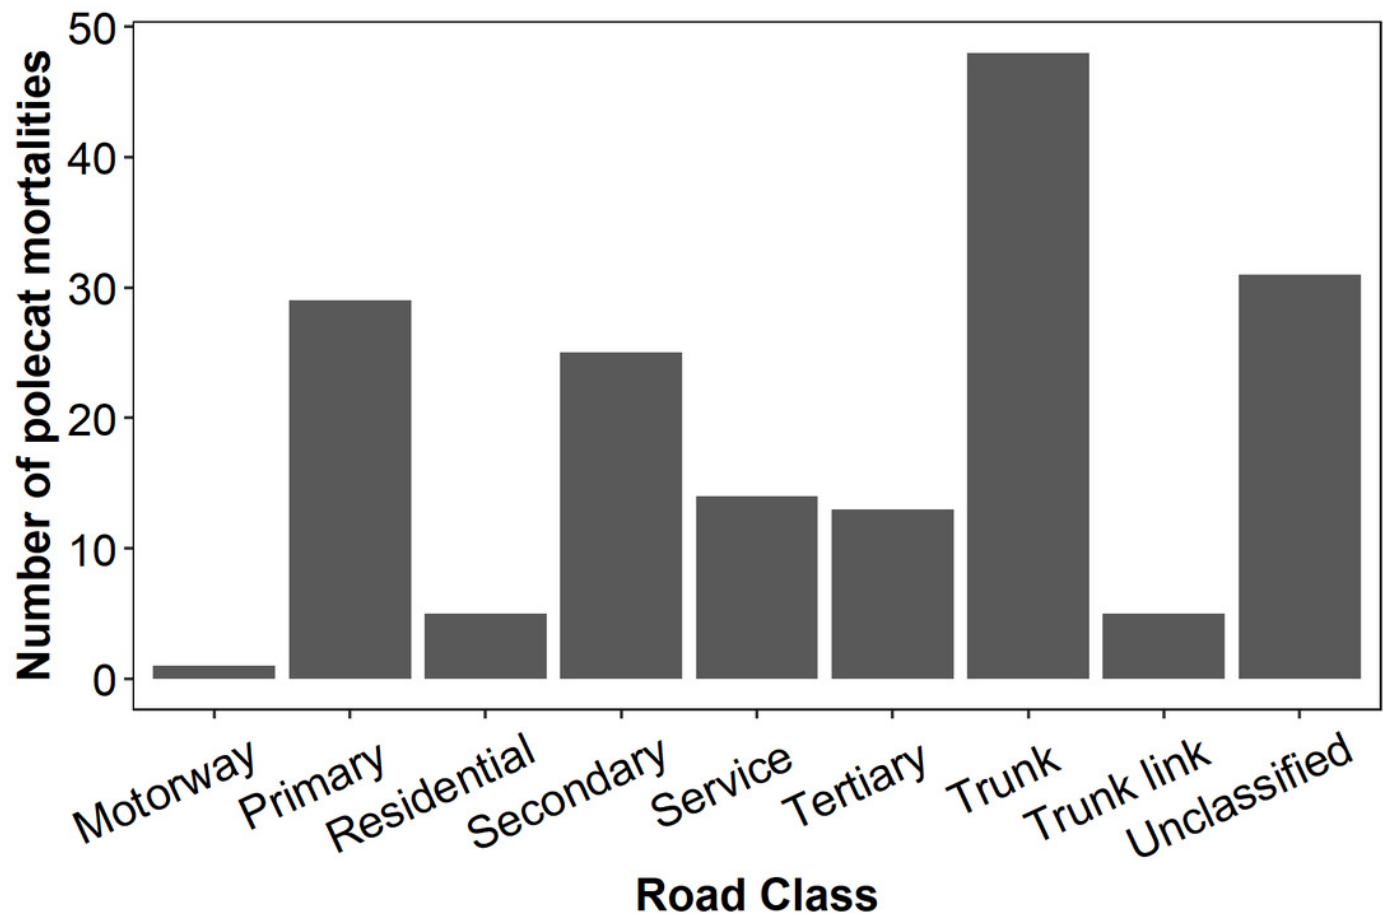

Figure 3

Seasonal fluctuation in polecat WVC showing smoothed number of detections with 95% confidence intervals.
