Eurypterids (sea scorpions) are extinct aquatic chelicerates. Within this group, members of Pterygotidae represent some of the largest known marine arthropods. Representatives of this family all have hypertrophied, anteriorly-directed chelicerae and are commonly considered Silurian and Devonian apex predators. Despite a long history of research interest in these appendages, pterygotids have been subject to limited biomechanical investigation. Here we present finite element analysis (FEA) models of four different pterygotid chelicerae—those of *Acutiramus bohemicus*, *Erettopterus bilobus*, *Jaekelopterus rhenaniae*, and *Pterygotus anglicus*—informed through muscle data and finite element models (FEM) of chelae from 16 extant scorpion taxa. We find that *Er. bilobus* and *Pt. anglicus* have comparable stress patterns to modern scorpions, suggesting a generalised diet that probably included other eurypterids and, in the Devonian species, armoured fishes, as indicated by co-occurring fauna. *Acutiramus bohemicus* is markedly different, the stress being concentrated in the proximal fixed ramus rather than the serrated denticles. This stress, focused into one region, indicates a morphology better suited for targeting softer prey. *Jaekelopterus rhenaniae* exhibits much lower stress across the entire model. This, combined with an extremely large body size, suggests that this species likely preyed on larger and harder prey, including heavily armoured fishes. The range of cheliceral morphologies and stress patterns within Pterygotidae demonstrate that members of this family had variable diets, with only the most derived species likely to feed on armoured prey, such as placoderms. Indeed, increased sizes of these forms throughout the mid-Palaeozoic may represent an ‘arms race’ between eurypterids and armoured fishes, with Devonian pterygotids adapting to the rapid diversification of placoderms.

# Abstract

Eurypterids (sea scorpions) are extinct aquatic chelicerates. Within this group, members of Pterygotidae represent some of the largest known marine arthropods. Representatives of this family all have hypertrophied, anteriorly-directed chelicerae and are commonly considered Silurian and Devonian apex predators. Despite a long history of research interest in these appendages, pterygotids have been subject to limited biomechanical investigation. Here we present finite element analysis (FEA) models of four different pterygotid chelicerae—those of *Acutiramus bohemicus*, *Erettopterus bilobus*, *Jaekelopterus rhenaniae*, and *Pterygotus anglicus*—informed through muscle data and finite element models (FEM) of chelae from 16 extant scorpion taxa. We find that *Er. bilobus* and *Pt. anglicus* have comparable stress patterns to modern scorpions, suggesting a generalised diet that probably included other eurypterids and, in the Devonian species, armoured fishes, as indicated by co-occurring fauna. *Acutiramus bohemicus* is markedly different, the stress being concentrated in the proximal fixed ramus rather than the serrated denticles. This stress, focused into one region, indicates a morphology better suited for targeting softer prey. *Jaekelopterus rhenaniae* exhibits much lower stress across the entire model. This, combined with an extremely large body size, suggests that this species likely preyed on larger and harder prey, including heavily armoured fishes. The range of chelicerall morphologies and stress patterns within Pterygotidae demonstrate that members of this family had variable diets, with only the most derived species likely to feed on armoured prey, such as placoderms. Indeed, increased sizes of these forms throughout the mid-Palaeozoic may represent an ‘arms race’ between eurypterids and armoured fishes, with Devonian pterygotids adapting to the rapid diversification of placoderms.

# Introduction

Feeding toolkits of proposed fossil predators are typically explored through functional morphology, often with comparison to modern analogues. In the last two decades, there has been a focus on modelling animals using two-dimensional (2D) and three-dimensional (3D) biomechanical analyses, including finite element analyses (FEA) (Ross, 2005; Rayfield, 2007; van Heteren et al., 2021; Rowe & Snively, 2022). This latter method has been an effective approach for modelling fossil vertebrates and, as such, applications of FEA in palaeontology have largely focused on select vertebrate groups (Rayfield et al., 2001; Wroe et al., 2005, 2007, 2018; Kupczik et al., 2009; Strait et al., 2009; Attard et al., 2016). By comparison, fossil arthropods have not been examined as thoroughly with 3D FEA (Bicknell et al., 2018a, 2021; Esteve et al., 2021). Recent focus on modelling extinct arthropods has increased knowledge of the biomechanical capability of these fossil forms.

Fossil predatory arthropods are epitomised by the large, aquatic eurypterid family, Pterygotidae, known from Silurian and Lower Devonian deposits (Braddy et al., 2008; McCoy et al., 2015; Lamsdell & Selden, 2017). Some forms have bodies reaching ~2.5 m in length and represent the largest known marine arthropods, living or extinct (Braddy et al., 2008; Lamsdell & Braddy, 2010; Vermeij, 2016). A key feature of pterygotids is their large, anteriorly-directed chelicerae that often show enlarged denticles (Ciurca & Tetlie, 2007), likely used to capture and subdue prey (Kjellesvig-Waering, 1964; Waterston, 1964; Miller, 2007b; Braddy et al., 2008; Kennedy et al., 2012; Bicknell et al., 2020). Given this, pterygotids are presumed to have been apex predators within their respective ecosystems (Selden, 1984; Plotnick & Baumiller, 1988; Braddy et al., 2008). Despite the striking appearance of pterygotid chelicerae, to date, biomechanical investigations of these structures have been limited to 2D lever arm studies

(Selden, 1984; Laub et al., 2010). Examination of these chelicerae using 3D biomechanical analysis could therefore present a more complete understanding of their functional morphology. Importantly, modern scorpion pedipalp chelae can inform on the mechanical performance of pterygotid chelicerae, as the former are perhaps the closest functional analogue for the fossil forms. Furthermore, as scorpions are a diverse chelicerate group that are phylogenetically closer to eurypterids than other arthropod groups with chelate appendages such as decapod crustaceans (Shultz, 2007; Legg et al., 2013; Haug, 2020), and likely have comparable cuticular properties to eurypterids, scorpions are one of the more informative groups to function as modern analogues.

Pterygotid chelicerae occasionally preserve with sufficient anatomical fidelity to allow for detailed reconstructions. In particular, *Acutiramus bohemicus*, *Erettopterus bilobus*, *Jaekelopterus rhenaniae*, and *Pterygotus anglicus* are four exceptionally preserved and well documented species, making them ideal for biomechanical analysis (Waterston, 1964; Chlupáč, 1994; Poschmann & Tetlie, 2006; Miller, 2007b; Braddy et al., 2008; Dunlop et al., 2020). Furthermore, modern scorpions provide a diverse and well-studied group for comparative purposes (Van der Meijden et al., 2012a; Lourenço, 2021). Building on previous FEAs of scorpions (Van der Meijden et al., 2012a) and analyses of extinct arthropods (Bicknell et al., 2021), here we present 3D finite element models (FEMs) of the chelicerae of *Ac. bohemicus*, *Er. bilobus*, *Ja. rhenaniae*, and *Pt. anglicus* and compare them to models of chelae of 16 scorpion taxa.

## Methods

### *Extant models*

Information on the muscle that adducts the moveable finger in a scorpion chela follows Snodgrass (1952), Gilai & Parnas (1970), and Van der Meijden et al. (2012a) (Figure 1A). One primary muscle mass fills the majority of the proximal manus region and is responsible for adducting the moveable finger. There is also a secondary closing muscle in the patella (Gilai & Parnas, 1970). We have not considered this muscle here because: (a) scans of patellar sections needed to estimate muscle size were not made; and (b) there is no fossil evidence for this muscle (such as scars or fibres) in eurypterids. Data for calculating force of the primary closing muscle were collected from micro computed tomography (micro-CT) scans. The scans were made with a Skyscan 1076 micro-CT scanner using a source voltage of 31 kV and a source current of 187  $\mu$ A at 35  $\mu$ m resolution, as detailed in Van der Meijden et al. (2012a). Sixteen specimens, each representing a different scorpion genus and spanning six families, were scanned and chelae segmented with Amira/Avizo 5 (Thermo Fischer Scientific). The external chela cuticle and internal manus content were segmented either manually or using the “Thresholding” tool in Amira. Internal manus content, excluding regions where adducting muscles were not present, was segmented as a globular structure to estimate muscle volume, surface area, and cross-sectional area. Values of volume and area were calculated with the “Surface Area Volume” module in Avizo, while the cross-sectional area was calculated by bisecting the muscle volume transversely (i.e. perpendicular to the proximal-distal axis of the manus and approximately perpendicular to muscle fibre directions) in Meshlab v. 2020.12 (Cignoni et al., 2008). Analysed specimens are preserved in ethanol and housed in the Centro de Investigação em Biodiversidade e Recursos Genéticos, Vila do Conde, Portugal (CIBIO) collection and assigned the prefix of ‘Sc’.

Maximum pinch force data were only known from the micro-CT scanned specimens of *Androctonus bicolor* and *Pandinoides cavimanus* (Simone & Van der Meijden, 2018). As we did not measure in-vivo pinch forces of the micro-CT scanned individuals of other species, pinch forces were estimated for those specimens using data available from other individuals of the same species. As such, chela length, height, and width (Stahnke, 1970) were used to predict pinch force for our FEMs based on known pinch forces of other individuals of the same species (Van der Meijden et al., 2010, 2012a; Supplemental Table 1). The data were  $\log_{10}$  transformed to linearise variables with different dimensionality and used to produced species-specific linear models, and associated regression coefficients (Supplemental Table 2).

The mechanical advantage of the moveable finger was calculated from the micro-CT scans following Simone & Van der Meijden (2018). However, as in-vivo pinch forces were measured approximately two thirds of the finger length from the joint and not the distal-most point of movable fingers, the mechanical advantage was corrected by shortening the length of the out-lever by one third. Muscle force at insertion was then calculated for scanned specimens by dividing pinch force by the specimens' mechanical advantage (Supplemental Table 3). Muscle stresses used here were derived from Van der Meijden et al. (2012b), where the stress of *Galeodes* sp. (203 kPa) and *Rhagodes* sp. (905 kPa) were employed as upper and lower bounds, respectively (Supplementary Table 4). The manus and movable finger reconstructions were exported from Amira as .STL files for analysis. The manus and moveable finger sections for assessed specimens were then imported into 3-matic version 12 (Materialise, Leuven, Belgium) and solid-meshed as distinct solid homogeneous structures consisting of tet-4 elements and the gape angle was set to biologically realistic values between 10–30°. These models were then exported as Nastran files for import into Strand7 (Strand7 Pty Ltd, NSW, Sydney, Australia)

FEA software. Material properties used are a Young's modulus of 7 GPa and a Poisson's ratio of 0.3—values used for scorpion cuticle following Van der Meijden et al. (2012a). Muscle origins were tessellated as beam elements onto the Nastran models (Bicknell et al., 2018b). This was done following successful applications to other arthropods (Bicknell et al., 2018b, 2021) and allowed for a large muscle origin area to be modelled. Muscle forces (Supplemental Table 3) were assigned to trusses directed toward the insertion site – the most proximal section of the moveable finger. These insertions were treated as static points at the beam terminus. Three denticles along both the manus and moveable finger were constrained in all directions at their most apical node (Figure 1A); selected denticles were located at the proximal, mid-length, and distal regions of the manus and finger. A hinge between the manus and moveable finger was constructed using two sections: one link on either side of the proximoventral section of the moveable finger. This emulates a simplified action of manus and moveable finger closure. A colour-coded von Mises (VM) stress map was generated after solving models. Loaded Strand7 models are presented as Supplemental Data 1–16. These data are found at [10.17605/OSF.IO/GV8J5](https://doi.org/10.17605/OSF.IO/GV8J5) Additionally, the analysed .STL files were used to generate 3D PDFs using Tetra4D (Adobe Systems). Scorpion 3D PDFs are available from [10.17605/OSF.IO/GV8J5](https://doi.org/10.17605/OSF.IO/GV8J5).

### *Fossil models*

3D reconstructions of the *Acutiramus bohemicus*, *Erettopterus bilobus*, *Jaekelopterus rhenaniae*, and *Pterygotus anglicus* chelicerae (fixed and free rami) were rendered in Zbrush (Pixologic, Inc). Reconstructions were informed by examining selected fossils and published high resolution images of chelicerae (Størmer, 1936; Waterston, 1964; Selden, 1984; Chlupáč, 1994; Poschmann & Franke, 2006; Poschmann & Tetlie, 2006; Miller, 2007a, b; Braddy et al., 2008; Lomax et al.,

2011; Kennedy et al., 2012; Supplemental Table 4). These specimens permitted the modelling of chelicerae with anatomically correct dimensions in lateral view. Considering the modern analogues and the 2D preservation of the fossil forms, the degree of cheliceral ‘inflation’ was informed through examining the three-dimensionality of the modelled scorpion chelae. Furthermore, as there is no evidence to suggest that the fixed ramus is more inflated than the movable ramus, both pterygotid rami were modelled with a similar degree of inflation. The models were built with internal cavities informed by the scorpion scans and internal cavities of fixed and free rami do not extend into the denticles, following the observations of modern scorpions (Van der Meijden et al., 2012a; Kellersztein et al., 2019). These reconstructions were required as the examined chelicerae are preserved as compression fossils, with very little relief. There is little to no density difference between the fossil and the host matrix, and scanning these fossils would have produced unreliable 3D data. Furthermore, if the scans were successful, the models would have been retro-deformed, likely using scorpions as the reference. The reconstructions presented here circumvent this limitation of the fossil record. Reconstructions were exported as .STL files from Zbrush. These can be found in Supplemental Data 17–20, available from [10.17605/OSF.IO/GV8J5](https://doi.org/10.17605/OSF.IO/GV8J5).

The .STL files were scaled to the size of the largest known chelicerae of the respective species to allow for a comparison between presumed adult forms (Waterston, 1964; Chlupáč, 1994; Miller, 2007b; Braddy et al., 2008). This scaling also allowed the calculation of muscle force values for adult pterygotids and permitted the modelling of appendages at ‘life size’ scales. We did not scale the pterygotid models to the size of scorpion chelae (Dumont et al., 2009; Bicknell et al., 2021) as there are orders of magnitude difference in size between scorpion chelae and pterygotid chelicerae. Scaling down chelicerae would likely have introduced allometric

errors to the modelling, increasing the uncertainty associated with the pterygotid models. Also, deciding on a particular size to scale the specimens down to is highly subjective. Finally, we were interested in examining the absolute size of chelicerae in particular in this study, thus scaling to the volume of a scorpion chela would have not permitted this approach.

After scaling to life size, the .STL files of fixed and free rami were loaded into Meshlab version 2020.12 to estimate the internal volume of the fixed ramus; a proxy for muscle force at the insertion. The internal volume was calculated with the “Ambient Occlusion” filter in Meshlab. All non-occluded elements and the fixed ramus finger were removed to produce the proximal fixed ramus internal morphology. A convex hull of this morphology was then produced and used to calculate the volume and surface area of the internal proximal fixed ramus—a proxy for the size of the adducting muscle. The transverse section of this convex hull representing the muscle mass was used as an estimate of muscle cross-sectional area. These data were  $\log_{10}$  transformed and input into the scorpion muscle force regression model to calculate pterygotid muscle force (Supplemental Table 5).

Force at the muscle insertion for pterygotid species was estimated using data from extant scorpions by two methods: 1) extrapolation of a linear model; and 2) using muscle stress and estimated pterygotid muscle cross sectional area. We only used the force estimates from the first approach in the FEA models of the pterygotids, as this approach has the fewest assumptions. However, we report and discuss both methods here, as the differences in estimated muscle force obtained may be a cautionary example for other workers using only a single method to estimate muscle force.

In the first approach, all calculated forces at muscle insertions, derived from in-vivo pinch force measurements of the scorpions, were used to create a linear model to predict

pterygotid muscle force (Supplemental Tables 6, 7). The forces at muscle insertions were considered dependent variables against the independent variables of muscle surface and volume. Data were linearized by  $\log_{10}$  transformation before running the model. The regression coefficients were then used to estimate pterygotid input force at muscle insertions. All the statistical regressions were performed in R version 4.1.2 (R Development Core Team, 2021; Supplemental Code 1). Estimated muscle forces employed in the FEMs are shown in Supplemental Table 3. In the second approach, estimates of muscle stress from Van der Meijden et al. (2012b) were used to calculate pterygotid muscle force by multiplying these values with pterygotid muscle cross-sectional area.

Boundary, loading, and restraining conditions applied to the cheliceral reconstructions (Figure 1) were comparable to the scorpion models. Material properties used were the same as scorpions, as the cuticle properties of pterygotid chelicerae are unknown. Muscle origin location, size, and vectors were estimated based on the scorpion comparisons. Muscle origins are located in the fixed ramus proximal region. Similar to scorpion models, muscle origins were tessellated as beam elements. Muscle forces (Supplemental Table 8) were assigned to trusses directed toward the insertion, in the proximal free ramus section, following Braddy et al. (2008). Similar to scorpion models, three denticles on the fixed and movable rami were constrained. However, as pterygotid denticles vary in size, the largest denticles were constrained because these points would be the first regions to have contacted prey (Figure 1B). A colour-coded VM brick stress map was generated after solving models. The loaded Stand7 models are presented in Supplemental Data 17–20, available from [10.17605/OSF.IO/GV8J5](https://doi.org/10.17605/OSF.IO/GV8J5).

As the pterygotid chelicerae cannot be scanned, there is uncertainty regarding the thickness of the ramus cuticle. Although eurypterid cuticle from the carapace and gnathobases has been

sectioned in previous studies (Dalingwater, 1973, 1975, 1985; Bicknell et al., 2018b), there is no published information on the cuticle thickness of pterygotid chelicerae. Therefore, sensitivity tests for pterygotid models were conducted to explore the impact of cuticle thickness on the biomechanical modelling. *Erettopterus bilobus* fixed and free rami were reconstructed with thinner and thicker cuticle relative to the presented model. Further, this taxon was reconstructed and analysed with cuticle extending into the constrained denticles. These sensitivity test models (loading and boundary conditions outlined below) showed very comparable stress distributions (Supplemental Figure 1; Supplemental Data 17). This suggests that hollowing the rami and denticles has limited impact on the VM stress distribution, but does influence the stress magnitudes.

Since pterygotid material properties are unknown, it is possible that the values used here may have influenced the VM stresses estimated from the FEMs. Consequently, our results should be considered in comparative contexts only. We therefore limit our interpretation of the models to stress distributions rather than magnitudes, as the former is less sensitive to variation in the assumptions included in our models, such as muscle force, cuticle thickness and material properties.

Mean VM stress values were calculated from all FEM models in Strand7. These values were plotted against the volume of chelae and chelicerae models, exported from Geomagic Studio (3D Systems, North Carolina, USA). Both values were  $\log_{10}$  transformed (Supplemental Table 9) and plotted in bivariate space.

## Results

The linear model used to estimate muscle force for the scorpions has a statistically significant adjusted  $R^2$  value of 0.657 (p-value:  $3.8e^{-04}$ ; Figure 2). Furthermore, estimated muscle volume has a significant correlation to the pinch force estimation (F-value: 29; p-value:  $1.1e^{-04}$ ). The pterygotid muscle forces predicted from muscle cross-sectional area and muscle stress were considerably higher than those based on the linear model (Supplemental Table 5).

The VM stress distributions for the examined scorpion chelae are categorised into three main groups. The first group comprises *Androctonus amoreuxi*, *Caraboctonus keyserlingi*, *Chactas* sp., *Hadogenes paucidens*, *Opisthophthalmus boehmi*, and *Scorpio maurus*, each of which exhibit relatively high VM stress across the entire model, with the highest VM stress proximal to the articulation between the manus and moveable finger and along chelae (Figure 3A–F). These forms are typically stouter and have more pronounced proximal manus regions. Notably, *Ca. keyserlingi*, *Ha. paucidens*, and *Sc. maurus* have higher stress along the movable finger. The second group consists of *Androctonus australis*, *An. bicolor*, *Grophus flavopiceus*, *Hadrurus arizonensis*, *Hottentotta gentili*, *Leiurus quinquestriatus*, and *Parabuthus transvaalicus*. These models have overall lower VM stress in the manus and variable degrees of VM stress along elongate chelae fingers (Figure 3G–M). *Androctonus australis*, *An. bicolor*, *Ha. arizonensis*, *Le. quinquestriatus* and *Pa. transvaalicus* have high VM stress proximal to the articulation between the manus and moveable finger, contrasting with *Gr. flavopiceus* and *Ho. gentili* that have lower VM stress over the entire model. The third group contains *Bothriurus* sp. and *Pandinoides cavimanus*. These models show low VM stress in the proximal manus section, high VM stress at the articulation between the manus and moveable finger, and lower VM stress along stout chelae (Figure 3N, P). Finally, *Opisthacanthus maculatus* is unique, with low VM stress in the proximal manus region and higher VM stress along the chelae (Figure 3O). Overall,

these groupings are comparable to those presented by Van der Meijden et al. (2012a), where chelae models were standardized for scale using force to surface area ratio.

Distributions of VM stress in the pterygotid models are broadly comparable to those of scorpion FEMs (Figure 4). Although these appendages are not homologous—representing the first and second limb-bearing segments in eurypterids and scorpions, respectively—the functional analogy of the two can be tested with FEA. The observed VM stress similarity strongly supports the idea that pterygotid chelicerae functioned like scorpion chelae indicating an informative analogue for these fossil forms. Considering the mean VM stress distributions of the scorpion and pterygotid models, the former have higher mean stress values (Figure 5). There is limited clustering of family groups in bivariate space, reflecting the range of input force values for the modelled scorpions (Supplemental Table 9). Taxa within the Buthidae in particular have a large spread of stress within similar volume values. Within the pterygotids, the larger models (*Jaekelopterus rhenaniae* and *Acutiramus bohemicus*) show the lowest mean stress.

Of the pterygotid models, *Erettopterus bilobus* and *Pterygotus anglicus* have comparable VM stress along the fixed and free rami and proximal to the region of articulation between the fixed and free rami (Figure 4A, B). *Pterygotus anglicus* shows high VM stress on the large denticles and *Er. bilobus* has lower VM stress along the distal section of the free ramus. *Jaekelopterus rhenaniae* has the lowest overall VM stress and its only high VM stress region is proximal to the point of articulation between the fixed and free rami and along the proximal section of the free ramus (Figure 4C). *Acutiramus bohemicus* has high VM stress in the region proximal to the point of articulation between the fixed and free rami and along the proximal section of the free ramus (Figure 4D). Further, the highest strain areas are located along the oblique, serrated denticles.

In all FEMs, the VM stress is predictably concentrated in areas with high loads, such as muscle insertions and around the fixed vertices on the denticles. In the scorpion models, higher VM stress areas are visible on the proximal manus region – the location of simulated muscle origins. However, scorpion chelae muscle origins are distributed across the majority of the proximal manus region. As such, VM stress concentration on the proximal manus region reflect where the models were constrained.

The large difference in estimated muscle force and stress distributions for the pterygotids between the linear model and the cross-sectional area method is striking. As both methods are commonly used, and both have weaknesses and assumptions, we opted to present the results of both approaches to see if similar values could be predicted. The linear model predicted high muscle force values for the pterygotids. However, as no extant chelicerates have comparably-sized chelae or chelicerae, muscle forces were estimated by extrapolation rather than interpolation. An unavoidable result of extrapolation is increased error. The cross-sectional area method of muscle force estimation has more explicit assumptions, each with a level of uncertainty. The range of lowest to highest muscle stress estimates illustrate this uncertainty (Supplemental Table 5). For these reasons, we did not use the muscle force estimates derived from cross-sectional area in the FEA models, and did not focus on absolute magnitudes of stress or force in our analysis and discussion.

# Discussion

The results of the scorpion FEA analysis show similar groupings as in Van der Meijden et al. (2012a). The differences in magnitudes of VM stresses (Figure 3) indicate that some species (e.g. *Pandinoides cavimanus*, *Ophistacanthus maculatus*, *Hottentotta gentili*) could exhibit a higher ‘safety factor’ (i.e., a measure of how much stronger a morphology needs to be compared to the

input forces; Hicks & Wang, 2021) than others (e.g. *Caraboctonus keyserlingi*, *Hadogenes paucidens*, *Parabuthus transvaalicus*), although the pattern does not seem to correspond to defensive behaviour (Van der Meijden et al., 2013) or relative pinch force (Simone & Van der Meijden, 2018). Considering the modelled scorpions in the context of possible ecomorphs, there is limited overlap between groups identified here and recently proposed ecomorphologies (Coelho et al., 2022). This suggests that the FEMs produced here present more of an insight into the effectiveness of these feeding tools, rather than inform on possible ecological groupings and associated microhabitats. Combining these biomechanical analyses with detailed examination of scorpion life modes will undoubtedly uncover new links between chelae mechanics and the diets of these ecomorphs. However, this is beyond the scope of this work, as we have focused on using scorpions to inform aspects of the pterygotid models. On this point, it is worth considering other possible modern analogues for understanding and modelling pterygotids. Of particular note are the camel spiders (Solifugae), which have large, dentate chelicerae that can grasp and disarticulate prey for consumption (Van der Meijden et al., 2012b). These chelicerae are anteriorly directed, but do not extend notably beyond the prosoma (Harms & Duperre, 2018). While they may be informative for understanding how chelicerae can break prey, they are less useful than scorpion pedipalps as functional analogues for prey capture by pterygotid chelicerae.

The morphology of pterygotid chelicerae suggests that these structures were used in capturing prey for subsequent mastication by the coxal gnathobases (Waterston, 1964; Miller, 2007a). The solifuge comparisons made above suggest that the dentition of pterygotid chelicerae may have allowed for some initial tearing of prey. This inferred feeding mode aligns with the occurrence of pterygotids and proposed prey species, including other eurypterids, fishes, and a likely array of soft-bodied animals that are not preserved (Rolfe, 1973; Chlupáč et al., 1980;

Kennedy et al., 2012). Furthermore, links between cheliceral and lateral compound eye morphologies have been drawn to propose an apex predatory life mode for some pterygotids (Anderson et al., 2014; McCoy et al., 2015).

Results of the FEA support previous inferences that pterygotid chelicerae, while having a similar overall morphology, had differing functional capabilities (McCoy et al., 2015). The comparable VM stress distributions between the chelicerae of *Erettopterus bilobus* and *Pterygotus anglicus* suggest that these taxa would have experienced similar stresses during predation and therefore probably targeted similar prey. Based on the known faunal assemblages that co-occur with these pterygotid species (Dunlop et al., 2002; Miller, 2007b; Lebedev et al., 2009; McCoy et al., 2015; Fyffe et al., 2016; Blieck, 2017; Supplemental Tables 10, 11), coupled with the large body lengths of *Er. bilobus* (0.7 m) and *Pt. anglicus* (1.6 m), proposed prey includes other eurypterids and fishes; in the case of the Devonian *Pt. anglicus*, the latter could include armoured forms, such as ostracoderms and placoderms. This is further supported by the moderate to high visual acuity in these pterygotid genera (McCoy et al., 2015), allowing them to identify and pursue such mobile, possibly smaller prey. Indirect evidence for *Er. bilobus* consuming fish comes in the form of coprolites rich in agnathan fragments from the Lesmahagow Inlier, which have been previously attributed to eurypterid predation (Rolfe, 1973; Selden, 1984). It therefore seems that *Er. bilobus* and *Pt. anglicus* were apex predators within their respective ecosystems (Selden, 1984; Dunlop et al., 2002; Kennedy et al., 2012). This seems to contradict the previous suggestions that *Er. bilobus* was a more generalised predator than *Pt. anglicus* (McCoy et al., 2015).

The FEM of *Acutiramus bohemicus* produced a unique VM stress distribution associated with its different cheliceral morphology. All *Acutiramus* species have elongate (some

hypertrophied), oblique, anteriorly-directed, serrated denticles (Chlupáč, 1994; Laub et al., 2010; McCoy et al., 2015). High VM stress along the free rami and within the constrained denticles suggest that *Acutiramus* was not well adapted to capture armoured or thick-shelled prey and may have experienced failure when doing so (Laub et al., 2010). Indeed, *Acutiramus* does not co-occur with a diverse fish fauna, but rather an array of other eurypterid taxa (Laub et al., 2010; Anderson et al., 2014; Supplemental Table 12). The angled, serrated denticles would be more consistent with piercing eurypterid cuticle (Laub et al., 2010; Anderson et al., 2014; Fyffe et al., 2016) and the proximal denticles on the free ramus may have impaled prey (Laub et al., 2010). After impaling, the prey would have been sliced by the serrated denticles as the chelicerae closed. The serrations documented by Laub et al. (2010) are proximally orientated, suggesting that after impaling, a victim would have had to tear itself from the serrations, likely causing more damage. This conforms to the idea that *Acutiramus* was likely an ambush predator or scavenger that fed on soft-bodied and lightly cuticularized taxa, based on its limited vision and cheliceral morphology (Anderson et al., 2014; McCoy et al., 2015).

The *Jaekelopterus rhenaniae* model has overall low VM stress compared to the other pterygotid models. These data, combined with a proposed 2.5 m body length (Braddy et al., 2008), high visual acuity (McCoy et al., 2015; Poschmann et al., 2016), good swimming abilities (Plotnick & Baumiller, 1988; Tetlie, 2007), and a diverse co-occurring fauna containing several eurypterid and armoured fish species (Fyffe et al., 2016; Poschmann et al., 2016; Supplemental Table 13), suggest that *Ja. rhenaniae* was capable of capturing large, highly mobile, armoured prey. The robust chelicerae would have enabled the initial grabbing and manipulation of food items, while the heavily sclerotised gnathobases on large coxae would have been employed in prey mastication (including crushing of thick cuticle or biomineralised structures), comparable to

extant xiphosurids (Waterston, 1964; Botton, 1984; Poschmann et al., 2017; Bicknell et al., 2018a, b). The large reinforced chelicerae, giant body size, and phylogenetically-derived position of *Ja. rhenaniae* (Figure 6; Braddy et al., 2008) appear to represent a peak in pterygotid cheliceral evolution that coincides with the rapid diversification of placoderms (Randle & Sansom, 2019). As such, predatory Devonian eurypterids, epitomised by *Ja. rhenaniae*, likely developed a toolkit to target armoured fish in the form of robust chelicerae for grabbing prey and stout gnathobases for masticating said prey (Poschmann et al., 2017), as opposed to eurypterids driving the radiation of placoderms (*contra* Romer, 1933). The extinction of pterygotids in the Late Devonian is consistent with them ultimately being outcompeted by vertebrates (particularly jawed fishes), cephalopods, and various other groups during the Devonian Nekton Revolution (Lamsdell & Braddy, 2010; Klug et al., 2010, 2018), as well as falling victim to environmental changes (Lamsdell & Selden, 2017).

## Conclusions

Finite element models of chelicerae from four pterygotid eurypterids (*Acutiramulus bohemicus*, *Erettopterus bilobus*, *Jaekelopterus rhenaniae*, and *Pterygotus anglicus*) are presented and compared with FEMs of modern scorpion chelae. Overall similarity in VM stress distribution indicates that pterygotid chelicerae are functionally analogous to scorpion chelae, as suggested by the morphological similarity of these structures. Considering the pterygotid VM stress distributions in the context of their palaeoecology (including visual capabilities) and overall cheliceral morphology, we have demonstrated, with FEA, the morpho-functional ability of these ancient marine predators. We conclude that *Er. bilobus* and *Pt. anglicus* were apex predators within their respective ecosystems and likely targeted other eurypterids and fishes. Stress distributions of the *Ac. bohemicus* model, together with its unique denticle morphology, suggest

that the chelicera of this species was well adapted to piercing and slicing the cuticle of other eurypterids. Finally, *Ja. rhenaniae*, the largest known pterygotid, experienced low VM stress across the chelicera, suggesting that it was well adapted to capturing large, highly mobile, armoured prey. These results demonstrate how 3D FEA can be applied across a range of morphologies and used to explore the mechanical performance of extinct predatory arthropods.

# **Data accessibility**

Scorpion pincer 3D PDFs, pterygotid chelicerae .STL models, and loaded FEA models can be downloaded from [10.17605/OSF.IO/GV8J5](https://doi.org/10.17605/OSF.IO/GV8J5).

# **Author contributions**

R.D.C.B., J.R.P., G.D.E, A.v.d.M., and S.W. conceived the study. R.D.C.B., S.W., A.v.d.M., and Y.S. collected and analysed the data. R.D.C.B., J.R.P., A.v.d.M., Y.S., and G.D.E. interpreted the results, with input from the other authors. R.D.C.B. constructed figures. R.D.C.B. J.R.P., A.v.d.M., Y.S., and G.D.E. wrote the text. All authors discussed, edited and approved the manuscript.

# **Competing interests**

We declare we have no competing interests.

# **Funding**

This research was supported by funding from an Australian Research Council Discovery Project grant (DP200102005 to J.R.P., S.W., and G.D.E.), and a UNE Postdoctoral Research Fellowship (to R.D.C.B). A.v.d.M. is financed through FCT, I.P. under contract number

DL57/2016/CP1440/CT0009. Y.S. was funded by a PhD scholarship by Fundação para Ciências  
Tecnologia (SFRH/BD/136934/2018).

# Acknowledgements

We thank Katrina Kenny for producing the 3D reconstructions of the fossil taxa, Thomas  
Kleinteich for his help in scanning the scorpion chelae, and Jason Dunlop and Carolin Haug for  
their constructive reviews.

**Figure 4:** Lateral views of solved finite element models of assessed pterygotids showing von Mises (VM) brick stress maps. (A): *Erettopterus bilobus* from the Silurian (latest Llandovery and Wenlock) Patrick and Kip Burn formations, Scotland. (B): *Pterygotus anglicus* from the Devonian (Emsian) Campbellton Formation, Canada. (C): *Jaekelopterus rhenaniae* from the Devonian (Emsian) Klerf and Nellenköpfchen formations, Germany. (D): *Acutiramus bohemicus*

from the Silurian (Pridoli) Požáry Formation, Czech Republic. Biomechanical models are found in Supplemental Data 17–20.

**Figure 5:** Scatterplot of the relationship between log transformed VM stress and log transformed model volume for scorpions and pterygotids.

**Figure 6:** Simplified phylogeny of analysed pterygotid taxa showing total body lengths (in metres), associated time ranges and FEMs. Derived from Braddy et al. (2008; fig. 2) and Lamsdell & Selden (2017; fig. 1).

**Supplemental Figure 1:** Lateral views of solved *Erettopterus bilobus* FEMs, exploring the impact of modelled cuticle thickness and use of cross-sectional area to predict input force. Overall similarity in stress distributions illustrates how cuticle thickness has limited impact on the model. The majority of the variation occurs proximal to the hinge. The use of cross-sectional area to predict muscles produces higher stress, but the distribution is comparable to the model in Figure 3. (A): *Erettopterus bilobus* model in Figure 3. (B): *Erettopterus bilobus* with constrained hollow denticles. (C): *Erettopterus bilobus* with thicker fixed and free ramus cuticle. (D): *Erettopterus bilobus* with thinner fixed and free ramus cuticle. (E): *Erettopterus bilobus* model in Figure 3 using input force derived from cross-sectional area. The stress is higher than Figure 3, but the distribution is consistent. Biomechanical models are found in Supplemental Data 17.

- 661 **Supplemental Data 1:** 3D PDF and loaded Strand7 model for *Androctonus amoreuxi*.
- 662 **Supplemental Data 2:** 3D PDF and loaded Strand7 model for *Caraboctonus keyserlingi*.
- 663 **Supplemental Data 3:** 3D PDF and loaded Strand7 model for *Opisthophthalmus boehmi*.
- 664 **Supplemental Data 4:** 3D PDF and loaded Strand7 model for *Chactas* sp.
- 665 **Supplemental Data 5:** 3D PDF and loaded Strand7 model for *Hadogenes paucidens*.
- 666 **Supplemental Data 6:** 3D PDF and loaded Strand7 model for *Scorpio maurus*.
- 667 **Supplemental Data 7:** 3D PDF and loaded Strand7 model for *Androctonus australis*.
- 668 **Supplemental Data 8:** 3D PDF and loaded Strand7 model for *Parabuthus transvaalicus*.
- 669 **Supplemental Data 9:** 3D PDF and loaded Strand7 model for *Androctonus bicolor*.
- 670 **Supplemental Data 10:** 3D PDF and loaded Strand7 model for *Grophus flavopiceus*.
- 671 **Supplemental Data 11:** 3D PDF and loaded Strand7 model for *Hottentotta gentili*.
- 672 **Supplemental Data 12:** 3D PDF and loaded Strand7 model for *Leiurus quinquestriatus*.
- 673 **Supplemental Data 13:** 3D PDF and loaded Strand7 model for *Hadrurus arizonensis*.
- 674 **Supplemental Data 14:** 3D PDF and loaded Strand7 model for *Bothriurus* sp.
- 675 **Supplemental Data 15:** 3D PDF and loaded Strand7 model for *Opisthacanthus maculatus*.
- 676 **Supplemental Data 16:** 3D PDF and loaded Strand7 model for *Pandinoides cavimanus*.
- 677 **Supplemental Data 17:** 3D reconstructions as .STLs and loaded Strand7 model for *Erettopterus*
- 678 *bilobus*, including sensitivity analyses.

679 **Supplemental Data 18:** 3D reconstructions as .STLs and loaded Strand7 model for *Pterygotus*  
 680 *anglicus*.

681 **Supplemental Data 19:** 3D reconstructions as .STLs and loaded Strand7 model for  
 682 *Jaekelopterus rhenaniae*.

683 **Supplemental Data 20:** 3D reconstructions as .STLs and loaded Strand7 model for *Acutiramus*  
 684 *bohemicus*.

685

686 **Supplemental Table 1:** Dataset used to estimate pinch force of the scanned specimens.

687 **Supplemental Table 2:** Regression coefficients of the species-specific models.

688 **Supplemental Table 3:** Dataset used to calculate muscle force at insertion.

689 **Supplemental Table 4:** Summary of specimens that were used to reconstruct the pterygotid  
690 chelicerae for analysis.

691 **Supplemental Table 5:** Lower and upper values of input force for pterygotids as predicted by  
692 cross-sectional area.

693 **Supplemental Table 6:** Summary of the linear model.

694 **Supplemental Table 7:** ANOVA results of the linear model.

695 **Supplemental Table 8:** Muscle volume, muscle surface, and input force estimation of  
696 eurypterids.

697 **Supplemental Table 9:** Mean VM stress and model volumes.

698 **Supplemental Table 10:** Faunal list of the Lower Devonian (Emsian) Campbellton Formation,  
699 Canada. Modelled species in bold. Data derived from Shear et al. (1996), Wilson (2006),  
700 Kennedy et al. (2012), Miller et al. (2012), Fyffe et al. (2016), and Burrow et al. (2017).

701 **Supplemental Table 11:** Faunal list of the Silurian (latest Llandovery and Wenlock) Patrick and  
702 Kip Burn formations, Scotland. Modelled species in bold. Data derived from Jones & Woodward  
703 (1885), Rolfe & Fritz (1966), Howells (1982), Boucot & Janis (1983), Briggs & Clarkson  
704 (1987), Märss & Ritchie (1997), Anderson (1999), Tetlie & Braddy (2003), Tetlie & Poschmann  
705 (2008), and Perrier et al. (2019).

**Supplementary Table 12:** Faunal list of the Silurian (Pridoli) Požáry Formation, Czech Republic. Modelled species in bold. Data derived from Chlupáč et al. (1980), Kříž et al. (1986), Kříž (1992), Chlupáč (1994), Mergl (2001, 2019), Horný (2004, 2005), Südkamp & Burrow (2007), Manda & Turek (2009), Manda & Frýda (2010), and Budil et al. (2014).

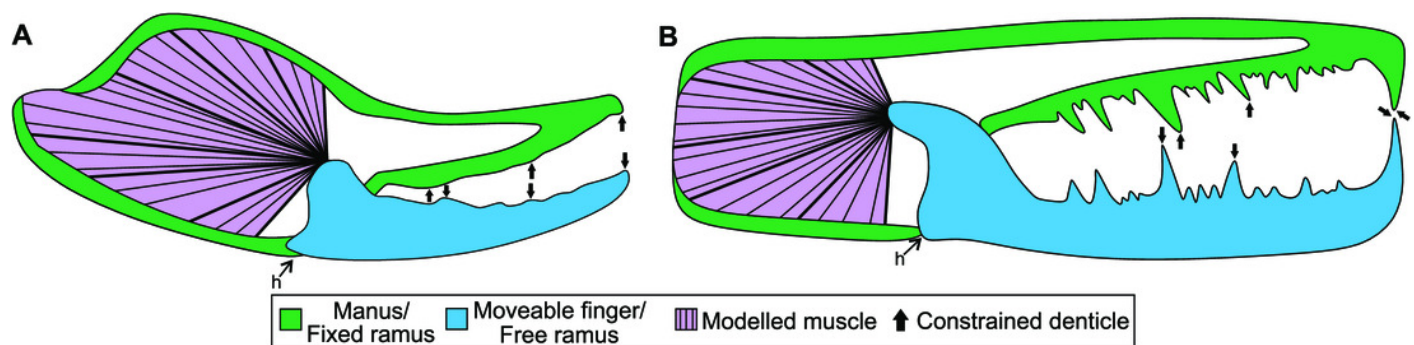

**Supplemental Table 13:** Faunal list of the Lower Devonian (Emsian) Klerf and Nellenköpfchen formations, Germany. Modelled species in bold. Data derived from Fürsich & Hurst (1980), Dunlop & Poschmann (1997), Anderson et al. (1998), Wehrmann et al. (2005); Poschmann (2006), Poschmann & Franke (2006), Poschmann & Tetlie (2006), Braddy et al. (2008), Poschmann et al. (2017), Schultze & Cumbaa (2017), Müller et al. (2018), Van Viersen & Taghon (2020), and Mondéjar-Fernández et al. (2021).

**Supplemental Code 1:** R code used in regression analyses.

# Figure 1

Figure 1: Theoretical models used for the biomechanical analyses, colour coded for analogous structures.

(A) Scorpion model. (B) Pterygotid model. Abbreviation: h, hinge. Muscle fibre organisation is used to illustrate generalised muscle directions but was not used to determine muscle force (see Methods).

# Figure 2

Figure 2: 3D scatterplot of the relationship between scorpion pinch force and muscle volume and surface.

The grey section represents the correlation across the three variables.

# Figure 3

Figure 3: Lateral views of scorpion finite element models showing von Mises (VM) brick stress maps.

(A): *Androctonus amoreuxi* Sc450. (B): *Caraboctonus keyserlingi* Sc3009. (C): *Opisthophthalmus boehmi* Sc696. (D): *Chactas* sp. Sc999. (E): *Hadogenes paucidens* Sc1041. (F): *Scorpio maurus* Sc1. (G): *Androctonus australis* Sc707 (H): *Parabuthus transvaalicus* Sc 2. (I) *Androctonus bicolor* Sc2623. (J): *Grophus flavopiceus* Sc881. (K): *Hottentotta gentili* Sc172. (L): *Leiurus quinquestriatus* Sc1062. (M): *Hadrurus arizonensis* Sc1004. (N): *Bothriurus* sp. Sc675. (O): *Opisthacanthus maculatus* Sc877. (P): *Pandinoides cavimanus* Sc761. (B, E, F, H, J, K, O) mirrored to align with other appendages. Biomechanical models are found in Supplemental Data 1–16.

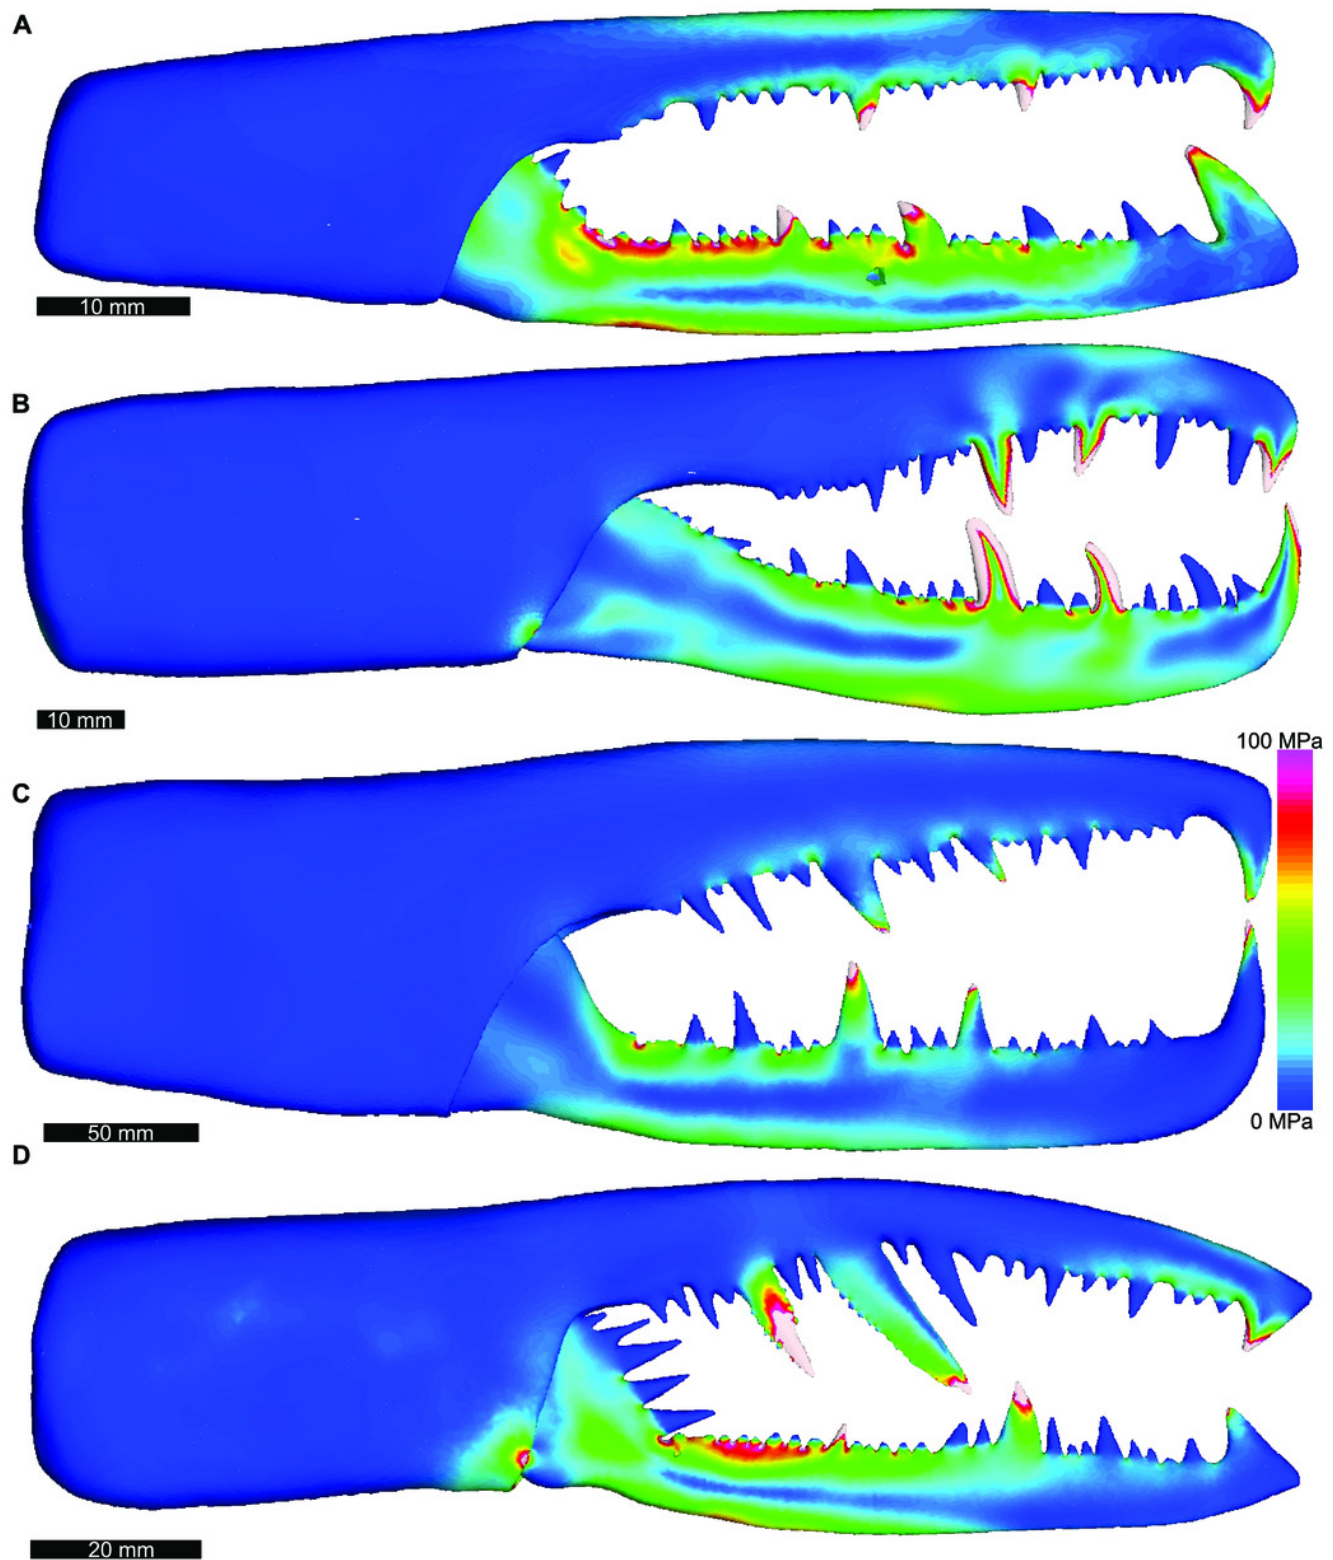

# Figure 4

Figure 4: Lateral views of solved finite element models of assessed pterygotids showing von Mises (VM) brick stress maps.

(A): *Erettopterus bilobus* from the Silurian (latest Llandovery and Wenlock) Patrick and Kip Burn formations, Scotland. (B): *Pterygotus anglicus* from the Devonian (Emsian) Campbellton Formation, Canada. (C): *Jaekelopterus rhenaniae* from the Devonian (Emsian) Klerf and Nellenköpfchen formations, Germany. (D): *Acutiramus bohemicus* from the Silurian (Pridoli) Požáry Formation, Czech Republic. Biomechanical models are found in Supplemental Data 17–20.
