Abstract

More than 50% of congenital hearing loss is hereditary, in which the majority form is non-syndromic. In this study we estimate the most prevalent pathogenic genetic changes in an Ossetian cohort of patients. This is useful for local public health officials to promote genetic counseling of affected families with regard to high allele frequencies of prevalent pathogenic variants and assortative mating in the community of people with hearing loss. In this study, genetic heterogeneity of hereditary non-syndromic sensorineural hearing loss (NSNHL) in a cohort of 109 patients and an assessment of the frequency of two *GJB2* gene pathogenic variants in a cohort of 349 healthy individuals from the populations of the Republic of North Ossetia–Alania (RNO–Alania) were assessed. The molecular genetic cause of NSNHL in the *GJB2* gene in RNO–Alania was confirmed in ~30% of the cases, including ~27% in Ossetians. In Russian patients, the most frequent variant is *GJB2*:c.35delG (~83%). The *GJB2*:c.358_360delGAG variant was found to be the most frequent among Ossetians (~54%). Two genetic variants in *GJB2*, c.35delG and c.358_360delGAG, accounted for 91% of *GJB2* pathogenic alleles in the

40   Ossetian patients. A search for large genome rearrangements revealed etiological cause in two
41   Ossetian patients, a deletion at the *POU3F4* gene locus associated with X-linked hearing loss
42   (type DFNX2). In another Ossetian patient, a biallelic pathogenic variant in the *MYO15A* gene
43   caused hearing loss type DFNB3 was identified, and in one Russian family a heterozygous
44   *MYH14* gene variant associated with dominant NSNHL was found. Thus, the informative value
45   of the diagnosis was ~37% among all patients with NSNHL from RNO–Alania and ~32% among
46   the Ossetians. These estimates correspond to the literature data on the fraction of recessive
47   genetic forms of hearing loss within the affected population. The importance of this study
48   consists not only in the estimation of the most prevalent pathogenic genetic changes in the
49   Ossetian cohort of patients which could be useful for the public health but also in the genetic
50   counselling of the affected families with regard to the high allele frequencies of revealed
51   pathogenic variants as well as to the assortative mating in community of people with hearing
52   loss.
53
54   **Introduction**
55
56   Congenital hearing impairment is one of the most common causes of human disability. It occurs
57   in 1–2 out of 1000 newborns, and more than half of these are accounted for by hereditary forms
58   [1,2]. According to the World Health Organization, around 360 million people (~5% of the
59   World's population) have hearing loss leading to disability, and 32 million of them are children
60   [3,4]. In the structure of prelingual isolated hearing loss in children, sensorineural hearing loss
61   prevails (detected in ~91% of the patients), mixed hearing loss is detected in ~7% of the patients,
62   and conductive hearing loss is present in only in ~1.5% of cases [5]. In the Russian Federation,
63   8–9 million people have various hearing impairments [6,7] that manifest in different time periods
64   of life.
65
66   Most cases (~70%) of hereditary hearing loss (HHL) are non-syndromic forms characterized by
67   wide locus and allelic heterogeneity. More than 6,000 pathogenic variants in more than 120
68   genes have been identified to date. In the structure of HHL forms, those of autosomal recessive
69   (AR) type of inheritance prevail (~70–80%), autosomal dominant forms (AD) account for up to
70   20%, X-linked and mitochondrial forms being relatively rare at ~1–2% and ~1% respectively
71   [3,5,8]. The same genes can be involved in either AD or AR hearing loss and contribute to
72   disability with digenic mode of inheritance [1,3,5]. About 20–30% of hereditary hearing
73   disorders are detected as part of various hereditary syndromes, i.e., hearing loss is accompanied
74   by damage to other organs and systems, the other damage not always being simultaneously
75   manifested [1,3,5]. Early detection of hearing impairment and subsequent clinical and precise
76   DNA diagnostics of the genetic forms of hearing loss allows the cause of the disease to be
77   determined at early age in the patients. Timeliness in taking measures to rehabilitate children
78   with hearing impairment should contribute to the success of their social adaptation.
79

80   Non-syndromic sensorineural hearing loss (NSNHL) occurs due to damage to the organs of the
81   inner ear, the auditory nerve, or the center in the brain that is responsible for the perception of
82   sound. Mapping the genes responsible for the occurrence of NSNHL was a breakthrough in
83   understanding the mechanisms of the occurrence and inheritance of hearing loss. Mutations in
84   the *GJB2* gene have been shown to be the most common cause of NSNHL (OMIM #220290) [9].
85   On average, about half of the cases of AR NSNHL in European populations are associated with
86   mutations in the *GJB2* gene [9]. The highest contribution of pathogenic variants of the *GJB2*
87   gene is shown in European countries (~27% of the cases), whereas in African countries it is
88   much smaller (~6%) [10]. In most European countries the most common *GJB2* pathogenic
89   variant in patients with AR NSNHL is c.35delG. [10]. Variant c.35delG prevails among Russians
90   with NSNHL, accounting for up to 80% of mutant alleles of the *GJB2* gene [11]. Pathogenic
91   variants in the *STRC*, *USH2A*, *SLC26A4*, *MYO7A*, *OTOF*, *MYO15A*, and *TECTA* genes are less
92   frequent but occur in Europe and elsewhere in the World. Mutations in other genes have been
93   found in rare cases [12].
94
95   Our previous studies have shown that both allelic and locus heterogeneity genetic causes of
96   NSNHL are observed in populations and ethnic groups of the Russian Federation: in Mari-El
97   Republic [13]; Udmurt Republic [14]; Chuvash Republic [15]; Karachay–Cherkess Republic
98   [16]; Rostov region [17,18]; Kirov region [19,20]; and in the Nogai population [21,22]. The
99   following mutation rates of c.35delG were found: Chuvash, 0.78%; Bashkirs, 0.25%; Karachay,
100   0.14%; Udmurts, 0.25%; Russians in general, ~0.04–0.05% (1:2000–2500 newborns).
101   Sequencing of the *GJB2* gene has made it possible to identify additionally only 1 or 2 mutations
102   that have very low population frequencies. Further, in our works locus heterogeneity was
103   determined for Chuvash, for whom NSNHL associated with the *GIPC3* gene variants was found.
104   The frequency of *GIPC3* genetic variant c.245G>A in Chuvash NSNHL patients was ~21%, and
105   the frequency of carrying variant c.245G>A was 1/44 in the Chuvash, the population frequency
106   being 0.01143, i.e., more than 1% [23].
107
108   The main diagnostic protocols and algorithms developed in the Russian Federation are based on
109   general population data concerning the title ethnic group of Russia ("Russians"), who make up
110   more than 80% of the population of the country. Given that the population of the Russian
111   Federation is represented by many nationalities, it is necessary to study the ethnic characteristics
112   of molecular diagnostics with subsequent optimization of existing research protocols, and this is
113   currently being carried out by workers of the Laboratory of Genetic Epidemiology of the
114   Research Centre for Medical Genetics [13, 23].
115
116   In this work the results of the study of the genetic and allelic genetic heterogeneity of hereditary
117   non-syndromic hearing loss (NSNHL) in the Republic of North Ossetia–Alania (RNO–Alania) is
118   reported and the frequencies of a number of *GJB2* gene variants and their heterozygous carrier
119   rate in healthy Ossetians are assessed.

120

Materials & Methods

121

122

123 The material studied was DNA isolated from blood samples of NSNHL patients and healthy
124 Ossetians from RNO–Alania. Informed consent was obtained from all participants or their legal
125 guardians. The study was approved by the Ethics Committee of the Research Centre for Medical
126 Genetics. The study was conducted in accordance with the Declaration of Helsinki and was
127 approved by the Institutional Ethics Committee of the Research Centre for Medical Genetics
128 (protocol No. 5 dated December 20, 2010).

129

130 *1. Characteristic of NSNHL patients*

131

132 The cohort of patients with hearing loss from RNO–Alania consisted of 109 individuals from 93
133 unrelated families: 83 Ossetian: 12 Russian: 3 Ingush: 2 Avar; 9 people of other ethnicities. The
134 ethnicity of the participants was determined upon completion of a questionnaire that gathered
135 information about three generations of direct relatives from both parents.

136

137 All of the studied patients had prelingual bilateral sensorineural hearing loss of degrees 2–4 or
138 complete deafness as determined by an audiologist. There were no known external
139 environmental risk factors for the development of hearing loss in the anamneses of the patients.
140 The age of the patients ranged from 0.5 to 68 years (mean age 19.87 ± 17.10 years); the
141 male/female sex ratio was 58/53. The diagnosis was made on the basis of the clinical picture in
142 the hearing center of Vladikavkaz, RNO–Alania. The diagnosis was established upon birth (in
143 ~73% cases) or within the 1st year of life. Patients were also examined by a geneticist at the
144 Research Centre for Medical Genetics (Moscow) to exclude syndromic forms of sensorineural
145 hearing loss.

146

147 *2. Characteristics of the cohort of healthy individuals*

148

149 The cohort of healthy individuals consisted of 349 North Ossetians living in the city of
150 Vladikavkaz as well as in the Prigorodny, Alagirsky, Ardonsky, Digorsky, and Irafsky Districts.
151 Ethnic origin to the third generation was determined when compiling the questionnaire of
152 informed consent to participate in the study.

153

154 *3. DNA isolation*

155

156 DNA from peripheral blood was isolated using the "Wizard Genomic DNA Purification Kit"
157 (Promega, USA) in accordance with the manufacturer's recommendations.

158

159 ***4. Molecular genetic testing***

160

161   *4.1. Search for point mutations in the GJB2, GJB6, and GJB3 genes*

162

163   The presence of the c.35delG variant in the *GJB2* gene was determined by amplified fragments
164   length analysis (AFLP). Fragments containing the first and second exons of the *GJB2* gene as
165   well as coding exons of the *GJB6* and *GJB3* genes were subjected to Sanger sequencing.

166

167   In the cohort of healthy individuals, the c.35delG and c.358_360delGAG variants in the *GJB2*
168   gene were screened by AFLP using the primer sequences shown in Table 1.

169

170   *4.2. Search for large genome rearrangements associated with NSNHL*

171

172   Copy number variations (CNVs) in causative genome loci were analyzed by multiplex ligase-
173   dependent probe amplification (MLPA) analysis using the SALSA MLPA P163-GJB-WFS1-
174   POU3F4 kit (MRC-Holland, Amsterdam, The Netherlands). The MLPA results were analyzed
175   using the Coffalyser.Net program software (MRC-Holland). The set of probes for the MLPA
176   analysis P163-GJB-WFS1-POU3F4 contains probes for each of the genes: *GJB3* (1p34.3); *WFS1*
177   (4p16.1); *GJB2* (13q12.11); *GJB6* (13q12.11); *POU3F4* (Xq21 .1). The CNVs are named
178   according to the ISNC-2020 recommendations using the GRCh37/hg19 human genome reference
179   and the LiftOver tool (UCSC Genome Browser).

180

181   *4.3. Whole-exome sequencing*

182

183   The DNA samples from two patients were subjected to whole-exome sequencing (WES) with an
184   BGISEQ-500 instrument using pair-end readings with a length of 2×100 bp and average on-
185   target coverage of $75 \times$ with the MGIEasy Exome Capture V4 reagents (MGI, China) for library
186   preparation by Genomed Ltd, Moscow, Russia. Bioinformatic analysis was performed using an
187   in-house software pipeline designed to detect both single-nucleotide variants (SNVs) and copy
188   number variations (CNVs) as described earlier [24]. The results were further filtered for
189   functional consequences and population frequencies (gnomAD AF < 0.5% and < 0.1% for
190   recessive and dominant genes, respectively) as well as for clinical relevance according to the
191   Human Phenotype Ontology database [25]. The pathogenicity status of the identified DNA
192   sequence variants was established based on the recommendations of the American College of
193   Medical Genetics and the Association of Molecular Pathology [26].

194

195   *4.4. Analysis of variants in the MYO15A gene*

196

197   The SNVs in the *MYO15A* gene detected during WES were analyzed by bidirectional Sanger
198   sequencing of two fragments of the first coding exon and a fragment containing exon 18.

199 Specific primers were developed (Table 2) for amplification and sequencing of fragments of the
200 *MYO15A* gene (isoform NM_016239.4).
201
202 *4.5. Statistical analysis*
203
204 The frequency of identified alleles was calculated according to the formula: $p_i=n_i/n$, where n_i is
205 the number of i-th alleles and n is the sample size [27]. The population frequencies of variants in
206 different cohorts were compared using Fisher's exact test according to a generally accepted
207 methodology [27].
208
Results
210
211 During this genetic epidemiological study of the population of RNO–Alania, 117 patients with
212 NSNHL from 100 unrelated families were revealed. Of these, 115 patients from 96 families of
213 Ossetian origin were identified. Considering the total size of the Ossetian population in RNO–
214 Alania (366,748) according to the All-Russia Census, 2010, this number of patients gives us the
215 prevalence of NSNHL of 1/3,189 in the population (95% confidence interval 1/2,657–1/3,863)
216 (or 31.36 per 100,000 population; 95% confidence interval 25.89–37.64 per 100,000). These
217 prevalence numbers are in accordance with global estimates [1,2]. Of these 117 patients, 109
218 individuals from 93 unrelated families (83 Ossetians, 12 Russians, 3 Ingush, 2 Avar, and 9
219 people of other ethnicity) were available for the genetic analysis.
220
221 In the studied cohort of NSNHL patients from RNO–Alania, ~30% of the cases (33/109) were
222 caused by pathogenic variants in the *GJB2* gene: ~27% in Ossetians (22/83); half in Russians
223 (6/12) (Table 3). The most frequent genotype in the total cohort was the homozygous genotype
224 *GJB2*:c.[35delG];[35delG] identified in ~39% (13/33): 5 Ossetian; 4 Russian; 2 Ingush; 2 others.
225 The second most common genotype in the total cohort was the homozygous genotype
226 *GJB2*:c.[358_360delGAG];[358_360delGAG] identified in ~27% (9/33), with all of the patients
227 of that genotype being Ossetians. This genotype was the most frequent at ~40% (9/22) in the
228 Ossetians. The second most common genotype was the compound heterozygous
229 GJB2:c.[35delG];[358_360delGAG] found in ~27% (6/22). Five patients had only one
230 pathogenic *GJB2* allele. No pathogenic variants in the coding regions of the *GJB3* and *GJB6*
231 genes were detected in NSNHL patients from that cohort.
232
233 The frequency of the *GJB2*:c.358_360delGAG and the *GJB2*:c.35delG variants was analyzed in
234 349 healthy individuals from the Ossetian population, which included 246 Iron-Ossetians, 45
235 Digor-Ossetians, and 17 Kudar-Ossetians (Table 4).
236
237 Six heterozygous carriers of variant *GJB2*:c.358_360delGAG and three heterozygous carriers of
238 variant *GJB2*:c.35delG were identified in the Iron-Ossetians, and only one carrier of variant

239 *GJB2*:c.358_360delGAG was found among Digor-Ossetians (but differences of the frequencies
240 of these variants were not significant) (Table 4).
241
242 Large copy number variations (CNVs) were analyzed by MLPA in patients who were negative or
243 carried only one pathogenic *GJB2* variant. Pathogenic hemizygous deletion rsa[GRCh37]
244 Xq21.1(81789851×1,81841838_81842142×0,81979450×1) affecting the upstream regulatory
245 region of the *POU3F4* gene was revealed in two Ossetian patients (Table 3).
246
247 Due to the relatively low proportion of patients who had a molecular cause established at the first
248 stage, whole-exome DNA sequencing of two NSNHL patients was performed. In the Ossetian
249 patients, two probably pathogenic heterozygous variants in the *MYO15A* gene were identified –
250 NM_016239.4(*MYO15A*):c.3576G>A, p.(Trp1192Ter) and c.5192T>C, p.(Phe1731Ser) (see
251 Table 3). In a Russian patient, the NM_024729.3(*MYH14*):c.500G>A, p.(Arg167His) variant in
252 the *MYH14* gene was revealed (Table 3).
253

Discussion

255
256 Non-syndromic sensorineural hearing loss (NSNHL; OMIM PS220290) is a group of disabilities
257 in which hearing loss occurs due to damage to the organs of the inner ear, the auditory nerve, or
258 the center in the brain that is responsible for the perception of sound. About 75% of all cases of
259 hereditary hearing loss are related to recessive non-syndromic hearing disorders. Considering the
260 key role of the *GJB2*, *GJB6*, and *GJB6* connexin genes in the development of NSNHL, analysis
261 for the c.35delG variant and sequencing of the non-coding and coding exons of the *GJB2* gene
262 was performed in the first step of the study. Then point mutations in coding exons of the *GJB3*
263 and *GJB6* genes were analyzed. The CNVs of the *GJB2*, *GJB3*, *GJB6*, *WFS1*, *POU3F4* loci were
264 searched by MLPA analysis in patients negative for intragenic mutations in the *GJB2*, *GJB6* and
265 *GJB3* genes.
266
267 *1. Spectrum of GJB2 variants associated with hereditary hearing loss in RNO–Alania*
268
269 In the total patient cohort, six different pathogenic variants of the *GJB2* gene were identified
270 (Table 3, Table 5). The most frequent mutation causing NSNHL in many European populations,
271 *GJB2*:c.35delG, accounted for a significant proportion of the identified alleles in the total patient
272 cohort (~53%, 38/71): in Russian patients (~83%, 10/12); in Ossetian patients (~38%, 18/48).
273 Hence, in Ossetian patients the frequency of the *GJB2* variant c.35delG was significantly lower
274 than in the Russian patients ($p = 0.0076$) (Table 5).
275
276 The variant *GJB2*:c.358_360delGAG was the second most frequent in the total patient cohort
277 (~38%; 27/71) and it was the most frequent variant in Ossetian patients (~54%; 26/48) of the
278 identified alleles (Table 5).

279

280   The in-frame deletion variant *GJB2*:c.358_360delGAG, p.(Glu120del), which does not change
281   the reading frame, leads to the loss of one amino acid. A functional study showed that
282   GJB2:p.Glu120del cannot form homotypic slit channels, which leads to the loss of their
283   conductivity [28]. This variant has been described in at least 20 patients with hearing loss
284   including 7 homozygotes and 12 compound heterozygotes [29,30]. This variant was classified as
285   pathogenic (ClinVar Variation ID: 17006) [30].

286

287   According to Bliznetz and coauthors [31], the variant *GJB2*:c.358_360delGAG was the sixth
288   most common variant of the *GJB2* gene (~0.9%) in NSNHL patients from the Russian
289   Federation, but the ethnicity of patients carrying this variant was not presented in that report. The
290   *GJB2*:c.358_360delGAG variant was found in healthy Chechen individuals from the Republic of
291   Chechnya and the Republic of Ingushetia [31]. In the study of NSNHL in the Karachay–
292   Cherkess Republic, the *GJB2*:c.358_360delGAG variant was found in four patients from three
293   families (Circassians and Kabardians) [16]. The geographical proximity of the studied regions
294   and the high level of migration in the historical past suggest a common source of origin of this
295   variant among the North Caucasian peoples.

296

297   Comparing the frequencies of the *GJB2*:c.35delG and *GJB2*:c.358_360delGAG variants, we
298   found no statistically significant difference between Ossetians and the studied populations of the
299   North Caucasian and Volga–Ural regions (Table 4).

300

301   Two variants, *GJB2*:c.358_360delGAG and *GJB2*:c.35delG, accounted for a large proportion of
302   *GJB2*-associated NSNHL in Ossetians. Their total share was ~92% of the identified alleles
303   (Table 5). Therefore, to evaluate the frequency of NSNHL associated with the *GJB2* gene in the
304   Ossetian population, it was sufficient to test the variants c.358_360deGAG and c.35delG. A
305   cohort of 349 healthy Ossetians was tested for the two common pathogenic *GJB2* variants (Table
306   4). Allele frequency of the *GJB2*:c.35delG variant was 0.0072, that of the
307   *GJB2*:c.358_360delGAG was 0.0129, so their summed frequency is 0.0201. According to the
308   Hardy–Weinberg equilibrium, the frequency of all pathogenic alleles of the *GJB2* gene (q)
309   should be 0.0219 ((0.0201 × 100%)/91.67%); the frequency of hearing loss due to the variants of
310   the *GJB2* gene (q^2) in Ossetians should be 0.0004796 (1/2,085 of population).

311

312   *2. GJB2-negative hearing loss in RNO–Alania*

313

314   For ~70% of NSNHL patients from the total patient cohort (78/111), in ~75% (63/84) of
315   Ossetians and half (6/12) of Russians the molecular cause of hearing loss was not related to the
316   *GJB2* gene (Table 3). In five patients (four of them Ossetians), only one heterozygous
317   pathogenic variant in the *GJB2* gene was detected, two patients had the
318   *GJB2*:c.313_326delAAGTTCATCAAGGG variant, two had the *GJB2*:c.358_360delGAG

319 variant, and one Avar patient carried the *GJB2*:c.35delG variant. Hearing loss in those patients
320 was apparently not associated with the *GJB2* gene, and the heterozygous carrier state was due to
321 the relatively high population frequency of *GJB2* variants. Indeed, for two of those five patients
322 it was possible to identify the molecular cause of hearing loss: in one, a carrier of the variant
323 *GJB2*:c.358_360delGAG, the cause was found when analyzing CNVs; in the second, a carrier of
324 the *GJB2*:c.313_326delAAGTTCATCAAGGG variant, the cause was found through whole
325 exome sequencing. In addition, the latter patient's affected sibling was found not to have the
326 *GJB2*:c.313_326delAAGTTCATCAAGGG variant.
327
328 *2.1. Large genome rearrangements causing X-linked deafness*
329
330 The analysis of large genome rearrangements revealed pathogenic CNVs associated with X-
331 linked deafness in two unrelated male patients. They were Ossetians and represented sporadic
332 cases of hearing impairment.
333
334 In a male patient, a heterozygous carrier of the *GJB2*:c.358_360delGAG variant, hearing loss
335 was found to be caused by hemizygous deletion rsa[GRCh37]
336 Xq21.1(81789851×1,81841838_81842142×0,81979450×1) found by MLPA analysis. The
337 patient's healthy mother was a heterozygous carrier of both of the variants carried by the
338 proband, the rearrangement and the *GJB2*:c.358_360delGAG variant. A healthy sister was a
339 heterozygous carrier of the *GJB2*:c.358_360delGAG variant.
340
341 A deletion found by the same MLPA probes was identified in another male patient in whom no
342 pathogenic variant was found in the *GJB2*, *GJB3* and *GJB6* genes. Thus, X-linked hearing loss
343 was found in two male Ossetian patients, and this accounted for ~6% of the cases (2/33).
344
345 The abovementioned chromosome deletion located in the Xq21.1 region removed a distal *cis*-
346 regulatory region ~920 kb upstream from the *POU3F4* gene, and it did not affect the coding
347 sequence. Exact chromosome breakpoints were not determined. Size could vary from 300 bp to
348 200,000 bp. Previously, two other deletions in the same area (~8 kb and ~200 kb in size) were
349 identified in patients from Europe. They were associated with non-syndromic hearing loss
350 (OMIM #304400; DFNX2) [30]. Observations of similar chromosome region deletions in
351 patients from different populations from West Europe and the North Caucasus indicate that the
352 Xq21 region with its multiple conserved non-coding sequences is a hotspot for chromosome
353 breaks. Earlier, Petrina and coauthors [22] revealed the variant c.907C>T in the *POU3F4* gene as
354 a cause of X-linked hearing loss in a Nogai family from the Karachay–Cherkess Republic. These
355 findings are the reason to include Xq21 deletion screening as well as target Sanger sequencing of
356 the *POU3F4* gene in the protocols of routine molecular genetic analysis of inherited deafness in
357 the Russian Federation.
358

359   *2.2. Search for disability-causing variants by NGS analysis*

360

361   Due to the relatively low proportion of patients for whom a molecular cause was established in
362   the first stage, whole-exome DNA sequencing (WES) was performed for two NSNHL patients.

363

364   One of these patients was from a family with one affected sibling and healthy parents, and they
365   are ethnic Iron-Ossetians who were born of a non-consanguineous marriage. Three single
366   nucleotide variants had been identified in the *MYO15A* gene, each in a heterozygous state. The
367   first two were in exon 1 – c.823G>C, p.(Gly275Arg) and c.3576G>A, p.(Trp1192Ter). The third
368   was in exon 18 – c.5192T>C, p.(Phe1731Ser). Of the three identified variants, only the
369   c.823G>C (rs183969516) variant was registered in the gnomAD database with frequency
370   0.0014384 [32]. It had been found in one study of NSNHL patients from the United States and
371   was regarded as variant of unknown clinical significance [33]. The two other pathogenic variants
372   were identified for the first time. The results of the pathogenicity prediction for the new variants
373   are included in Supplementary Table 1.

374

375   The NM_016239.4(*MYO15A*):c.3576G>A, p.(Trp1192Ter) variant leads to creation of a
376   premature stop codon and can be regarded as probably pathogenic. The
377   NM_016239.4(*MYO15A*):c.5192T>C, p.(Phe1731Ser) variant is a missense mutation, and the
378   gnomAD database contained two missense variants that result from substitutions in neighboring
379   nucleotides: c.5191T>C (p.Phe1731Leu; rs1459406061; found on one of 248,934 alleles with
380   frequency 0.000004017) and c.5193C>T (p.Phe1731Phe; rs767426819; found on 18 of 280,172
381   alleles with frequency 0.00006424, the pathogenicity of the latter variant being considered
382   contradictory [30].

383

384   Mutations of myosin XVA encoded by the *MYO15A* gene are the cause of severe congenital
385   deafness type DFNB3 [30]. The full-size transcripts of myosin XVA contain 66 exons >12
386   thousand bp long and encode a 365-kDa protein that differs from other myosins by the presence
387   of a very long 1,200-a.a. N-terminal region preceding the conservative motor domain. The tail
388   regions of myosin XVA protein contain two MyTH4 domains, two regions similar to the
389   membrane-coupled FERM domain, and a putative SH3 domain. Northern-blot analysis showed
390   that myosin XVA is expressed in the pituitary gland in both humans and mice. In *in situ*
391   hybridization experiments, myosin XVA transcripts were observed in areas corresponding to the
392   sensory epithelium of the cochlea and the vestibular system in the developing inner ear of mice.
393   Immuno-staining of the organ of Corti in adult mouses showed that myosin XVA protein is
394   concentrated in the cuticle plate and stereocilia of the cochlear sensory hair cells. These results
395   indicate a probable role of myosin XVA in the formation or maintenance of unique, actin-rich
396   structures of sensory hair cells of the inner ear [34].

397

398   To confirm the diagnosis, we performed segregation analysis of all three identified *MYO15A*
399   variants in the in the proband's family (Table 6). All three variants were confirmed by Sanger
400   sequencing in the proband and were found in his affected sibling, each variant being in the
401   heterozygous state, and the healthy mother was found to be a heterozygous carrier of the two
402   variants, c.823G>C and c.5192T>C, i.e., those variants making up a single complex allele of the
403   *MYO15A* gene.

404

405   Next, we searched for the three described *MYO15A* variants in 54 patients with NSNHL in whom
406   the molecular cause of the disease had not been identified. The c.823G>C variant in
407   heterozygous state was detected in four patients with frequency 0.03704 (4/108). Variants
408   c.3576G>A and c.5192T>C were not found. With a high degree of probability, the c.823G>C
409   variant could not be considered as pathogenic since its frequency in the population exceeds 1%
410   according to the gnomAD database [32]. Thus, in the affected family, c.3576G>A and
411   c.5192T>C variants should be considered as causative.

412

413   In a Russian family with two affected patients, WES was performed for one of the patients. The
414   variant NM_024729.3(*MYH14*):c.500G>A (rs776632941), p.(Arg167His) in heterozygous state
415   was identified. Sanger sequencing of the *MYH14* gene fragment confirmed the heterozygosity for
416   the variant in the proband and his affected father. This variant was present in the gnomAD
417   database, and it was found on five alleles from 280,642 with frequency 0.0000178 among
418   healthy people [32], but this was not mentioned in the ClinVar dataset as a pathogenic mutation
419   [30]. The p.Arg167His substitution is located in a functionally significant domain of the myosin
420   head of the protein. The results of pathogenicity prediction for this variant are included in
421   Supplementary Table 1. This variant should be regarded as having uncertain clinical significance
422   with a level of significance PM2 (moderate piece of evidence for pathogenicity), PP3 (Multiple
423   lines of computational evidence support a deleterious effect on the gene or gene product), and
424   PP4 (phenotype or family history is highly specific for a disease with a single genetic etiology)
425   according to the American College of Medical Genetics and Genomics (ACMG) criteria.

426

427   The *MYH14* gene encodes one of the heavy chains of class II non-muscle myosin (NMIIC), a
428   member of the myosin superfamily, and it is a causative gene for autosomal dominant
429   sensorineural hearing loss (AD NSNHL, OMIM #600652, DFNA4). It is widely expressed in the
430   inner ear, including the organ of Corti. *MYH14*-associated hearing loss is rare, the currently
431   available information regarding the variant spectrum and clinical characteristics being limited.
432   There have been reports of 43 *MYH14* variants causing AD NSNHL, most of which were
433   missense mutations [35,36].

434

435   **Conclusions**

436

437 Our molecular genetic analysis of the causes of NSNHL in the RNO–Alania population revealed
438 pathogenic variants of the *GJB2* gene in 29.7% of the cases, including 26.5% of cases among
439 Ossetians. In Russian patients the most frequent variant was *GJB2*:c.35delG identified in ~83%
440 of the patients. In Ossetian patients two genetic variants shared more than 91% of the pathogenic
441 alleles of the *GJB2* gene. The most frequent variant in the Ossetian patients was
442 *GJB2*:c.358_360delGAG, which accounted for ~54% (26/48) of the identified pathogenic alleles
443 of the *GJB2* gene. The *GJB2*:c.35delG variant was the second most frequent (~38%, 18/48). The
444 search for large genome rearrangements by MLPA revealed the etiological cause of X-linked
445 hearing loss (type DFNX2), a hemizygous deletion in the *POU3F4* gene locus in two unrelated
446 Ossetian patients. In one of these Ossetian patients, biallelic pathogenic variants in the *MYO15A*
447 gene were associated with DFNB3, and in one Russian family a variant in the *MYH14* gene was
448 associated with autosomal dominant hearing loss of type DFNA4. Thus, the informativity of our
449 molecular genetic diagnostics in the total cohort of NSNHL patients from RNO–Alania was
450 ~37%, or ~32% among Ossetians, which is typical for other populations.
451

Acknowledgements

452

454 We are grateful to all employees of local healthcare who participated in the organization of the
455 expeditionary survey of the populations as well as to all the patients, family members, and
456 healthy controls. We thank Richard H. Lozier for his interest in our work and for English-
457 language editing.
