Apex predators ideally require vast intact spaces that support sufficient prey abundances to sustain them. In a developing world, however, it is becoming extremely difficult to sustain large enough areas to facilitate apex predators outside of protected regions. Free-roaming leopards (*Panthera pardus*) are the last remaining apex predator in the Greater Cape Floristic Region, South Africa, and face a variety of threats, including competition for space and resources with humans. Land modification affects species diversity, but little is known about how this impacts African leopards in agricultural landscapes. Using camera-trap data, our study investigated the influence of anthropogenic land modification on leopards and the availability of their natural prey species in two contrasting communities - primarily protected (Cederberg) and agriculturally transformed (Piketberg). Potential prey species composition and diversity were determined, to provide a baseline understanding of prey availability for each region. Factors influencing space-use and detection behaviour of leopards and their main prey species were also assessed. Estimated potential prey species richness (Cederberg = 27, Piketberg = 26) and diversity indices (Cederberg - $H' = 2.64$, $D_s = 0.90$; Piketberg - $H' = 2.46$, $D_s = 0.89$) were found to be fairly similar across the two regions. Furthermore, both the Jaccard's Index ($J = 0.73$) and Sørensen's Coefficient ($CC = 0.85$) suggested high levels of similarity. Both regions accounted for all main leopard prey species, but their relative abundances (i.e. evenness) in each community differed. Leopards were found to persist across the agriculturally transformed landscape despite these perceived differences. Occupancy modelling revealed that the spatial dynamics of leopards differed between the two regions, except for both populations preferring areas further away from human habitation. Overall, anthropogenic factors played a larger role in affecting spatial utilisation by leopards and their main prey species in the transformed

region, whereas environmental factors had a stronger influence in the protected region. We argue that greater utilisation of alternative main prey species to those preferred in the protected region, including livestock, likely facilitates the persistence of leopards in the transformed region, and believe that this has further implications for human-wildlife conflict. Our study provides a baseline understanding of the potential direct and indirect impacts of agricultural landscape transformation on the behaviour of leopards and shows that heavily modified lands have the potential to facilitate biological diversity, including apex predators. We iterate that conservation measures for the persistence of apex predators should be prioritised where they are present on working lands, and encourage the collaborative development of customised, cost-effective, multi-species conflict management approaches that facilitate coexistence.

31 Abstract

32 Apex predators ideally require vast intact spaces that support sufficient prey abundances to
33 sustain them. In a developing world, however, it is becoming extremely difficult to sustain large
34 enough areas to facilitate apex predators outside of protected regions. Free-roaming leopards
35 (*Panthera pardus*) are the last remaining apex predator in the Greater Cape Floristic Region,
36 South Africa, and face a variety of threats, including competition for space and resources with
37 humans. Land modification affects species diversity, but little is known about how this impacts
38 African leopards in agricultural landscapes. Using camera-trap data, our study investigated the
39 influence of anthropogenic land modification on leopards and the availability of their natural
40 prey species in two contrasting communities - primarily protected (Cederberg) and agriculturally
41 transformed (Piketberg). Potential prey species composition and diversity were determined, to
42 provide a baseline understanding of prey availability for each region. Factors influencing space-
43 use and detection behaviour of leopards and their main prey species were also assessed.
44 Estimated potential prey species richness (Cederberg = 27, Piketberg = 26) and diversity indices
45 (Cederberg - $H' = 2.64$, $D_s = 0.90$; Piketberg - $H' = 2.46$, $D_s = 0.89$) were found to be fairly
46 similar across the two regions. Furthermore, both the Jaccard's Index ($J = 0.73$) and Sørensen's
47 Coefficient ($CC = 0.85$) suggested high levels of similarity. Both regions accounted for all main
48 leopard prey species, but their relative abundances (i.e. evenness) in each community differed.
49 Leopards were found to persist across the agriculturally transformed landscape despite these
50 perceived differences. Occupancy modelling revealed that the spatial dynamics of leopards
51 differed between the two regions, except for both populations preferring areas further away from
52 human habitation. Overall, anthropogenic factors played a larger role in affecting spatial
53 utilisation by leopards and their main prey species in the transformed region, whereas
54 environmental factors had a stronger influence in the protected region. We argue that greater
55 utilisation of alternative main prey species to those preferred in the protected region, including
56 livestock, likely facilitates the persistence of leopards in the transformed region, and believe that
57 this has further implications for human-wildlife conflict. Our study provides a baseline
58 understanding of the potential direct and indirect impacts of agricultural landscape
59 transformation on the behaviour of leopards and shows that heavily modified lands have the
60 potential to facilitate biological diversity, including apex predators. We iterate that conservation
61 measures for the persistence of apex predators should be prioritised where they are present on
62 working lands, and encourage the collaborative development of customised, cost-effective,
63 multi-species conflict management approaches that facilitate coexistence.

64 Introduction

65 Apex predators are generally large carnivores that can act as keystone species and as such, they
66 have been labelled as ecosystem engineers (Palazón, 2017). One way in which apex predators
67 primarily influence ecosystems is by exhibiting prey species control (Terborgh, 1988; Miller et
68 al., 2001): they can directly reduce prey species numbers by predating on them (reducing
69 competitive exclusion among herbivores, thus inducing greater diversity), but also by influencing
70 them indirectly through behavioural changes, which affect ecosystem resources (Miller et al.,
71 2001; Frank, 2008; Estes et al., 2011; Rosenblatt et al., 2013). Therefore, the local extinction of
72 apex predators within ecosystems can often bear drastic trophic cascade consequences (Terborgh
73 et al., 2001; Hebblewhite et al., 2005; Ripple et al., 2014; 2016; Suraci et al., 2016). For
74 example, biodiversity can be reduced (Estes et al., 2011); the transmission of infectious diseases
75 to humans can increase (Keesing et al., 2010); and damages to crops can increase (Brashares et
76 al., 2013). Apex predators also tend to be seen as charismatic species sought after by tourists and
77 hunters (Lindsey et al., 2007; van der Meer, Badza & Ndhlovu, 2016) and therefore hold an
78 important economic value to society. Thus, the disappearance of apex predators from ecosystems
79 is likely to stimulate knock on effects which may adversely impact human wellbeing (Díaz et al.,
80 2006; Estes et al., 2011).

81 Traditionally, it was believed that vast, relatively intact ecosystems were required to effectively
82 support viable apex predator populations (Sillero-Zubiri & Laurenson, 2001; Morrison et al.,
83 2007). Their high trophic position and large body size suggests that they require extensive home
84 ranges which sustain sufficient prey abundance (Morrison et al., 2007; Ripple et al., 2014).
85 These spatial requirements often bring apex predators into conflict with humans (Inskip &
86 Zimmerman, 2009; Nyhus, 2016) as they are amongst the first species to be affected by the
87 expansion of human populations and associated cultivation of previously untouched habitats
88 (Morrison et al., 2007; Ripple et al., 2014; Aebischer et al., 2020). A species that is influenced by
89 such anthropogenic activities across the globe is the leopard (*Panthera pardus*; Linnaeus, 1758).
90 Leopards are the most widespread large felid and occur through much of Africa and tropical Asia
91 (Nowell & Jackson, 1996; Stein et al., 2020). They are highly adaptable and successfully occupy
92 a large variety of habitats across their range (Jacobson et al., 2016; Stein et al., 2020), including
93 areas alongside large urban spaces (Kuhn, 2014). However, their ability to occupy areas in such
94 close proximity to humans makes them particularly susceptible to competition with humans for
95 space and resources, inevitably placing leopards at great risk.

96 Globally, leopards are considered as Vulnerable as their populations are declining and they face
97 multiple threats to their survival (IUCN Red List of Threatened Species; Stein et al., 2020). An
98 estimated 75% of their historic range has been lost (Jacobson et al., 2016), where the average
99 loss for large carnivore species is only around 53% (Ripple et al., 2014). Although suitable
100 habitat in southern Africa, which arguably hosts the healthiest leopard population across its range
101 (Stein et al., 2020), remains widely distributed, it is highly fragmented, having experienced

102 ~51% decline since 1750 (Jacobson et al., 2016). Anthropogenic activities, in particular
103 agricultural practices, are primarily responsible for this fragmentation (Swanepoel et al., 2013).
104 Brink & Eva (2009) have shown that agricultural land increased by 57% at the expense of natural
105 vegetation in sub-Saharan Africa in only 25 years (1975-2000). In South Africa, ~68% of
106 remaining habitat suitable for leopards occurs in non-protected areas that are naturally
107 susceptible to land-use transformation (Swanepoel et al., 2013). Leopards in non-protected areas
108 are most at risk of being killed by human-induced causes such as snares, hunts, poison, or motor
109 vehicle collisions (Balme, Slotow & Hunter, 2010; Swanepoel et al., 2013; 2015). Unfortunately,
110 most published research on leopards in South Africa has taken place inside protected areas
111 (Balme et al., 2014), and inadequate data jeopardizes the conservation of the species on working
112 lands. Thus, it is vitally important that conservation measures be established to accommodate
113 and preserve free-roaming leopards in non-protected transformed regions (Balme, Slotow &
114 Hunter, 2010; Swanepoel et al., 2013; Swanepoel, Somers & Dalerum, 2015).

115 Free-roaming leopards are the last remaining apex predator found in the Cape Floristic Region
116 (including Fynbos and Renosterveld) and Succulent Karoo Region, which are both biodiversity
117 hotspots and together form the Greater Cape Floristic Region (Born, Linder & Desmet, 2007), in
118 the Western Cape province of South Africa (Martins & Martins, 2006). The human population of
119 the Western Cape (± 55 people per km²; Statistics South Africa, 2021) has consistently grown at a
120 faster rate than the national population (Partridge, Morokong & Sibulali, 2021), and almost 90%
121 of the total area of the province is regarded as potential agricultural land. Leopards within this
122 region generally occupy significantly larger home ranges (Patterson, 2008) and occur at much
123 lower densities (Martins & Martins, 2006) than leopards found elsewhere in Africa (excluding
124 the Kgalagadi; Mizutani & Jewell, 1998; Bothma & Bothma, 2012). These leopards are also
125 generally considered smaller than most leopards found elsewhere in Africa (Stuart, 1981;
126 Martins & Martins, 2006) and across the species range (excluding Arabian leopard; Spalton & Al
127 Hikmani, 2006). The Western Cape is therefore an ideal study location to investigate the
128 influence of humans, both directly and indirectly, on this apex predator.

129 The aforementioned characteristics of leopards in the Western Cape all presumably reflect
130 adaptation to a different diet (Martins et al., 2010). With a great diversity in habitat usage,
131 leopards opportunistically hunt a wide range of prey, depending on local and temporal
132 availability (Hayward et al., 2006). A decline in their primary prey base can, however, impact
133 leopard population structure (Marker & Dickman, 2005; Ray, Hunter & Zigoris 2005; Wolf &
134 Ripple, 2016), and may also affect human-wildlife conflict levels (Khorozyan et al., 2015).
135 Human-wildlife conflict between farmers and leopards in the Western Cape has long been
136 prevalent (Martins & Martins, 2006; Nieman, Wilkinson & Leslie, 2020). Leopards in this region
137 are not only deemed responsible for livestock losses (C. Luyt, 2020, Community Outreach
138 Officer - Cape Leopard Trust), but direct conflict also exists between crop farmers and leopard
139 prey species, often regarded as crop raiders (Norton, 1980; Kingdon, 1982; Estes, 1991; Skinner
140 & Chimimba, 2005). The primary (main) natural prey base for leopards across the Western Cape

141 include common duiker (duiker; *Sylvicapra grimmia*, Linnaeus, 1758), Cape grysbok (grysbok;
142 *Raphicerus melanotis*, Thunberg, 1811), klipspringer (*Oreotragus oreotragus*, Zimmermann,
143 1783), and grey rhebok (rhebok; *Pelea capreolus*, Forster, 1790), as well as rock hyrax (hyrax;
144 *Procavia capensis*, Pallas, 1766), Cape porcupine (porcupine; *Hystrix africaeaustralis*, Peters,
145 1852), and chacma baboons (baboon; *Papio ursinus*, Kerr, 1792) (Martins et al., 2010; Drouilly,
146 Nattrass & O’Riain, 2018; Mann et al., 2019; Müller et al., 2022a). In addition, most of these
147 species are targeted by humans for the illegal harvesting of bushmeat through snare captures in
148 the province (Nieman et al., 2019). A similar competitive relationship between humans and
149 leopards has been documented in the Congo Basin (Henschel et al., 2011), with seemingly
150 negative consequences for leopards. Illegal hunting, which impacts prey species availability, is a
151 continuous concern for wildlife worldwide (Lindsey et al., 2013; Heurich et al., 2018). Besides,
152 snares can also be responsible for the direct capture of leopards resulting in injury or death
153 (Swanepoel et al., 2015; Williams et al., 2017; Nieman, Leslie & Wilkinson, 2019; Gubbi,
154 Kolekar & Kumara, 2021).

155 As the last remaining apex predator of the Western Cape, free-roaming leopards are expected to
156 be sensitive to changes in prey species populations. But little is known about the extent to which
157 this relationship is influenced by humans. Several studies investigating the drivers of leopard
158 occurrence, density, or ranging behaviour (e.g. Jiang et al., 2015; Allen et al., 2020; Searle et al.,
159 2020; Snider et al., 2021; Loveridge et al., 2022), and predator-prey overlap (e.g. Dias, de
160 Campos & Rodrigues, 2018; Havmøller et al., 2020; Palei et al., 2021; Sehgal et al., 2022;
161 Zaman et al., 2022), have been performed worldwide. However, until relatively recently, few
162 studies have investigated African leopard ecology in human-disturbed landscapes (e.g. Marker &
163 Dickman, 2005; Williams et al., 2017; Strampelli et al., 2018), particularly in commercial
164 agricultural regions. Furthermore, limited direct comparisons of predator populations between
165 protected and non-protected regions have been made (e.g. Swanepoel, Somers & Dalerum, 2015;
166 Drouilly, Nattress & O’Riain, 2018; Curveira-Santos et al., 2020; Faure et al., 2021).
167 Understanding the factors which could best enable the persistence of an apex predator in
168 agriculturally transformed environments, including variables affecting the availability of their
169 natural prey species, are vital to aid management decision making and account for in cost-benefit
170 models that aim to minimise conflict. Inferences about spatial variation in species composition
171 and diversity are also important, both to ecological hypotheses about structure and function of
172 communities and to community-level conservation management (Nichols et al., 1998).

173 Our study investigated potential prey species diversity, community structure, and factors
174 affecting the behaviour of leopards of the Western Cape and their main prey species, in both an
175 agriculturally transformed and a largely protected landscape, using camera-trap data. First, we
176 aimed to determine whether any real differences exist with reference to potential prey species
177 found in each community and whether any such difference is reflected in the respective leopard
178 subpopulations. Second, we aimed to evaluate and compare factors affecting space-use and
179 detection behaviour of leopards and their main prey in each region. We predicted a greater

180 diversity of potential leopard prey species to exist in the protected community, as well as
181 differences in community structure. Relative leopard and prey abundances in the protected
182 wilderness region were predicted to be higher than in the transformed agricultural region. And
183 anthropogenic factors were expected to negatively influence habitat utilisation of leopards, as
184 well as their main prey species, across the greater landscape.

185 **Materials & Methods**

186 **Ethical statement**

187 Relevant permissions to conduct our research were granted by the Social, Behavioural and
188 Education Research Ethics Committee at Stellenbosch University (Project ID #15315),
189 CapeNature (Permit #CN44-59-12321), and in writing by all landowners involved.

190 **Study area**

191 The Piketberg region (hereafter Piketberg) encompasses a transformed landscape that is
192 primarily characterised by mixed agricultural practices. Our study area is located approximately
193 130 to 160 km north of Cape Town, South Africa, and situated southwest of the Cederberg
194 region (Figure 1). The survey area was approximately 1500 km² in size (53 - 864 metres above
195 sea level), covering 55 privately owned mixed agricultural farms extending north from the town
196 of Piketberg to Paleisheuwel, with Citrusdal in the east and Aurora on the western boundary
197 (Figure 1). The area consists of natural vegetation forming a mosaic, highly fragmented by
198 livestock (e.g. cattle (*Bos taurus*, Linnaeus, 1758), horses (*Equus ferus caballus*, Linnaeus,
199 1758), sheep (*Ovis aries*, Linnaeus, 1758), goats (*Capra hircus*, Linnaeus, 1758), pigs (*Sus
200 domesticus*, Erxleben, 1777)), fruit, and other crop farmlands in and around mountainous terrain
201 (Linder, 1976; Mucina & Rutherford, 2006).

202 The Cederberg region (hereafter Cederberg), known for its rugged remoteness, is a largely
203 protected area first proclaimed in 1973 and located 200 to 250 km northeast of Cape Town
204 (Figure 1). The survey area was approximately 1700 km² in size (254 - 1455 metres above sea
205 level) and included the Matjiesrivier Nature Reserve and the Cederberg Wilderness Area. Both
206 areas are formally protected and managed by the provincial conservation regulation body and
207 authority in the Western Cape, known as CapeNature (Figure 1). Privately owned areas included
208 were Bushmans Kloof Wilderness Reserve, community owned land used for the harvesting of
209 rooibos and limited pastoralism by subsistence farmers, and the Cederberg Conservancy,
210 consisting of pro-conservation farms that are used for ecotourism and largely kept in a natural
211 ecological state. The two main biomes present are Fynbos and Succulent Karoo in mountainous
212 terrain (Mucina & Rutherford, 2006).

213 [Insert Figure 1 here]

214 The Western Cape has a Mediterranean type climate characterised by hot, dry summers and cold,
215 wet winters (Cowling & Holmes, 1992). Localised climatic conditions vary across the greater
216 study area because of its mountainous nature, and the vastness of the landscape makes it
217 extremely difficult to describe the climate of the study area in general terms. In essence, average
218 annual rainfall appears slightly higher, and average summer air temperatures somewhat lower in
219 Piketberg compared to the Cederberg (Climate-Data.org, 2020). Average winter air temperatures
220 are more uniform across both regions, but snowfall is more abundant in the Cederberg which is
221 generally at a higher altitude (Climate-Data.org, 2020).

222 **Field sampling methods**

223 *Camera-trap surveys*

224 Single season (dry summer – November to March) subsets of detection and non-detection data
225 that were collected in the Cederberg (2017-2018) and Piketberg (2019-2020) were used for our
226 study. The 73 camera-trap stations (n = 146 cameras) in the Cederberg were all located within
227 areas with protected status, whereas the 64 camera-trap stations (n = 128 cameras) in Piketberg
228 were situated in non-protected areas nestled between and on farmlands (Figure 1). Paired motion
229 and heat detecting Cuddeback X-Change series camera-traps were used at each camera station
230 during both surveys. Our setup procedures followed standard protocols optimised for the
231 detection of leopards, whereby the landscape across both study regions was divided into 50 km²
232 blocks (Figure 1), based on the minimum estimated home range size recorded for a female
233 leopard with cubs in the Western Cape (37 km²; Martins, 2010; also see Müller et al., 2022a;
234 2022b). Camera-trap stations were dispersed across mountainous habitat with mean distances of
235 2.78 km (Cederberg) and 3.09 km (Piketberg) between individual stations and two to three
236 stations per block (Figure 1). Camera-trap locations were selected based on the presence of
237 tracks and signs of leopards and their main natural prey species found in the nearby vicinity on
238 initial site investigation. Cameras were mounted ~40 cm above the ground and perpendicular to a
239 game trail, road, or drainage line. Camera-traps were serviced at an interval of about eight weeks
240 to download images, change batteries, perform site data collection (i.e. recording covariates
241 around each site), and for general maintenance.

242 *Covariate data*

243 Environmental (i.e. altitude, vegetation type, vegetation age, nearest water source type and its
244 distance) and anthropogenic (i.e. distances to the nearest road and human habitation, evidence of
245 disturbance, livestock and hunting) covariates surrounding each camera-trap station were
246 recorded during each servicing period (see Supplementary Material, Table S1). Some categorical
247 and binomial covariates were determined with a repeated physical site inspection of the
248 surroundings performed by a trained and experienced individual covering a 100 m radius around
249 each station (Table S1). Other variables were determined by a combination of physical
250 investigation, with recordings made using a GPS unit (Garmin ETrex 10), and local knowledge

251 (Table S1). Any further verification was performed using Google Earth (Google, n.d.) and
252 historical fire records (Table S1). The chosen covariates reflect natural and human-induced
253 factors that could influence predator and prey space-use or detection at each site. Tracks and
254 signs of all mammalian wildlife species found and positively identified during the site
255 inspections were also recorded.

256 **Data analyses**

257 *Camera-trap data*

258 Camera Base software (Tobler, 2010) was used to process images and extract meta-image
259 information from each photograph (image name, date, and time) while correcting for any time
260 stamp errors. Faunal species and number of individuals in each photograph was identified where
261 possible. Primary analyses were performed using the Camera Trap Analysis Package (CTAP)
262 software developed by the Zoological Society of London (Amin & Wachter, 2017). Only
263 terrestrial mammals > 0.5 kg, including leopard (see Charsley (1977), Steyn & Funston (2006),
264 and Balme & Hunter (2013) for examples of reported cannibalism), were considered as potential
265 leopard prey species for analyses as they are the main target group for camera-traps set up in this
266 manner, and are also generally regarded as the main dietary component of leopards (Hayward et
267 al., 2006; Tobler et al., 2008; Martins et al., 2010; Drouilly, Natrass & O’Riain, 2018; Mann et
268 al., 2019; Müller et al., 2022a). Relative abundance indices (RAI; i.e. number of events, where
269 an “event” is defined as any image sequence for a given species occurring after an interval of \geq
270 60 minutes from a previous sequence of that species, per 100 days of camera trapping; Karanth
271 & Nichols, 1998; Amin et al., 2018) per camera-trap station were calculated for known main
272 prey species of leopards in the study area, sympatric meso-carnivores - caracal (*Caracal caracal*,
273 Schreber, 1776) and black-backed jackal (*Canis mesomelas*, Schreber, 1775) - and leopards, and
274 used as biotic covariates for the occupancy models (Table S1). Despite being influenced by
275 sampling design or species’ behaviour (Sollmann et al., 2013), RAI is still considered a suitable
276 tool for assessing species occurrence (Hedwig et al., 2018; Palmer et al., 2018).

277 *Community structure*

278 Biological communities can differ in species composition, total number of species (richness), and
279 the relative abundance of species (evenness) (Colwell, 2009). Species diversity refers to a
280 community level concept that integrates both richness and evenness (Colwell, 2009). Species
281 sample-based rarefaction curves were constructed and the terrestrial medium-to-large (> 0.5 kg)
282 mammal species richness (S) - representing potential leopard prey species - was estimated for
283 each surveyed community using a non-parametric incidence-based estimator Jackknife with
284 order one (Bunge & Fitzpatrick, 1993). Livestock and other domestic species were excluded
285 from analyses. Simpson’s (D_s) and Shannon-Wiener (H') diversity indices were calculated for
286 each community using RAI values in the package ‘vegan’ in R statistical software (see Table S2;
287 Oksanen et al., 2019). Simpson’s diversity index is most sensitive to changes in more common

288 highly abundant species, while the Shannon-Wiener diversity index is most sensitive to changes
 289 in rare less abundant species (Magurran, 2004). Community structure plots representing the RAI
 290 as a factor of trophic level and mean adult body weight of potential prey species were also
 291 constructed. Jaccard's Index (J) and the Sørensen's Coefficient (CC) were calculated as
 292 measures of similarity, directly comparing Piketberg and the Cederberg, using the following
 293 formulae:

$$294 \quad J = \frac{A}{[A + B + C]} \quad CC = \frac{2A}{[2A + B + C]}$$

295 A = Number of species shared by two communities,
 296 B and C = Number of species unique to each of the two communities, respectively.

297 The latter places more emphasis on the shared species present rather than the unshared and
 298 retains sensitivity in more heterogeneous data sets. Sørensen's ecological distance ($D_{CC} = 1 - CC$)
 299 is therefore useful as many species may potentially be present in a community, but not present in
 300 a sample from that community (Magurran, 2004).

301 *Occupancy modelling*

302 Naïve occupancy, defined as the proportion of sites that recorded at least one photograph of the
 303 target species, was calculated for leopards of each community:

$$304 \quad \psi_{naïve} = \frac{\# \text{ of sites detected}}{\# \text{ of sites sampled}}$$

305 To accurately model occupancy, unique detection histories consisting of 1s (detection) and 0s
 306 (non-detection) were created for leopards and their main prey species (i.e. baboon, duiker,
 307 grysbok, hyrax, klipspringer, porcupine, and rhebok) in the Cederberg and Piketberg. The unique
 308 detection histories reflected the presence or absence of each species at each camera-trap site on
 309 each occasion (maximum value '1' per 24 hr period) for each region. Original unique detection
 310 history datasets (Cederberg N occasions = 151; Piketberg N occasions = 132) for each species
 311 were collapsed into data subsets by merging the occasions into intervals of between five to 11-
 312 day sampling occasions. This was deemed appropriate as it reduced each species dataset into
 313 manageable sizes for computational purposes and accurately represented the rarity of the study
 314 species (Sollmann, 2018).

315 All continuous covariate values were scaled into standardized z-scores (Bruggeman et al., 2016).
 316 Multi-collinearity was tested for by calculating variance inflation factors (VIF), whereby
 317 covariates with VIF scores greater than three were removed (Wang et al., 2018). A global
 318 occupancy model that included all ecologically relevant covariates (see Table S1) was applied to
 319 the subsets of data for each species and tested for goodness-of-fit (MacKenzie & Bailey, 2004).

320 Subset data for each species that had the closest over dispersion statistic (\hat{c}) to 1 (extreme values
321 over (> 3) or under 1 (< 0.90) indicate poor fit of the data) and an insignificant chi-square
322 probability ($\chi^2_p > 0.05$), was chosen for further occupancy analyses (see Table S3; Mazerolle,
323 2017). This showed maximum model fit without over compressing statistical power of the data
324 (Burnham & Anderson, 2004; MacKenzie & Bailey, 2004). Our study violates the assumption of
325 spatial autocorrelation and independence of camera-trap sites, which means that our results will
326 be interpreted as area (i.e. space) used rather than area occupied (MacKenzie & Nichols, 2004).

327 For each species, only combinations of covariates that could affect the two parameters (space-use
328 probability, ψ , and detection probability, p) and that presented ecologically reasonable
329 hypotheses were included (McDonald et al., 2016). With such a large number of covariates, the
330 set of candidate models that we might have examined was extremely vast (Schuette et al., 2013).
331 Therefore, we used a stepwise procedure following Dugger, Anthony & Andrews (2011),
332 whereby the first step was to model p by investigating additive combinations of covariates while
333 treating ψ as constant (i.e. intercept only). For model selection, the over dispersion statistic (\hat{c})
334 estimated from the global model for each species was used to compute quasi-likelihood
335 information criteria (QAICc: for small sample sizes) by scaling the log-likelihood of each model,
336 for each species, by its corresponding \hat{c} value (Mazerolle, 2017). Therefore, QAICc model-
337 selections were used to retain the best p model for each species to use in subsequent analyses of
338 factors affecting ψ . The second step was to model ψ by investigating additive combinations of
339 covariates. The package ‘unmarked’ (Fiske & Chandler, 2011) was used to fit models and to
340 estimate covariate coefficients for each parameter in R (version 4.1.2, R Development Core
341 Team, 2017). The R package ‘AICcmodavg’ was used for all model selection computations
342 (Mazerolle, 2017).

343 The lowest Δ QAICc scores (< 2) and highest QAICc weights ($w > 0.10$) were used to select the
344 best-approximating models for each species in each community (see Table S4 & S6; Burnham &
345 Anderson, 2004). We drew conclusions about strength of evidence of relationships between
346 covariates and parameters based on 95% confidence intervals (CIs) of coefficients and the
347 direction of relationships (see Table S5 & S7; Arnold, 2010).

348 Results

349 A total of 10114 operational camera-trap days (mean 140 days/station) were accumulated in the
350 Cederberg, with only one station failure (refer to Figure 1). In Piketberg, 6258 operational
351 camera-trap days (mean 103 days/station) were accumulated, and three camera-trap stations
352 failed (Figure 1). The outcomes of our study are unlikely to be affected by this difference as
353 sampling effort across both regions was sufficient (see Figure 2) and indices based on relative
354 abundance values were employed, providing equal weight to both communities, therefore
355 allowing comparison.

356 *Species richness*

357 Cederberg had an estimated potential prey species richness ($S = 27$) similar to that of Piketberg
358 ($S = 26$). The rarefied species accumulation curves do however show more species detected per
359 unit effort in the Cederberg compared to Piketberg (Figure 2). Both the Shannon-Wiener (H')
360 and Simpson diversity (D_s) indices were only marginally higher in the Cederberg ($H' = 2.64$, D_s
361 $= 0.90$) compared to Piketberg ($H' = 2.46$, $D_s = 0.89$). Thirty potential natural prey species were
362 photographed across the two regions (Cederberg: 27; Piketberg: 25), with Cederberg having five
363 unique species and Piketberg three (Table S2).

364 [Insert Figure 2 here]

365 *Community structure*

366 Differences in community structure were largely complementary, providing a similar pattern
367 across trophic guilds for both the Cederberg and Piketberg (Figure 3). The same number of
368 carnivore species were detected in both areas ($n = 10$), but no Cape fox (*Vulpes chama*, Smith,
369 1833) or large grey mongoose (*Herpestes ichneumon*, Linnaeus, 1758) were recorded in the
370 Cederberg, whereas black-backed jackal and water mongoose (*Atilax paludinosus*, Cuvier, 1826)
371 were not observed in Piketberg. Herbivore species were the most frequently encountered guild
372 across both areas; more herbivores were encountered in the Cederberg ($n = 13$) than in Piketberg
373 ($n = 11$). Main leopard prey species were all accounted for in both communities.

374 Across all guilds, trap rates (RAI) for species detected were generally higher in Piketberg (Figure
375 3 & Table S2). Noteworthy exceptions include hyrax (Cederberg: 4.05; Piketberg: 3.16),
376 klipspringer (Cederberg: 3.56; Piketberg: 2.41), and rhebok (Cederberg: 0.84; Piketberg: 0.14).
377 A marked difference was the higher RAIs of all carnivores > 4 kg - including leopard
378 (Cederberg: 3.52; Piketberg: 4.65) - as well as most medium (> 0.5 kg and < 100 kg) herbivores,
379 in the transformed Piketberg region (Figure 3 & Table S2). Baboons were the most frequently
380 detected species across both communities (Cederberg: 608 events; Piketberg: 592 events),
381 followed by hyrax in the Cederberg (410 events) and porcupine in Piketberg (540 events). No
382 single species dominated (i.e. $> 50\%$ of total trap rates) in any of the two communities.

383 [Insert Figure 3 here]

384 High levels of similarity between the two study regions are shown by the Jaccard's Index ($J =$
385 0.73) and Sørensen's Coefficient ($CC = 0.85$). The Jaccard's Index suggests that 73% similarity
386 exists between the contrasting communities. Similarly, the Sørensen Coefficient suggests that the
387 ecological distance is only 15%, supporting close relatedness of ecological make-up in each
388 community.

389 *Occupancy*

390 Camera-trap stations were excluded from occupancy analyses when cameras were operational
391 for < 80% of occasions (see Figure 1). Baboon and rhebok were excluded due to insufficient
392 model fit (Table S3). Only strong relationships with space-use and detection probabilities are
393 discussed (see Table 1). Factors that strongly influenced spatial dynamics of leopard and their
394 main prey species in the Cederberg were primarily environmental (56%), whereas anthropogenic
395 (32%) and biotic variables (12%) played a less significant role (Table 1). In contrast,
396 anthropogenic variables (41%) dominated in Piketberg compared to strong influences by
397 environmental (23%) and biotic (36%) factors (Table 1).

398 [Insert Table 1 here]

399 *Leopard*

400 Leopards occurred across the landscape in both communities and were detected at 55 camera-
401 trap stations in Piketberg and 60 stations in the Cederberg, providing naïve occupancy estimates
402 of 0.852 (Piketberg) and 0.833 (Cederberg) respectively. The spatial dynamics of leopards
403 differed between the Cederberg and Piketberg, except for both leopard populations preferring to
404 utilise areas further away from human habitations (Table 1; Figures 4A & 5A). In the Cederberg,
405 leopards also preferred areas in closer proximity to permanent rather than seasonal water sources
406 (Table 1; Figure 4B) but were more likely to be detected further away from water (Table 1;
407 Figure 4E). Furthermore, leopards of the Cederberg were generally less likely to be detected in
408 areas where sympatric meso-carnivores were more abundant (Table 1; Figure 4C) and at higher
409 altitudes (Table 1; Figure 4D). In Piketberg, leopards were less likely to be detected when
410 present at sites characterised by Sandveld vegetation and in areas utilised for grazing, as was
411 indicated by the presence of signs of livestock (Table 1; Figures 5B & C).

412 [Insert Figure 4 here]

413 [Insert Figure 5 here]

414 *Main prey species*

415 The space-use of grysbok, hyrax, klipspringer, and porcupine were influenced by slightly
416 different factors in the Cederberg and Piketberg (Table 1). None of the variables we considered
417 were found to strongly influence duiker space-use (Table 1). In the primarily protected
418 Cederberg, grysbok preferred areas further away from roads (Table 1), porcupine preferred areas
419 of older vegetation (Table 1), while hyrax preferred areas of Karoo vegetation and seemingly
420 avoided areas where caracal and black-backed jackal were abundant (Table 1). In the
421 agriculturally transformed Piketberg, hyrax, as well as klipspringer, also avoided areas where
422 caracal (black-backed jackal are absent) were prevalent (Table 1). Interestingly, porcupine in
423 Piketberg appeared to prefer areas with greater caracal presence (Table 1).

424 Various combinations of factors affected the detection probability of these prey species in the
425 Cederberg and Piketberg (Table 1). In both the Cederberg and Piketberg, grysbok were more

426 likely to be detected if present in areas closer to roads. In Piketberg, detectability of klipspringer
427 was also higher nearer to roads, as was the case for duiker. In the Cederberg, the detection
428 probability of porcupine near roads was also greater. In contrast, the detectability of hyrax in the
429 Cederberg increased further away from roads. Duiker were more likely to be detected closer to
430 human habitations in both the Cederberg and Piketberg, as was grysbok in Piketberg. Oppositely,
431 porcupine in Piketberg were less likely to be detected closer to human habitations. These
432 porcupine were however more likely to be detected in areas that showed evidence of
433 anthropogenic disturbance. In the Cederberg, grysbok were more likely to be detected in areas
434 that experienced anthropogenic disturbance, but klipspringer experienced an opposite effect. In
435 Piketberg, detectability of klipspringer was higher closer to water, particularly permanent water
436 sources. In comparison, duiker in the Cederberg were more likely to be detected further away
437 from water. In Piketberg, duiker and hyrax were both less likely to be detected in areas where
438 leopard RAI was greater. In contrast, grysbok in this region had an opposite relationship and
439 were more likely to be detected where leopards were more prevalent. Interestingly, the relative
440 abundance of leopards played a role in the detection of prey species in Piketberg only. Contrary
441 to their relationship with leopards, hyrax in Piketberg were more likely to be detected in areas
442 where caracal (meso-carnivore) were more abundant. Furthermore, klipspringer were less likely
443 to be detected in both regions in areas where meso-carnivore RAI was higher. Considering the
444 role of vegetation, klipspringer and hyrax in the Cederberg were more likely to be detected in
445 Karoo vegetation, but grysbok and porcupine less so. Porcupine in the Cederberg were also less
446 likely to be detected in older vegetation, as was duiker. Lastly, the detection probability of duiker
447 in both regions were higher at lower altitudes. The same relationship was observed for hyrax in
448 the Cederberg, and the opposite for grysbok in Piketberg.

449 **Discussion**

450 **Prevalence of leopards**

451 Contrary to expectations, our results, in terms of both relative abundance indices (RAI:
452 Cederberg: 3.52; Piketberg: 4.65) and naïve occupancy ($\psi_{naïve}$: Cederberg: 0.833; Piketberg:
453 0.852), suggest that leopards are at least equally abundant, or possibly even slightly more
454 abundant, across the agriculturally transformed Piketberg landscape than they are in the
455 primarily protected Cederberg region. A similar observation was made for all carnivores > 4 kg
456 shared between the two communities (Figure 3 & Table S2). Assuming comparable average
457 activity levels, leopards of Piketberg are therefore likely occupying either smaller (i.e. greater
458 density; Snider et al., 2021) or more overlapping home ranges than leopards found in the
459 Cederberg (refer to Müller et al., 2022b). Greater predator abundance can only be sustained by a
460 greater relative carrying capacity (i.e. prey availability), and currently, prey populations in
461 Piketberg appear sufficient to facilitate and sustain relatively larger, potentially denser, and at
462 least equally successful predator populations to those found in the Cederberg. This conclusion is
463 further supported, also contrary to expectation, by higher RAIs in Piketberg compared to the

464 Cederberg for most medium sized (> 0.5 kg and < 100 kg) herbivores (Figure 3 & Table S2).
465 Differences observed in the abundances of main leopard prey species between the two study
466 regions (Table S2) suggest that leopard diet composition differs (based on prey availability), and
467 that leopards may have had to adapt to a different diet in order to persist in Piketberg.

468 The main prey species considered in our study are known to comprise approximately 85% of the
469 biomass consumed by leopards in the Cederberg (Müller et al., 2022a), while in other areas of
470 the Western Cape they comprise as much as 91% (Boland) and as little as 57% (Little Karoo) of
471 leopard diets (Mann et al., 2019). Leopards in the Cederberg appear heavily reliant on hyrax and
472 klipspringer in particular, which together made up 61% of biomass consumed (Martins et al.,
473 2010; Müller et al., 2022a). Despite lower abundances recorded for both these prey species in
474 Piketberg relative to the Cederberg during our study (Table S2), the leopard population in
475 Piketberg appeared unaffected. Our findings thus suggest the persistence of leopards in an
476 agriculturally transformed region, highlighting the adaptability, but also the potential
477 vulnerability, of these large apex predators. In the Soutpansberg and Waterberg mountains
478 (Limpopo Province) of South Africa, leopards have also been shown to thrive outside of
479 protected areas (Chase Grey, Kent & Hill, 2013; Swanepoel, Somers & Dalerum, 2015), as is the
480 case across a densely populated agricultural landscape in India (Athreya et al., 2013). Diet
481 composition of leopards in Piketberg is unknown, but our results suggest that these leopards are
482 likely to be less reliant on hyrax and klipspringer than in the Cederberg.

483 **Natural prey species availability**

484 Our camera surveys appear to have recorded almost all natural potential prey species (mammals
485 > 0.5 kg) present, as the number of species captured was very close or equal to the total number
486 estimated in both communities. Community composition of potential prey species did differ, but
487 niche composition remained relatively intact across both regions, and each supports complete
488 communities of carnivores and herbivores (Figure 3). Generally, carnivores do not play a
489 significant role in leopard diet in the Western Cape (Martins et al., 2010; Drouilly, Natrass &
490 O’Riain, 2018; Mann et al., 2019; Müller et al., 2022a), although elsewhere small carnivores are
491 commonly killed (Palomares & Caro, 1999; Hayward et al., 2006). Herbivores unique to each
492 community were all large antelope species (> 100 kg) which are also not of great importance in
493 leopard diet in most of the Western Cape (Martins et al., 2010; Drouilly, Natrass & O’Riain,
494 2018; Mann et al., 2019; Müller et al., 2022a), except in the Little Karoo, where their marked
495 presence in leopard diet is attributed to game farming (Mann et al., 2019). The very low
496 abundances and limited distributions (detected at only one station each) of the large antelopes re-
497 introduced on private land in Piketberg (Table S2), are however unlikely to explain why leopards
498 in Piketberg are able to flourish. Ultimately, such predation will also result in farmer-predator
499 conflict and consequently place leopards at risk (Constant, Bell & Hill, 2015). Hence, the minor
500 differences in potential prey species composition and richness we observed between the two
501 communities are unlikely to substantially affect leopard diet.

502 Variance of main prey species

503 Leopards in Piketberg are more likely to rely on other (than hyrax or klipspringer) main prey
504 species, based on the observed differences in their perceived availability (i.e. RAI; Table S2) in
505 each community. Due to the inability to model probabilities of space-use and detection for
506 baboon and rhebok, we did not speculate on probable causes for differences in their RAIs. It
507 should also be noted that our results for hyrax may be unintentionally skewed because of their
508 restricted habitat (being confined to rocky outcrops; Skinner & Chimimba, 2005) not accounted
509 for in camera set-up procedures, and therefore we suggest caution in interpretation thereof.

510 In essence, our spatial modelling suggests that anthropogenic factors were generally more likely
511 to affect the behaviour of preferred main prey species of the Cederberg (i.e. hyrax and
512 klipspringer) in a negative manner, and to facilitate alternative main prey species (duiker,
513 grysbok, and porcupine). Factors accompanying agricultural practices (i.e. roads, disturbances,
514 habitations) showed strong correlations across all species, as did environmental factors.
515 Vegetation played a role only in the Cederberg, seemingly facilitating the presence of hyrax and
516 klipspringer in this region (Birss et al., 2016; Visser & Wimberger, 2016). In general, vegetation
517 in Piketberg is denser than across the Cederberg, and thus catered for grysbok and porcupine in
518 particular (Bragg & Child, 2016; Palmer et al., 2016). The top-down influence of predators
519 largely affected hyrax (particularly favoured as prey in the Cederberg by leopard and caracal;
520 Müller et al., 2022a) and klipspringer, and both species seemingly avoided areas heavily utilised
521 by caracal and black-backed jackal (meso-predators) in both communities (resulting in an
522 indirect overlap with leopards in the Cederberg; Müller et al., 2022a). Caracal in Piketberg also
523 seemed to choose areas of greater hyrax activity. Porcupine, which co-exists with caracal in
524 Piketberg, does not generally feature in caracal diet (Müller et al., 2022a). Leopards (apex
525 predator) exhibited direct overlap with grysbok in Piketberg and we would thus expect relatively
526 higher levels of leopard predation on grysbok in this region. In contrast, hyrax and duiker were
527 less active in areas where leopards were more abundant, further suggesting that hyrax do not play
528 a prominent role in leopard diet in Piketberg. However, we cannot disregard the possibility that
529 hyrax, which is a highly preferred leopard prey species (Hayward et al., 2006), may in fact
530 experience very significant predation pressure and therefore their numbers and activity may
531 appear relatively limited in areas shared more frequently with leopards (Wittmer, Sinclair &
532 Mclellan, 2005).

533 Our findings thus suggest that a combination of anthropogenic, environmental, and biotic factors
534 influences prey species evenness and behaviour, and consequently prey availability. The greater
535 perceived abundance of duiker, grysbok, and porcupine in the agriculturally transformed region
536 may also be facilitated by a preference for readily available crop food resources (these prey
537 species, as well as baboon, are known to frequent the fringes of agricultural land where there is
538 suitable habitat in close proximity: Birss, Relton & Selier, 2016; Bragg & Child, 2016; Palmer et
539 al., 2016) which in turn facilitate leopards in this region. Aside from alternative main prey

540 species (i.e. grysbok and porcupine) playing an important role in Piketberg, unnatural prey (i.e.
541 livestock or domestic species) might also supplement leopard diet.

542 **Livestock – An alternative food source?**

543 In a national park in Pakistan and a human-dominated landscape in India, leopards are almost
544 completely dependent on livestock and other domestic species as prey (Shehzad et al., 2015;
545 Athreya et al., 2016). Our decision to exclude livestock and other domestic species from
546 abundance analyses was because the vastly greater use of livestock proof fences in the Piketberg
547 region prevented accurate and comparable detection of livestock at camera-trap stations. While
548 fences do not prevent the movement of leopards across a landscape, the energetic costs to
549 leopards that accompany their presence may be a driving factor for the killing of more livestock
550 (Wilmers et al., 2017). Müller et al. (2022a) showed that 7% biomass of leopard diet in the
551 Cederberg was comprised of livestock. We believe a greater proportion can be expected in
552 Piketberg, which is supported by the higher levels of confirmed livestock predation events
553 reported in recent years, especially during winter (C. Luyt, 2020, Community Outreach Officer -
554 Cape Leopard Trust, unpublished data; Müller et al., 2022b). Although not found to be of great
555 importance, the inverse relationship between space-use by leopards and presence of livestock in
556 the two contrasting study regions (Table 1), is noteworthy. Leopards in the Cederberg tended to
557 avoid areas with livestock, while in Piketberg they appear to have shown a greater preference for
558 areas with livestock. These results suggest a plausible tendency for greater reliance on livestock
559 by leopards in Piketberg. In the Cederberg, livestock roam more freely but tend to be guarded by
560 herders, whereas in Piketberg they are generally fenced and unguarded. Unguarded, fenced
561 livestock that are not completely predator-proofed may result in leopards being attracted to
562 livestock as prey, especially when natural main prey abundances are low (Odden, Nilsen &
563 Linnell, 2013; Khorozyan et al., 2015). This may subsequently result in an increase in illegal
564 retaliatory killings and make leopards in Piketberg particularly vulnerable (Inskip &
565 Zimmerman, 2009; Soofi et al., 2022).

566 If livestock serve as regular prey, this has the potential to result in less pressure and reduced
567 ecological regulation of natural prey species, regarded as agricultural pests (G. Malherbe, 2021,
568 Off-reserve Conservation Manager - CapeNature, unpublished damage causing animals
569 database). Examples of this has also been described with other apex predators like snow leopards
570 (*Panthera uncia*, Schreber, 1775) in Nepal and dingoes (*Canis lupis dingo*, Meyer, 1793) in
571 Australia (Johnson & Wallach, 2016; Shrestha, Aihartza & Kindlmann, 2021). Leopards that are
572 less reliant on livestock as prey, provided sufficient preventative measures for livestock
573 predation are employed, will partially limit population explosions of their natural prey species
574 (O'Bryan et al., 2018). Effective preventative mitigation of conflict with crop pests (i.e. prey)
575 will also cater for leopards, offering sufficient natural prey availability in the future which may
576 minimise livestock losses (Odden, Nilsen & Linnell, 2013; Khorozyan et al., 2015). Hence,
577 leopards and their prey species can be regarded as assets on a landscape scale, and pro-active

578 (preventative and non-lethal) measures employed together by livestock and crop farmers in a
579 community can thus benefit them both instead of either one indirectly inducing conflict for the
580 other. We therefore agree with Du Toit, Cross & Valeix (2017) that a shift in attitude towards
581 asset management, rather than problem control by means of retaliatory killings, will be
582 advantageous. The removal of conflict-prone species would instead be counter-productive for the
583 community (Conradie & Piesse, 2013; Lennox et al., 2018).

584 **Impacts on leopard behaviour**

585 Besides potential for retaliatory killings, further direct impacts of agriculture on leopards were
586 evident across both study regions as they avoided areas close to human habitations (Table 1;
587 Figures 4A & 5A). This suggests species sensitivity and echoes the loss of suitable leopard
588 habitat by anthropogenic landscape transformation (Swanepoel et al., 2013; Jacobson et al.,
589 2016). Interestingly, the availability of natural main prey species did not directly dictate spatial
590 utilisation by leopards, probably because leopards (and natural prey) still occurred widely across
591 the study area. However, we found the direct impact of anthropogenic variables on the behaviour
592 of various main prey species to be greater in Piketberg; these have the potential to indirectly
593 affect leopards. Environmental factors that influenced the spatial dynamics of leopards differed
594 between the two regions (Table 1). Greater detectability further away from water in the
595 Cederberg, where sources are presumably more limited, can be explained since leopards are
596 largely independent of water (Bothma, 2005). Leopards in this region did however show a
597 preference for areas closer to permanent (e.g. rivers; Table S1) rather than seasonal (e.g. streams;
598 Table S1) water sources, but this is likely to be a simple consequence of these water sources
599 being dry and unusable at the time. The lower detection probability of leopards in Sandveld
600 vegetation and areas presumably used for grazing in Piketberg indicate that fine-scale habitat
601 utilisation by leopards is likely to be selective and affected by agricultural activities. The
602 influence of altitude observed in the Cederberg is assumed to be a consequence of the slightly
603 higher density recorded for leopards in the region during the summer months, which relates to
604 individuals occupying smaller home ranges on the more accessible lower mountain slopes at this
605 time of year (Müller et al., 2022b). Finally, the relationship we observed between leopards and
606 meso-carnivores in the Cederberg is consistent with the conclusions of Müller et al. (2022a):
607 Caracal (meso-predator) tends to avoid leopards (apex predator) in time and space.

608 **Study limitations**

609 Potential criticisms of our study are that data were collected roughly two years apart, and that it
610 investigated factors influencing behaviour only at a single spatial scale. We are aware that
611 community structure could be influenced by weather on a seasonal or annual basis. The Western
612 Cape experienced a relatively dry year (South African Weather Service, 2021) prior to the
613 Cederberg survey and recorded precipitation of 212.9 mm below the annual mean (2017; Data
614 provided by www.meteoblue.com) in the region. A precipitation anomaly of 139.9 mm below

615 the mean (2019; Data provided by www.meteoblue.com) was also noted prior to the survey in
616 the Piketberg region. Ideally, ecological modelling should aim to incorporate different orders of
617 scale (e.g. Pitman et al., 2017), but this is not always practical. We concur that spatial scale must,
618 however, be accounted for in conservation decision-making (also see McManus et al., 2021).
619 Our results can be used to inform and support conservation policies that aim to cater for free-
620 roaming leopards in human-altered landscapes.

621 **Conclusions**

622 No real differences were apparent between the potential prey species composition or richness, or
623 the abundance of leopards, in the agriculturally transformed Piketberg and the primarily
624 protected Cederberg regions. Our results, therefore, suggest that transformed regions have the
625 potential to facilitate biological diversity, including apex predators (see Linell, Swenson &
626 Anderson, 2001). The main prey species of leopards in the Cederberg were, however, relatively
627 less abundant in Piketberg, but this difference was not reflected in the respective leopard
628 populations. We believe that greater utilisation of alternative main prey species to those preferred
629 in the Cederberg, likely including livestock, facilitates persistence of the Piketberg leopard
630 population, and that this is a probable driving factor of high levels of human-wildlife conflict.
631 Our findings also suggest that a variety of ecological factors strongly influenced the spatial
632 dynamics and behaviour of leopards and their main prey species in a complex manner, but
633 anthropogenic factors played a relatively larger role in the agriculturally transformed region (also
634 see Rogan et al., 2022). We argue that a multi land-use, multi-species (predator and prey), and
635 pro-active (non-lethal) management approach, that encourages co-existence and aims to limit the
636 cascade of ecosystem effects that could follow human-induced changes to the landscape, can
637 benefit both livestock and crop farmers. Ultimately, such a collaborative and holistic approach
638 can provide incentive to conserve apex predators and their prey and is therefore required to
639 ensure the conservation of apex predators on working lands worldwide. We also encourage
640 further detailed investigation of the leopard population in Piketberg, including density, home-
641 range, population structure, dietary and human-wildlife (both leopards and their prey) conflict
642 analyses, to further inform local conservation management decision-making and maintain its
643 leopard population going forward.

644 Acknowledgements

645 We are grateful to the Cape Leopard Trust who provided support and resources to enable this
646 research. We would like to extend our thanks to all the landowners and to CapeNature for
647 granting access to their properties and for their collaboration. We would like to extend a special
648 thank you to Jacobus Smit for providing accommodation and contacts within the Piketberg
649 community. We are grateful for the field assistance provided by Chavoux Luyt, Mari-Su de
650 Villiers, Ross de Bruin, Barbara Seele, Christiaan Lochner, Ismail Wambi, Ewan Brennan,
651 Hannes de Kock and Grant Baker, and contributions to data processing by Mari-Su de Villiers.
652 Thank you to Kathryn Williams for providing comments on this manuscript.

1043 **Figure legends**

1044 **Figure 1:** Maps showing the location of the Western Cape province within South Africa (a), and
1045 the proximity of the survey areas within the Western Cape (b). Main map shows the location of
1046 camera-trap stations for both Cederberg and Piketberg. Failed camera-trap stations (because of
1047 major camera malfunctioning, fire, other damage, or theft) are noted. Formally proclaimed
1048 protected areas (CapeNature reserves) are also highlighted.

1049 **Figure 2:** Rarefied species accumulation curves for medium-to-large (> 0.5 kg) terrestrial
1050 mammals (i.e. potential leopard prey species) photographed in the primarily protected Cederberg
1051 and agriculturally transformed Piketberg regions. Both curves approach an asymptote, indicating
1052 sufficient sampling effort.

1053 **Figure 3:** Distribution of medium-to-large (> 0.5 kg) terrestrial mammals (i.e. potential leopard
1054 prey species) in the Cederberg and Piketberg on the basis of body size and trophic category.
1055 Each circle represents a species in functional space. The size of the circle is proportional to the
1056 trapping rate (RAI) for that species.

1057 **Table 1:** QAICc weights (w) for covariates from well-supported models ($w > 0.10$ and QAICc $<$
1058 2) for each species (leopard + main prey) in each community. Either the direction of the
1059 relationship for covariates from the best fit models or the parameter probability estimate (\pm
1060 standard deviation) for top models are indicated in parentheses.

1061 **Figure 4:** Detection and space-use (i.e. occupancy) probabilities for leopards with regards to
1062 variables with strong associations in the Cederberg.

1063 **Figure 5:** Detection and space-use (i.e. occupancy) probabilities for leopards with regards to
1064 variables with strong associations in Piketberg. Values in graphs B and C are the detection
1065 probabilities for leopards across the various habitat types in areas without (B) and with (C)
1066 livestock signs present.

Figure 1

Location of survey regions.

Maps showing the location of the Western Cape province within South Africa (a), and the proximity of the survey areas within the Western Cape (b). Main map shows the location of camera-trap stations for both Cederberg and Piketberg. Failed camera-trap stations (because of major camera malfunctioning, fire, other damage, or theft) are noted. Formally proclaimed protected areas (i.e. CapeNature reserves) are also highlighted.

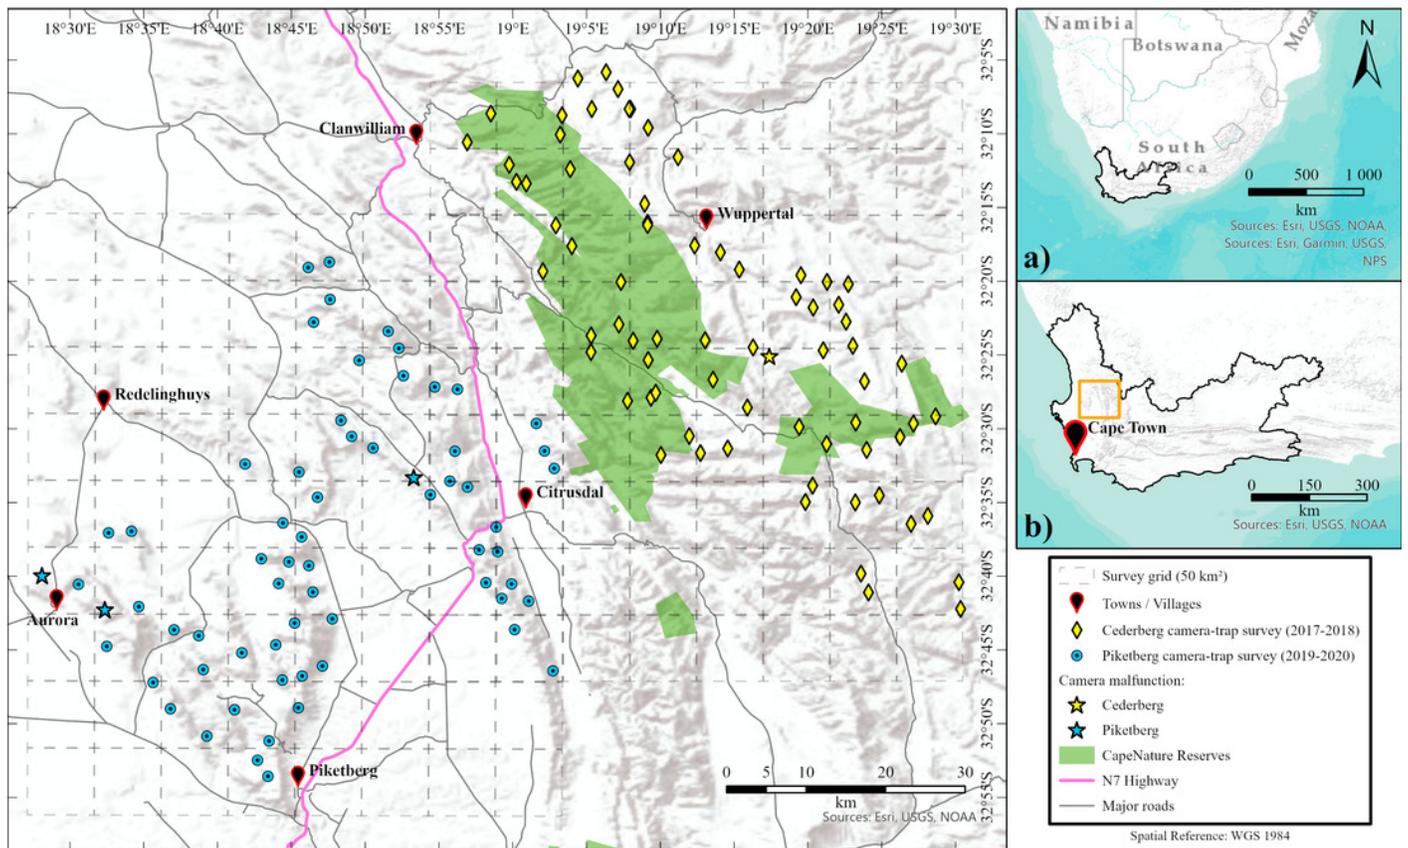

Figure 2

Rarefied species accumulation curves for medium-to-large (> 0.5 kg) terrestrial mammals (i.e. potential leopard prey species) photographed in the Cederberg and Piketberg regions.

Both curves approach an asymptote, indicating sufficient sampling effort.

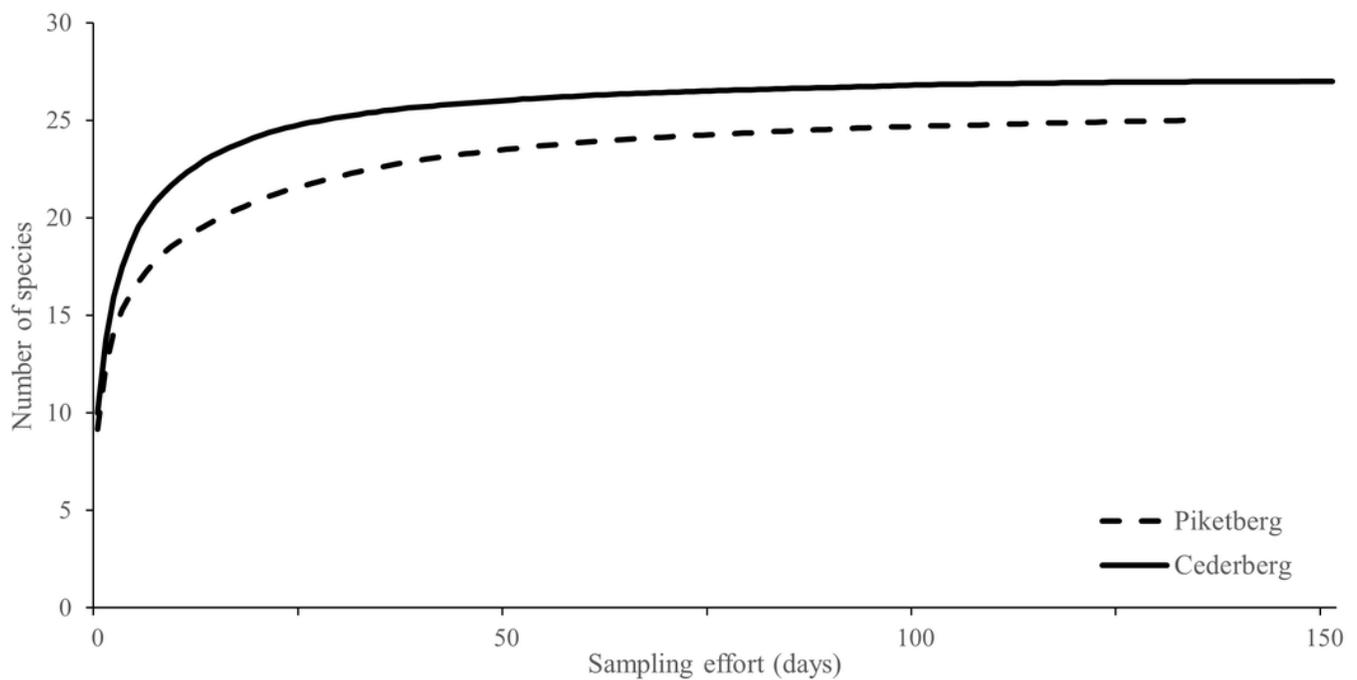

Figure 3

Distribution of medium-to-large (> 0.5 kg) terrestrial mammals (i.e. potential leopard prey species) in the Cederberg and Piketberg on the basis of body size and trophic category.

Each circle represents a species in functional space. The size of the circle is proportional to the trapping rate (RAI) for that species.

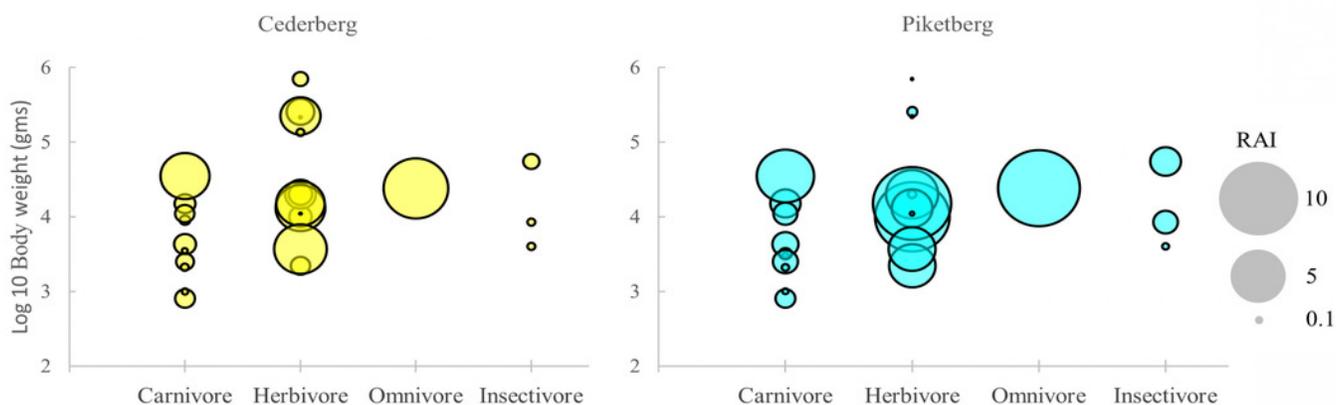

Table 1 (on next page)

QAICc weights (w) for covariates from well-supported models ($w > 0.10$ and QAICc < 2) for each species (leopard + main prey) in each community.

Either the direction of the relationship for covariates from the best fit models or the parameter probability estimate (\pm standard deviation) for top models are indicated in parentheses.

1 *strong evidence of relationship (CI estimates do not overlap 0)

2 ^a medium evidence of relationship (CI estimates overlap 0, but are not centred on 0)

3 ^b weak evidence of relationship (CI estimates overlap 0 and are centred on 0)

4

Figure 4

Detection and space-use (i.e. occupancy) probabilities for leopards with regards to variables with strong associations in the Cederberg.

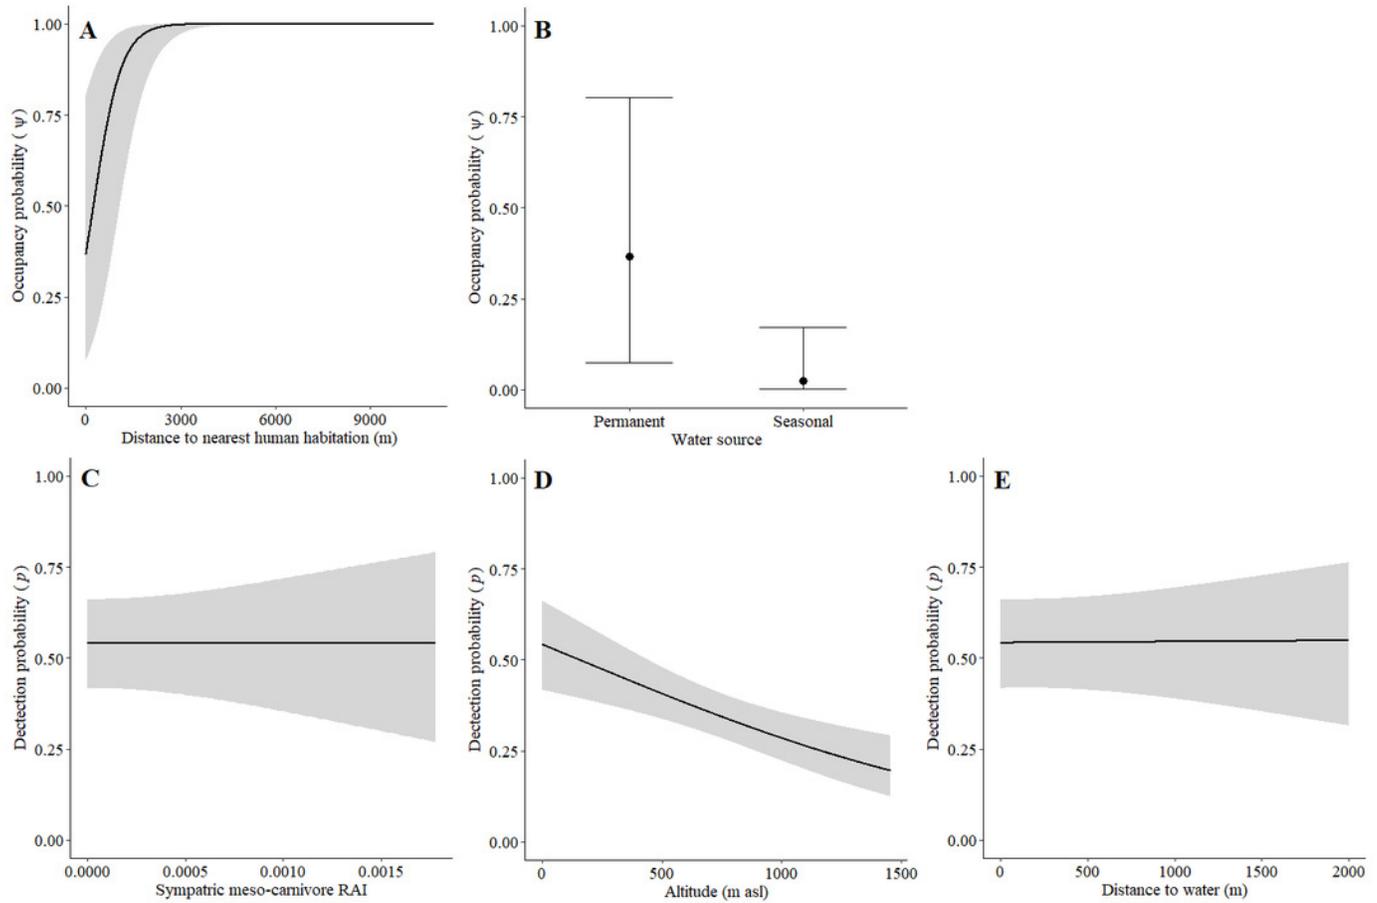

Figure 5

Detection and space-use (i.e. occupancy) probabilities for leopards with regards to variables with strong associations in Piketberg.

Values in graphs B and C are the detection probabilities for leopards across the various habitat types in areas without (B) and with (C) livestock signs present.
