Two studies explore possible psychological factors to explain the disposition to marginalize healthcare personnel (HP) in Mexico during the COVID-19 pandemic. In study one, 520 participants responded to three instruments that measure the disposition to marginalization, the perceived contagion risk, and the positive beliefs towards HP. Results showed a generalized low disposition to marginalization, where only a small percentage obtained high scores. A regression analysis identified that marginalization towards HP can derive mainly from the perception of risk of contagion, although positive beliefs of HP decrease this disposition. The second study extends this finding by analyzing responses of 286 participants to 7 instruments measuring factors hypothesized as predictors towards marginalization: uncertainty generated by the pandemic, selfish strategies to face off the pandemic, social capital, trust in institutions, perceived vulnerability of contagion, perceived risk of contagion, and positive beliefs towards HP. A path analysis reveals that the main predictor of marginalization is the perceived risk of contagion, increased by the strategy of selfishness, and the uncertainty generated by the pandemic. These results are discussed emphasizing the importance of cooperation and community ties to prevent marginalization of HP in the context of sanitary emergencies generated by contagious diseases.

21 **Abstract**

22 Two studies explore possible psychological factors to explain the disposition to marginalize
23 healthcare personnel (HP) in Mexico during the COVID-19 pandemic. In study one, 520
24 participants responded to three instruments that measure the disposition to marginalization, the
25 perceived contagion risk, and the positive beliefs towards HP. Results showed a generalized
26 low disposition to marginalization, where only a small percentage obtained high scores. A
27 regression analysis identified that marginalization towards HP can derive mainly from the
28 perception of risk of contagion, although positive beliefs of HP decrease this disposition. The
29 second study extends this finding by analyzing responses of 286 participants to 7 instruments
30 measuring factors hypothesized as predictors towards marginalization: uncertainty generated by
31 the pandemic, selfish strategies to face off the pandemic, social capital, trust in institutions,
32 perceived vulnerability of contagion, perceived risk of contagion, and positive beliefs towards
33 HP. A path analysis reveals that the main predictor of marginalization is the perceived risk of
34 contagion, increased by the strategy of selfishness, and the uncertainty generated by the
35 pandemic. These results are discussed emphasizing the importance of cooperation and
36 community ties to prevent marginalization of HP in the context of sanitary emergencies
37 generated by contagious diseases.

38

39 **Introduction**

40 Marginalization is a process by which individuals or groups are deprived of mobility, control over
41 self-will and/or critical resources; are subjected to undignified or humiliating treatment; exposed
42 to toxic environments; and/or physically or mentally exploited, implying greater security, health,
43 social and political risks (Hall and Carlson, 2016). Marginalization and social exclusion can
44 emerge when the population feels threatened by an individual or group, who is perceived as
45 having the capacity to disunite, undermine or contaminate the community. These reactions have
46 previously risen in the face of infectious diseases (Person, Sy, Holton, Govert, & Liang, 2004)
47 and have now emerged with greater intensity around the world in the face of the COVID-19
48 pandemic. Acts of violence have been observed in virtual environments, such as aggressive
49 posts on Facebook groups towards those with a Chinese ethnic background (Whitehead et al.,
50 2020). This aggressive form of discrimination also incurs physical consequences, such as a
51 denial of entry to restaurants and services to people who speak Mandarin, and even serious
52 hate crimes like physical assaults and stabbing cases. Such acts as justified by the argument of
53 punishing them for their alleged responsibility in causing the pandemic (Xu et al., 2021).

54 Healthcare personnel (HP), located in the first lines of defense against the disease, were one of
55 these marginalized sectors during the health contingency (Bhanot, Singh, Verma &
56 Sharad, 2021). For example, in the Philippines, there were chlorine attacks on HP (Economist,
57 2020). In India, the mistreatment of medical personnel escalated to the point of being
58 threatened, spat on, beaten, stoned, and thrown out of their homes (Manoj, Padubidri, Saran,
59 Rao, Shetty, & D'Souza, 2021). In Mexico, there were reports of medical and nursing staff
60 having eggs, hot coffee, and other verbal and physical attacks thrown at them (Semple, 2020).

61 In April 2020, less than a month after the World Health Organization (WHO) declared COVID-19
62 a pandemic, at least twenty-one complaints from health workers and close to one hundred and
63 forty calls related to acts of discrimination taken for one hour were registered with the National
64 Council to Prevent Discrimination in Mexico. This was equivalent to what they typically received
65 in a week (González Días, 2020). These aggressions can find their explanation in the fear of

66 being infected, but they require a deeper analysis since they violate human rights and obviously,
67 harming those who care for our health is extremely detrimental to common well-being,
68 especially when we face a health emergency such as that caused by COVID-19.
69 Based on these antecedents, two studies were carried out. The first study sought to quantify the
70 disposition of the population in Mexico to marginalize HP and to identify if this disposition was
71 associated with the perception of the HP as a possible risk of contagion. The second study
72 extends these results, analyzing in a second sample of Mexican population other explanatory
73 factors of marginalization towards health care personnel.

74

75 **Study 1. Descriptive and sociodemographic components of** 76 **marginalization**

77 Cases of violence and marginalization towards HP have been reported in Mexico under the
78 argument of implying a risk of contagion (Semple, 2020; González Días, 2020), but there are no
79 studies that analyze the perception of the general population towards HP. This first study
80 explores the perception of a sample of Mexican inhabitants towards HP, in terms of being
81 positive, being perceived as a risk of contagion, and the disposition to marginalize them socially.
82 Considering the isolated reports of violence, and assuming a widespread fear in the population
83 of a disease that has cost the lives of millions, it can be proposed that HP, who are exposed
84 daily to the virus more than others, are possibly perceived as a threat to society, due to an
85 assumed higher capacity to spread the virus. At the same time, the important work of HP for
86 caring community people against COVID-19 can generate a positive perception in the
87 population, which would protect them from being marginalized. To test this hypothesis, a
88 quantitative, cross-sectional, correlational study, with an explanatory scope, was carried out.

89

90 **Materials & Methods**

91 **Participants**

92 Participants were 193 (34.2%) men, 333 (58.9%) women, and 39 (6.9%) that no answer that
93 question, aged between 17 and 68 years ($M = 24.08$, $SD = 7.62$), residents of northern (76%)
94 and central-southern states (24%) from Mexico. 42.2% declared having unfinished careers,
95 34.2% upper secondary studies, and 19% completed undergraduate studies. 2.9% reported
96 working in a hospital and 29.2% declared having relatives who worked in a hospital. 74.5%
97 stated that they did not have children. No one reported having been diagnosed with COVID-19
98 up to the time of the survey and 92.9% confirmed that they had not had related symptoms. Only
99 2.8% stated that one of their family members had been diagnosed with COVID-19 and 84.4%
100 stated that no one in their family had experienced related symptoms.

101 **Instruments**

102 *Marginalization towards healthcare personnel.* It is made up of six items: If I had a neighbor
103 who works in a hospital, I would prefer not to find him on the street in order to not get infected;
104 Even if I could help a doctor or a nurse, I would prefer not to do it so as not to risk getting
105 infected; The children of nurses and doctors should not be admitted to nurseries because they
106 can infect other children; Staff working in hospitals should be prevented from using public
107 transport to avoid infecting others; If a person working in a hospital asked me for help I would
108 prefer not to do so in order to avoid being infected; It would be best if the doctors and nurses
109 moved near the hospitals in order to avoid infecting others. The exploratory factor analysis
110 identified a single factor that groups the six items and explains 52% of the variance with a
111 Cronbach's alpha index=.85.

112 *Perceived contagion risk towards healthcare personnel.* It is made up of three items: If I am
113 buying something and a doctor or a nurse arrives at the same place, I would worry that they
114 could infect me; If a doctor or a nurse are on the public transport as me, I would be afraid of
115 being infected by them; Being close to a doctor or a nurse implies a higher risk of contagion
116 than people who do not work in the medical industry. The exploratory factor analysis identified a

117 single factor that groups the three items, explaining 62% of the variance with Cronbach's alpha
118 =.80.

119 *Positive beliefs towards healthcare personnel.* It is made up of six items: Faced with this
120 contingency, people who work in hospitals are risking their lives for the good of everyone;
121 Nurses and doctors are the ones who most deserve our support in this contingency; Doctors
122 and nurses are acting with great courage at work since they are most at risk of infection ; If I
123 could support the doctors and nurses in this contingency, I would gladly do so; At the end of this
124 contingency, we will all be in debt to the country's doctors and nurses; While we stay at home,
125 doctors and nurses risk their lives to help others. The exploratory factor analysis identified a
126 single factor that groups the six items, explaining 39.8% of the variance with a Cronbach's alpha
127 index=.77.

128 Responses to these instruments were rated on a Likert-type scale ranging from 1 (Strongly
129 disagree) to 4 (Strongly agree). In addition, it required sociodemographic data such as age, sex,
130 educational level, whether they or a relative worked in a health care center, whether they had
131 children and whether they or their relatives had received a positive diagnosis for COVID-19, and
132 the state of residence.

133

134 **Procedure**

135 The Autonomous University of Juárez City granted full ethical approval to conduct the study
136 (Ethical Permission Reference: CEI-2020-2-43). Participants were invited to participate in the
137 study via email containing a link to the study website. Measures were administered through the
138 SurveyMonkey online tool (SurveyMonkey, San Mateo, CA, USA;
139 <http://www.surveymonkey.com>).

140 The survey was conducted from the second to the fourth week of April 2020, one month after
141 the WHO declared COVID-19 a pandemic on March 11, 2020 ("Coronavirus confirmed as a
142 pandemic", 2020), three weeks after essential face-to-face activities were partially or totally

143 abolished in Mexico on March 26, 2020 (Palma et al., 2020), and one week after a national
144 health emergency was declared in Mexico on March 31, 2020. 2020 (Borunda, 2020). The
145 support of students and acquaintances was requested to invite possible full-time workers as
146 participants. If they agreed to participate, the details of the informed consent and the procedures
147 for completing the measures were explained to them.

148 In order not to expose the health of the participants during the quarantine period, they were
149 reminded that these invitations should be made electronically, without leaving their homes. With
150 these characteristics, the sampling used in this study is considered non-probabilistic. Consent
151 was obtained by digital means from all participants. They were informed that their answers
152 would be confidential, their information would be protected by the research team and their
153 participation would be voluntary.

154 **Data analysis**

155 The construct validity of the instruments was verified by exploratory factor analysis with the
156 maximum likelihood extraction method, with an eigenvalue greater than 1 as an extraction
157 criterion. The internal consistency of each factor was calculated using Cronbach's alpha
158 formula. Once the structure and internal consistency were verified, new indicators were formed
159 for each instrument by averaging their items. Mean comparisons were performed using t-tests
160 and one-way analysis of variance using the software Jamovi (The jamovi project, 2021). To
161 verify the hypotheses of predictive effects on marginalization, multiple linear regressions were
162 performed using the stepwise method in the SPSS 22 program (IBM, 2013).

163

164 **Results**

165 As seen in figure 1, the averages of marginalization and perceived risk are generally low,
166 nearby to the response options "Totally disagree" and "Disagree", while the average of positive
167 perceptions is located closer to the "Totally agree" option. These would be the general trends,
168 but it is identified that 5% report average scores of marginalization between 2.5 and 4, that 10%

169 report average scores between 3 and 4 of the perceived risk of contagion, and that 5% report
170 scores of 3 and lower of positive beliefs towards HP.

171

172 INSERT FIGURE 1 HERE

173

174 Table 1 shows the comparison of marginalization averages through the different
175 sociodemographic indicators. Statistically significant differences are observed between those
176 who have or do not have family members who work in a health care center, with slightly higher
177 scores on marginalization in those who do not have family members working in these centers.
178 Those who reside in the north of the country also report slightly higher scores than the central-
179 southern states. In both cases the scores do not reach the value 2, indicating an opinion against
180 marginalization. Cohen's d with values close to .2 indicate a small effect size for both
181 differences.

182

183 INSERT TABLE 1 HERE

184

185 The regression analysis showed positive effects of the perceived risk of HP ($B=.44$, $\beta=.61$,
186 $t=18.95$, $p<.001$) and negative effects of positive beliefs towards HP ($B=-.15$, $\beta=-.11$, $t=-3.57$,
187 $p<.001$), which together explain 40% of the variance of marginalization towards HP ($R^2=.40$,
188 $F_{2,562}=189.03$, $p<.001$). With a tolerance level = .99, collinearity problems between the
189 independent variables are discarded.

190

191 **Conclusions of study 1**

192 The social perception of HP can be considered positive, with low scores of marginalization and
193 perceived risk of contagion and high scores of positive beliefs. Slightly higher scores of

194 marginalization are identified in those who do not have relatives working in healthcare centers
195 and inhabiting the northern region of the country. Although these scores are low, indicating a
196 rejection of beliefs of marginalization towards HP. However, it should be noted that a low
197 percentage reported high scores for disposition to marginalization and perceived risk of
198 contagion towards HP. The regression analysis identifies that marginalization towards HP can
199 derive mainly from the perception of risk of contagion, although the beliefs of HP as heroes who
200 risk their lives for the good of society decreases the disposition to marginalization derived from
201 the perceived risk of contagion.

202

203 **Study 2: Psychosocial predictors of marginalization towards HP**

204 Study 1 showed a generalized low disposition to marginalization in most of the population,
205 although a small percentage did report this disposition in high scores. It was also identified that
206 the perceived risk of contagion is an important predictor of marginalization, while positive beliefs
207 towards HP help to diminish this effect. Given these results, it is necessary to identify some
208 factors associated with a greater disposition to marginalization to understand this phenomenon.
209 This second study identify in the previous research and propose the exploration of the following
210 as explanatory factors of marginalization toward HP.

211

212 **Cooperation**

213 Cooperation is understood as a practice where an individual or group invests part of their
214 resources (e.g., time, money, work) in a joint task with another individual or group to obtain a
215 common benefit (Bowles & Gintis, 2011). This investment always involves some risk that the
216 other investors betray our trust, for example, not contributing their resources hoping that others
217 investment were sufficient or appropriating the obtained benefits and not sharing them.

218 Attacks on HP or ethnic groups under the argument that they imply a risk of contagion may be
219 indicating a tendency to reserve cooperation only for the closest members of our group. For
220 example, Strachman and Schimel (2006) argued that thinking about the possibility of dying
221 motivates the need to defend a general vision of how the world works according to our own
222 beliefs, showing evidence that generating thoughts about one's own mortality leads to a lower
223 commitment to the romantic partner, but only when both individuals endorse very different
224 beliefs. Using a similar methodology, Renkema et al. (2008) showed that people induced to
225 think about their own death were more likely to change their own ideas and adhere to ideas
226 common in their own group but rejected ideas coming from different groups. In addition, they
227 tended to perceive people from other groups based on stereotypes, without dwelling on their
228 differences, which can lead to a greater perception of threat from the group and its members
229 (Haner, Sloan, Pickett, & Cullen, 2020). This behavior would be explained as a psychological
230 strategy that would favor stronger alliances by motivating the formation of more heterogeneous
231 groups that would allow them to confront more successfully a possible death threat. These
232 individual cognitive processes can lead to the decomposition of the broader social fabric,
233 affecting bonds of trust and reciprocity fundamental to the well-being of more heterogeneous
234 communities, motivating individuals and communities to lock themselves in their closest social
235 nuclei, deny wider cooperation, and escalate the level of hostility towards others, in this case
236 towards health care personnel.

237

238 **Uncertainty**

239 Another factor that can exacerbate violence against others is the uncertainty generated by the
240 pandemic. Brizi, Mannetti, and Kruglansky (2015) found that people with a dispositional need to
241 find a quick response to situations of uncertainty, known as a need for closure, tended to
242 discriminate more frequently against people from other groups. However, this tendency for
243 discrimination was equally increased when uncertainty was intensified through an experimental

244 manipulation, even in individuals with lower levels of need for closure. That is, uncertainty,
245 whether due to a personality disposition or generated by external conditions (e.g., a pandemic),
246 increases the tendency to discriminate against those who are perceived as different. Cruz-
247 Torres and Martín del Campo-Ríos (2022) identified that the uncertainty generated by the
248 pandemic increases the disposition to selfishness (e.g., believing that during the contingency
249 seeing for others is a mistake) and the perceived selfishness in others (e.g., considering that
250 with contingency people try to get what they want, even going over others).

251

252 **Social capital**

253 These effects of uncertainty on cooperation may be less important in communities that have
254 stronger bonds of reciprocity and trust. In this sense, Putnam (1994) proposes that communities
255 vary in their levels of social capital, which is defined as the concordance between social trust,
256 norms of reciprocity and networks of civic commitment in an association of people to coordinate
257 collective actions. Thus, communities that maintain their networks after having successfully
258 become organized to solve common problems, trust each other and keep their bonds active
259 through reciprocal exchanges, are said to have high social capital.

260 These resources of the community have been related to a higher perception of safety, for
261 example, in the face of criminal violence (Hansen-Nord et al., 2014; Dinesen et al., 2013). In this
262 same sense, Cruz-Torres and Martín del Campo-Ríos (2022) identified that social capital acts
263 as a moderator of the uncertainty derived from the pandemic, reducing the negative effects
264 towards non-cooperation. After considering this capacity, higher levels of social capital can be
265 expected to be associated with a lower disposition to non-cooperation and the marginalization of
266 HP.

267

268 **Perceived vulnerability to contagion**

269 Given that the root of uncertainty, no cooperation, and marginalization is the fear of contagion, it is
270 likely that people who perceive themselves to be especially susceptible to contagion tend to
271 present greater fear and uncertainty, and with it, more intense selfishness and disposition to
272 marginalize others. In this regard, Duncan, Schaller, and Park (2009) have shown that the
273 perceived vulnerability to contagion can be considered an individual difference and that people
274 have higher or lower levels that can be quantified psychometrically. Mallett, Coyle, Kuang, &
275 Gillanders, (2021) showed that perceived vulnerability to contagion and intolerance of
276 uncertainty are associated with greater anxiety during the pandemic. In the same sense,
277 Padmanabhanunni, Pretorius, Stiegler, and Bouchard (2022) demonstrated that those who
278 report high levels of perceived vulnerability to contagion have suffered more anxiety,
279 depression, and hopelessness during the pandemic. These antecedents motivate a further
280 exploration of the hypothesis that higher levels of perceived vulnerability to contagion are
281 associated with a greater perception of the risk of contagion of HP and a greater willingness to
282 marginalize them.

283 In summary, the study conducted by Cruz-Torres and Martín del Campo-Ríos (2022) proved
284 that the uncertainty generated by the pandemic increased strategies of selfishness in the
285 community, an effect that was diminished in those who perceived that their community had
286 bonds of reciprocity, interpersonal trust, and civic engagement, which are all components of
287 social capital. In turn, the measurement of Duncan, Schaller, and Park (2009) makes it possible
288 to identify variations in the perceived vulnerability to contagion, a factor that could increase the
289 effects of uncertainty and the perceived risk of contagion on marginalization towards the HP.
290 Finally, a factor that cannot be ignored is the trust in government and health institutions, which
291 are elements that can help prevent violence against HP.

292 Considering this background, this second study aims to explore the effects of the uncertainty
293 generated by the pandemic, selfish strategies, social capital, trust in institutions, perceived risk
294 of contagion, positive beliefs towards HP and the perceived vulnerability of contagion on the

295 willingness to marginalize HP in a sample of Mexican inhabitants. It is proposed as a hypothesis
296 that the uncertainty generated by the pandemic, the perceived risk of contagion, the perceived
297 vulnerability of contagion and selfishness will increase the willingness to marginalize HP, while
298 positive ideas towards HP, the components of the social capital and trust in health and state
299 authorities will help reduce this disposition.

300

301 **Materials & Methods**

302 **Participants**

303 Participants consisted of 110 men (38.5%), 176 women (61.5%), and two people that do not
304 answer that question, aged between 18 and 63 years ($M = 23.98$, $SD = 7.57$), residents of
305 northern (79%) and central-southern (21%) states of Mexico. Regarding the educational level,
306 45.8% had unfinished undergraduate studies, 17.9% had intermediate level studies and 26.9%
307 had completed undergraduate studies. 1.8% reported working in a hospital and 25.7% declared
308 having relatives who worked in a hospital; 82.6% stated that they did not have children. No one
309 reported having been diagnosed with COVID-19 and 95.1% stated that they had not had related
310 symptoms. 7.7% stated that one of their relatives had been diagnosed with COVID-19 and
311 78.2% stated that no one in their family had experienced symptoms.

312 **Instruments**

313 In this study the same instruments of the study 1 were used besides the following
314 measurements.

315 *Community Assessment of Social Capital* (Cruz & Contreras, 2015). Responses are rated in 10
316 items on a 4-point Likert-type scale (1 = Strongly disagree to 4 = Strongly agree). Internal
317 reliability estimates for this scale are $\alpha > .80$ for three factors (Cruz & Contreras, 2015). The first
318 factor is called reciprocity and refers to the willingness to support and the expectation of
319 receiving support in response (e.g., If a neighbor asks me for a favor, I know that I will have their

320 support when I need it). The second factor refers to the ability and willingness of neighbors to
321 organize and solve community problems (e.g., if a problem arose on our streets, the neighbors
322 would organize quickly) and is called civic engagement networks. The third factor refers to
323 negative beliefs that denote distrust towards neighbors (e.g., If I am careless, my neighbors
324 would take the opportunity to do something bad to me). To facilitate their interpretation, the
325 estimates of these elements were recorded inversely, so the factor was named confidence.

326 Confirmatory factor analysis showed adequate goodness-of-fit indices (RMR = .03; GFI = .95;
327 AGFI = .91; CFI = .96; RMSEA = .07, CI 90% [.04, .09], PCLOSE= .08), except for the Chi²
328 indicator (Chi² = 55.24, df = 24, p <.001) (Cruz-Torres & Martín del Campo-Ríos, 2022).

329 *Strategies of selfishness during the pandemic.* Instrument that measures in its first factor named
330 selfishness (three items) the concentration of cooperation during the pandemic in the closest
331 social circles, (e.g., In these moments of contingency it is best to see for your family, not for
332 others); and in the second factor named perceived selfishness (three items) the perception that
333 others are not willing to cooperate either (e.g., During a health contingency people try to see
334 only for their own benefit). Responses are rated on a 4-point Likert-type scale (1 = Strongly
335 disagree to 4 = Strongly agree). Confirmatory factor analysis showed adequate goodness-of-fit
336 indices (RMR = .03; GFI = .97; AGFI = .93; CFI = .95; RMSEA = .07, CI 90% [.03, .11],
337 PCLOSE= .13), except for the Chi² indicator (Chi² = 19.98, df = 8, p = .01) (Cruz-Torres &
338 Martín del Campo-Ríos, 2022).

339 *Measurement of the uncertainty resulting from the coronavirus contingency.* Instrument adapted
340 from Lambert, et al. (2014) that evaluates through 5 items in a single factor the perception of
341 uncertainty in the face of changes derived from the health contingency (e.g., At this time I am
342 not sure of my ability to successfully face this contingency). Responses are rated on a 4-point
343 Likert scale (1 = Strongly Disagree to 4 = Strongly Agree).

344 Confirmatory factor analysis showed adequate goodness-of-fit indices ($\text{Chi}^2 = 4.18$, $\text{df} = 4$, $p =$
345 $.38$; $\text{RMR} = .01$; $\text{GFI} = .99$; $\text{AGFI} = .97$; $\text{CFI} = .99$; $\text{RMSEA} = .01$, 90% CI [$<.001$, $.09$],
346 $\text{PCLOSE} = .66$) (Cruz-Torres & Martín del Campo-Ríos, 2022).
347 *Perceived vulnerability to disease* (Schaler, 2009). It measures individual differences in
348 perceived vulnerability to infectious diseases across two factors. The Perceived Infectivity
349 subscale (seven items) examines individuals' beliefs about their susceptibility to infectious
350 diseases (e.g., In general, I am very susceptible to colds, the flu, and other infectious diseases).
351 The germ aversion subscale (eight items) measures people's discomfort in situations that
352 connote a higher probability of transmission of pathogens (e.g., I prefer to wash my hands soon
353 after shaking someone's hand). Confirmatory factor analysis showed adequate goodness-of-fit
354 indices ($\text{RMR} = .06$; $\text{GFI} = .96$; $\text{AGFI} = .94$; $\text{CFI} = .96$; $\text{RMSEA} = .05$, CI 90% [$.02$, $.08$],
355 $\text{PCLOSE} = .31$), except for the Chi^2 indicator ($\text{Chi}^2 = 36.19$, $\text{df} = 19$, $p = .01$) (Cruz-Torres &
356 Martín del Campo-Ríos, 2022).
357 *Trust in institutions*. Trust towards two institutions was evaluated through two independent
358 items: 1) "How much do you trust the health authorities of your state?" and 2) "How much do
359 you trust the governor of your state?", both presented in a Likert-type format with response
360 options ranging from 1 (not at all) to 5 (a lot).

361 **Procedure**

362 Were followed the same procedure and ethical care described in study one. The survey was
363 carried out from the last week of May and the first week of June 2020.

364 **Data Analysis**

365 To verify the hypotheses of predictive effects on marginalization, multiple linear regressions
366 were used using the stepwise method in the SPSS 23 program. To integrate the effects of the
367 independent on the dependent variables in a single model, a trajectory analysis was carried out
368 with the AMOS 22 program (Arbuckle, 2013).

369 **Results**

370 As in study 1, the averages of marginalization (1.4) and perceived risk of contagion (1.69) were
371 low and positive beliefs towards HP were high (3.17).

372 The hypotheses of effects of the independent on the dependent variables were verified by
373 means of linear regressions before proceeding to the trajectory analysis. The regression on
374 marginalization towards HP confirms the effects found in study 1 of the risk of contagion and
375 positive ideas towards HP, adding the effects of selfishness. The model explains 52% of the
376 variance of marginalization ($R^2=.52$, $F_{3,284}=106.18$, $p<.001$) derived from positive effects of the
377 risk of infection of HP ($B=.39$, $\beta=.58$, $t=13.98$, $p<.001$), selfishness ($B=.18$, $\beta=.27$, $t=6.52$,
378 $p<.001$) and negative effects of positive ideas towards HP ($B=-.16$, $\beta=-.10$, $t=-2.57$, $p=.01$). The
379 tolerance levels obtained higher than .93 rule out problems of collinearity between the
380 independent variables.

381 Subsequently, the effects of regression towards the risk of contagion perceived by HP were
382 explored, having as independent variables the factors of social capital (reciprocity, civic
383 engagement networks, and trust), trust towards state health authorities, trust towards the
384 governor of the state, the uncertainty in the face of COVID-19, their selfishness and the
385 selfishness perceived in others. The model explains 9% of the variance of the risk of contagion
386 perceived by HP ($R^2=.09$, $F_{3,281}=9.25$, $p<.001$) derived from the positive effects of selfishness
387 ($B=.21$, $\beta=.21$, $t=3.63$, $p=.01$), the uncertainty generated by the COVID-19 pandemic ($B=.13$,
388 $\beta=.13$, $t=2.39$, $p=.01$) and negative effects of confidence in the state health authorities ($B=-.12$,
389 $\beta=-.13$, $t=-2.39$, $p=.01$). Tolerance showed scores higher than .96, discarding collinearity
390 problems. The factors of social capital, trust in the governor, perceived selfishness in others,
391 aversion to germs, and contagion vulnerability did not show statistically significant regression
392 coefficients and were excluded from the model.

393 The same variables, plus the perceived risk of contagion from HP, were used as independent
394 variables to predict the positive beliefs of HP. The resulting model explains 7% of the variance
395 ($R^2=.078$, $F_{3,280}=7.73$, $p<.001$) derived from the positive effects of trust in health authorities
396 ($B=.10$, $\beta=.21$, $t=3.63$, $p<.001$) and selfishness perceived in others ($B=.10$, $\beta=.16$, $t=2.78$,
397 $p=.006$) and negative effects of the selfishness factor ($B=-.10$, $\beta=-.16$, $t=-.28$, $p=.005$). The
398 tolerance was greater than .90, discarding collinearity problems in the model. The factors of
399 social capital, trust in the governor, germ aversion, contagion vulnerability, and uncertainty did
400 not show statistically significant regression coefficients and were excluded from the model.
401 The analysis was also replicated to predict selfishness, finding positive effects of repeated
402 perceived selfishness in others ($B=.28$, $\beta=.29$, $t=5.32$, $p<.001$), the perceived risk of HP ($B=.18$,
403 $\beta=.19$, $t=3.45$, $p=.001$), trust in state authorities ($B=.10$, $\beta=.14$, $t=2.50$, $p=.01$), and negative
404 effects of positive beliefs towards HP ($B=-.21$, $\beta=-.13$, $t=-2.38$, $p=.01$). Together, these variables
405 explain 15% of the variance of selfishness ($R^2=.15$, $F_{4,279}=12.86$, $p<.001$), discarding collinearity
406 problems with tolerance values greater than .93. The factors of social capital, trust in the
407 governor, germ aversion, contagion vulnerability, and uncertainty did not show statistically
408 significant regression coefficients and were excluded from the model.
409 Once the relevant variables to predict the marginalization of HP and their relationships were
410 identified, these were integrated into a single model through path analysis. All trajectories show
411 statistically crucial Critical Ratio (CR) values. As shown in figure 2, the model explains 53% of
412 the variance of marginalization towards HP, where the risk of infection of HP ($CR=14.02$,
413 $p<.001$) and selfishness ($CR=6.56$, $p<.001$) increase the odds of marginalization, while positive
414 beliefs towards HP decrease them ($CR=-2.59$, $p=.009$). In turn, 9% of the variance in the risk of
415 contagion of HP is explained, derived from positive effects of selfishness ($CR=3.79$, $p<.001$),
416 from the uncertainty due to the COVID-19 pandemic ($CR=2.49$, $p=.01$) and negative trust in
417 health institutions ($CR=-2.72$, $p=.007$). The variance of positive beliefs towards HP is explained
418 by 7%, derived from the positive effects of trust in institutions ($CR=2.95$, $p=.003$) and perceived

419 selfishness ($CR=2.26$, $p=.02$), and negative effects of the perceived risk of contagion of HP
420 ($CR=-2.24$, $p=.02$). Finally, the variance of selfishness is explained by 8%, originating solely
421 from selfishness perceived in others during the pandemic ($CR=5.10$, $p<.001$).

422 The indicator $\chi^2=15.67$, $df=10$, $p=.10$ shows that the discrepancies between the relationships
423 established in the model and those observed in the data matrix are not statistically significant.

424 With a value of $SRMR=.04$, it can be assumed that the model has a tolerable level of residual
425 variance once the trajectories have explained the variance of the dependent variables. Being
426 above .95 and .90, respectively, the $GFI=.98$ and $AGFI=.95$ values indicate that the variance
427 explained by the model is generally adequate. The $CFI=.98$ indicator tells us that the fit of the
428 model is significantly better than the fit of a null relationship model. The indicator $RMSEA=.04$,
429 $CI\ 90\% [<.001, .08]$, $PCLOSE=.53$ indicates that we could expect an equally good fit for this
430 model when replicated in other samples from the same population. Overall, these indicators
431 indicate adequate competency in fit.

434

435 Discussion

436 No case of violence is acceptable, but fortunately so far only isolated cases of violence have
437 been observed in Mexico and no case, at least known, of lynching or more extreme forms of
438 violence that cost the lives of HP have been identified during the pandemic. This coincides with
439 the results presented here of low disposition to marginalization in the measurements of both
440 studies. However, the fact that there are minorities that report high scores in this measurement
441 should not be neglected. Although they are few, it must be considered that acts of extreme
442 social violence require only some committed inciters to ignite an entire community fearful for its

443 safety and lead it to commit inhumane acts of violence through processes of social contagion
444 (Bonnasse-Gahot, Berestycki, Depuiset, Gordon, Roche, Rodriguez, & Nadal, 2018).
445 In the model, the effects of uncertainty and selfish strategies generated by the pandemic that
446 increase the marginalization of HP should be highlighted. This reaction can be explained
447 because of the in-group bias (Hewstone, Rubin, & Willis, 2002), which is a strategy aimed at
448 seeking stable reciprocal links that encourage trust towards and cooperation with those who are
449 perceived as members of the group itself, seeking to reduce the risk of being betrayed by
450 members of other groups who do not share the same interests (Yamagishi & Kiyonari, 2000).
451 This bias does not necessarily imply hostility towards members of other groups (Brewer, 1999),
452 but Choi & Bowles (2007) have proposed that this hostility (known as parochialism) and ingroup
453 bias have evolved together in our species as strategies to appropriate scarce resources
454 essential for survival (Grossman & Mendoza, 2003).
455 This perception of HP as *others*, outside of the community, could also be explaining the inability
456 of social capital to reduce marginalization. Social capital could reduce the marginalization of
457 members of my community for instance (Cruz-Torres & Martín del Campo, 2022), but not
458 necessarily of people outside of it. In fact, the results of Alcorta, Smits, Swedlund, and de Jong
459 (2020) shows that social capital is a facilitator for achieving community goals, which are not
460 always peace-oriented. In reference to their study conducted in Africa, they note that a strong
461 identity with the community is associated with a greater disposition to political violence, where
462 social capital would serve as a catalyst for actions against other groups perceived as different.
463 This pandemic has exposed a risk of marginalization that seems new to most HP, although it
464 has been a constant experience for those fighting ancient endemic contagious diseases such as
465 malaria, Ebola, or leprosy. These experiences make it necessary to reflect on the integration of
466 healthcare centers and their staff in the communities they serve, as part of that same social
467 fabric, for which community interventions and the collaboration of health units with other local
468 authorities would be necessary. This integration would favor a common identity for the

469 inhabitants and HP, which would reduce the risk of marginalization, but would also facilitate
470 other prevention processes if they would be perceived as people interested in achieving good
471 for the community, namely, *their* community. If achieved, this integration would also favor trust
472 in health authorities, an element that is identified here as relevant for improving the perception
473 of HP.

474

475 **Conclusions**

476 The scores of marginalization and perceived risk of contagion are low, while the scores of
477 positive beliefs are high, indicating a general positive perception of HP. The main predictor of
478 marginalization is the perceived risk of contagion, which is increased by the strategy of
479 selfishness and the uncertainty generated by the COVID-19 pandemic. Social capital does not
480 contribute to preventing the marginalization of HP. Strategies of selfishness, contrary to
481 cooperation, motivate the marginalization of HP and increase the risk of contagion perceived in
482 HP. Confidence in the state health authorities reduces the perceived risk of contagion and
483 promotes positive beliefs towards HP, making clear the importance of the authorities to prevent
484 marginalization and their ability to support their personnel from the confidence that their work
485 generates in communities. The perceived susceptibility of contagion was not relevant to
486 predicting marginalization or antecedent factors such as personal selfishness or the risk of
487 contagion of HP, indicating that these factors can be explained by the high risk perceived in
488 others, and not in one's own vulnerability.
