Apex predators ideally require vast intact spaces that support sufficient prey abundances to sustain them. In a developing world, however, it is becoming extremely difficult to maintain large enough areas to facilitate apex predators outside of protected regions. Free-roaming leopards (*Panthera pardus*) are the last remaining apex predator in the Greater Cape Floristic Region, South Africa, and face a multitude of threats attributable to competition for space and resources with humans. Using camera-trap data, we investigated the influence of anthropogenic land modification on leopards and the availability of their natural prey species in two contrasting communities - primarily protected (Cederberg) and agriculturally transformed (Piketberg). Potential prey species composition and diversity were determined, to indicate prey availability in each region. Factors influencing spatial utilisation by leopards and their main prey species were also assessed. Estimated potential prey species richness (Cederberg = 27, Piketberg = 26) and diversity indices (Cederberg -  $H' = 2.64$ ,  $Ds = 0.90$ ; Piketberg -  $H' = 2.46$ ,  $Ds = 0.89$ ), supported by both the Jaccard's Index ( $J = 0.73$ ) and Sørensen's Coefficient ( $CC = 0.85$ ), suggested high levels of similarity across the two regions. Main leopard prey species were present in both regions, but their relative abundances differed. Grey rhebok, klipspringer, and rock hyrax were more abundant in the Cederberg, while Cape grysbok, Cape porcupine, chacma baboon, and common duiker were more abundant in Piketberg. Leopards persisted across the agriculturally transformed landscape despite these differences. Occupancy modelling revealed that the spatial dynamics of leopards differed between the two regions, except for both populations preferring areas further away from human habitation. Overall, anthropogenic factors played a greater role in affecting spatial utilisation by leopards and their main prey species in the transformed region, whereas

environmental factors had a stronger influence in the protected region. We argue that greater utilisation of alternative main prey species to those preferred in the protected region, including livestock, likely facilitates the persistence of leopards in the transformed region, and believe that this has further implications for human-wildlife conflict. Our study provides a baseline understanding of the potential direct and indirect impacts of agricultural landscape transformation on the behaviour of leopards and shows that heavily modified lands have the potential to facilitate mammalian diversity, including apex predators. We iterate that conservation measures for apex predators should be prioritised where they are present on working lands, and encourage the collaborative development of customised, cost-effective, multi-species conflict management approaches that facilitate coexistence.

## 31 Abstract

32 Apex predators ideally require vast intact spaces that support sufficient prey abundances to  
33 sustain them. In a developing world, however, it is becoming extremely difficult to maintain  
34 large enough areas to facilitate apex predators outside of protected regions. Free-roaming  
35 leopards (*Panthera pardus*) are the last remaining apex predator in the Greater Cape Floristic  
36 Region, South Africa, and face a multitude of threats attributable to competition for space and  
37 resources with humans. Using camera-trap data, we investigated the influence of anthropogenic  
38 land modification on leopards and the availability of their natural prey species in two contrasting  
39 communities - primarily protected (Cederberg) and agriculturally transformed (Piketberg).  
40 Potential prey species composition and diversity were determined, to indicate prey availability in  
41 each region. Factors influencing spatial utilisation by leopards and their main prey species were  
42 also assessed. Estimated potential prey species richness (Cederberg = 27, Piketberg = 26) and  
43 diversity indices (Cederberg -  $H' = 2.64$ ,  $D_s = 0.90$ ; Piketberg -  $H' = 2.46$ ,  $D_s = 0.89$ ), supported  
44 by both the Jaccard's Index ( $J = 0.73$ ) and Sørensen's Coefficient ( $CC = 0.85$ ), suggested high  
45 levels of similarity across the two regions. Main leopard prey species were present in both  
46 regions, but their relative abundances differed. Grey rhebok, klipspringer, and rock hyrax were  
47 more abundant in the Cederberg, while Cape grysbok, Cape porcupine, chacma baboon, and  
48 common duiker were more abundant in Piketberg. Leopards persisted across the agriculturally  
49 transformed landscape despite these differences. Occupancy modelling revealed that the spatial  
50 dynamics of leopards differed between the two regions, except for both populations preferring  
51 areas further away from human habitation. Overall, anthropogenic factors played a greater role in  
52 affecting spatial utilisation by leopards and their main prey species in the transformed region,  
53 whereas environmental factors had a stronger influence in the protected region. We argue that  
54 greater utilisation of alternative main prey species to those preferred in the protected region,  
55 including livestock, likely facilitates the persistence of leopards in the transformed region, and  
56 believe that this has further implications for human-wildlife conflict. Our study provides a  
57 baseline understanding of the potential direct and indirect impacts of agricultural landscape  
58 transformation on the behaviour of leopards and shows that heavily modified lands have the  
59 potential to facilitate mammalian diversity, including apex predators. We iterate that  
60 conservation measures for apex predators should be prioritised where they are present on  
61 working lands, and encourage the collaborative development of customised, cost-effective,  
62 multi-species conflict management approaches that facilitate coexistence.

## 63 Introduction

64 Apex predators are generally large carnivores that can act as keystone species and as such, they  
65 have been labelled as ecosystem engineers (Palazón, 2017). One way in which apex predators  
66 primarily influence ecosystems is by exhibiting prey species control: they can directly reduce  
67 prey species numbers by predating on them (reducing competitive exclusion among herbivores,  
68 thus inducing greater diversity), but also by influencing them indirectly through behavioural  
69 changes, which affect ecosystem resources (Miller et al., 2001; Frank, 2008; Estes et al., 2011;  
70 Rosenblatt et al., 2013). As such, the local extinction of apex predators within ecosystems can  
71 often bear drastic trophic cascade consequences (Terborgh et al., 2001; Hebblewhite et al., 2005;  
72 Ripple et al., 2014; 2016; Suraci et al., 2016). For example, biodiversity can be reduced (Estes et  
73 al., 2011) while the transmission of infectious diseases to humans (Keesing et al., 2010) and  
74 damages to crops can increase (Brashares et al., 2013). Apex predators also tend to be seen as  
75 charismatic species sought after by tourists and hunters (Lindsey et al., 2007; van der Meer,  
76 Badza & Ndhlovu, 2016), thereby holding an important economic value to society. Thus, the  
77 disappearance of apex predators from ecosystems is likely to stimulate knock on effects which  
78 may adversely impact human wellbeing (Díaz et al., 2006; Estes et al., 2011).

79 Traditionally, it was believed that vast, relatively intact ecosystems were required to effectively  
80 support viable apex predator populations (Sillero-Zubiri & Laurenson, 2001; Morrison et al.,  
81 2007). Their high trophic position and large body size suggests that they require extensive home  
82 ranges which sustain sufficient prey abundances (Morrison et al., 2007; Ripple et al., 2014).  
83 These spatial requirements often bring apex predators into conflict with humans (Inskip &  
84 Zimmerman, 2009; Nyhus, 2016) as they are amongst the first species to be affected by the  
85 expansion of human populations and associated cultivation of previously untouched habitats  
86 (Morrison et al., 2007; Ripple et al., 2014; Aebischer et al., 2020). A species that is influenced by  
87 anthropogenic development to an increasing extent across the globe is the leopard (*Panthera*  
88 *pardus*; Linnaeus, 1758). Leopards are the most widespread large felid, occurring across much of  
89 Africa and tropical Asia (Nowell & Jackson, 1996; Stein et al., 2020). They are very adaptable  
90 and successfully occupy a large variety of habitats across their range (Jacobson et al., 2016; Stein  
91 et al., 2020), including areas alongside large urban spaces (Kuhn, 2014; Braczkowski et al.,  
92 2018). However, their ability to inhabit areas in such close proximity to humans makes them  
93 particularly susceptible to competition with humans for space and resources, inevitably placing  
94 leopards at great risk.

95 Globally, leopards are considered as Vulnerable as their populations are declining and they face  
96 multiple threats to their survival (Stein et al., 2020). An estimated 75% of their historic range has  
97 been lost (Jacobson et al., 2016), where the average loss for large carnivore species is only  
98 around 53% (Ripple et al., 2014). Although suitable habitat in southern Africa – arguably hosting  
99 the healthiest leopard population across the species range (Stein et al., 2020) – remains widely  
100 distributed, it is highly fragmented, having experienced ~51% decline since 1750 (Jacobson et

101 al., 2016). Anthropogenic activities, in particular agricultural practices, are primarily deemed  
102 responsible for this fragmentation (Swanepoel et al., 2013). Indeed, Brink & Eva (2009) showed  
103 that agricultural land increased by 57% at the expense of natural vegetation in sub-Saharan  
104 Africa in just 25 years (1975-2000). In South Africa, ~68% of remaining habitat suitable for  
105 leopards is found in areas that are naturally susceptible to land-use transformation (Swanepoel et  
106 al., 2013). Leopards that occupy these non-protected regions are most at risk of being killed by  
107 human-induced causes such as snares, hunts, poison, or motor vehicle collisions (Balme, Slotow  
108 & Hunter, 2010; Swanepoel et al., 2013; 2015). Consequently, it is vitally important that  
109 conservation measures be established to accommodate free-roaming leopards across transformed  
110 landscapes to facilitate functional population connectivity and ensure ecosystem resilience  
111 (Balme, Slotow & Hunter, 2010; Swanepoel et al., 2013; Swanepoel, Somers & Dalerum, 2015).  
112 Most research on leopards in South Africa has taken place inside protected areas (Balme et al.,  
113 2014), which means that inadequate data is likely jeopardizing the conservation of the species on  
114 working lands.

115 Free-roaming leopards are the last remaining apex predator found in the Cape Floristic and  
116 Succulent Karoo Regions (Martins & Martins, 2006), which are both biodiversity hotspots and  
117 together forms the Greater Cape Floristic Region (Born, Linder & Desmet, 2007), in the Western  
118 Cape province of South Africa. Here, leopards generally occupy considerably larger home ranges  
119 (Patterson, 2008) and occur at much lower densities (Martins & Martins, 2006) than leopards  
120 found elsewhere in Africa (excluding the Kgalagadi; Mizutani & Jewell, 1998; Bothma &  
121 Bothma, 2012). Furthermore, these leopards are also considered to be smaller on average than  
122 most leopards (excluding Arabian leopard; Spalton & Al Hikmani, 2006) found elsewhere  
123 throughout the species range (Stuart, 1981; Martins & Martins, 2006). Almost 90% of the total  
124 area of the Western Cape is regarded as potential farmland, and the human population of the  
125 province ( $\pm 55$  people per km<sup>2</sup>; Statistics South Africa, 2021) has consistently grown at a faster  
126 rate than the national average (Partridge, Morokong & Sibulali, 2021). The Western Cape is  
127 therefore an ideal location to investigate the influence of landscape transformation, both directly  
128 and indirectly, on this apex predator.

129 The aforementioned characteristics of leopards in the Western Cape all presumably reflect  
130 adaptation to a different diet (Martins et al., 2010). With a great diversity in habitat usage,  
131 leopards opportunistically hunt a wide range of prey, depending on local availability (Hayward et  
132 al., 2006). A decline in their primary prey base can, however, impact leopard population  
133 structure (Marker & Dickman, 2005; Ray, Hunter & Ziguoris 2005; Wolf & Ripple, 2016), and  
134 may also affect human-wildlife conflict levels by altering leopard behaviour (Khorozyan et al.,  
135 2015). Human-wildlife conflict has long been prevalent in the Western Cape and remains a  
136 complex challenge to this day (Martins & Martins, 2006; Nieman, Wilkinson & Leslie, 2020).  
137 Indeed, leopards within this region are not only deemed responsible for livestock losses, but  
138 direct conflict also exists with leopard prey species, often regarded as crop raiders (G Malherbe –  
139 Off-reserve Conservation Manager at CapeNature, 2021, pers. comm.).

140 The primary (main) prey base for leopards across the Western Cape include common duiker  
141 (duiker; *Sylvicapra grimmia*, Linnaeus, 1758), Cape grysbok (grysbok; *Raphicerus melanotis*,  
142 Thunberg, 1811), klipspringer (*Oreotragus oreotragus*, Zimmermann, 1783), and grey rhebok  
143 (rhebok; *Pelea capreolus*, Forster, 1790), as well as rock hyrax (hyrax; *Procavia capensis*,  
144 Pallas, 1766), Cape porcupine (porcupine; *Hystrix africaeaustralis*, Peters, 1852), and chacma  
145 baboons (baboon; *Papio ursinus*, Kerr, 1792) (Martins et al., 2010; Drouilly, Nattrass & O’Riain,  
146 2018; Mann et al., 2019; Müller et al., 2022a). In addition to suffering retaliatory killings, these  
147 species are also targeted for the illegal harvesting of bushmeat by means of snaring in the  
148 province (Nieman et al., 2019). An akin competitive relationship between humans and leopards  
149 has previously been documented in the Congo Basin (Henschel et al., 2011), with profound  
150 negative consequences for leopards. Illegal hunting, which impacts prey species availability, is a  
151 continuous concern for wildlife worldwide (Lindsey et al., 2013; Heurich et al., 2018). Besides,  
152 snares can also be responsible for the direct capture of leopards resulting in severe injury or  
153 death (Swanepoel et al., 2015; Williams et al., 2017; Nieman, Leslie & Wilkinson, 2019; Gubbi,  
154 Kolekar & Kumara, 2021).

155 As the only terrestrial apex predator to persist in the Western Cape, free-roaming leopards are  
156 expected to be sensitive to changes in prey species populations. Yet, little is known about the  
157 extent to which this relationship may be influenced by humans in the context of commercial  
158 agriculture. Several studies investigating the drivers of leopard occurrence, density, or ranging  
159 behaviour (e.g. Jiang et al., 2015; Allen et al., 2020; Searle et al., 2020; Snider et al., 2021;  
160 Loveridge et al., 2022), and predator-prey overlap (e.g. Dias, de Campos & Rodrigues, 2018;  
161 Havmøller et al., 2020; Palei et al., 2021; Sehgal et al., 2022; Zaman et al., 2022), have been  
162 performed worldwide. However, until relatively recently, few studies have investigated African  
163 leopard (*P. p. pardus*) ecology in human-disturbed landscapes (see Marker & Dickman, 2005;  
164 Williams et al., 2017; Strampelli et al., 2018) – particularly in commercial agricultural regions.  
165 Furthermore, limited comparisons of predator populations between analogous protected and non-  
166 protected regions have been made (e.g. Swanepoel, Somers & Dalerum, 2015; Drouilly, Nattress  
167 & O’Riain, 2018; Curveira-Santos et al., 2020; Faure et al., 2021). Considering that half of all  
168 habitable land worldwide is used for agriculture (Ellis et al., 2010; Ritchie & Roser, 2013) –  
169 regarded as the biggest driver of terrestrial habitat loss (IPBES, 2019) – our understanding of  
170 factors which could best enable (or inhibit) the persistence of apex predators in agriculturally  
171 transformed environments, including variables influencing the availability of their natural prey  
172 species, is vital to aid management decision making and account for in cost-benefit models that  
173 aim to minimise conflict. Inferences about spatial variation in species composition and diversity  
174 (richness and evenness; Colwell, 2009) are also important, both to ecological hypotheses about  
175 structure and function of communities and to community-level conservation management  
176 (Nichols et al., 1998).

177 This study investigated potential prey species diversity, community structure, and factors  
178 affecting the spatial behaviour of leopards and their main prey species, in both an agriculturally

179 transformed and a largely protected landscape. First, we aimed to determine whether any real  
180 differences exist with reference to potential prey species found in each community and whether  
181 any such difference is evidently reflected in the respective leopard subpopulations. Second, we  
182 aimed to evaluate and compare drivers of habitat utilisation by leopards and their main prey in  
183 each region. We anticipated a greater diversity of potential leopard prey species to exist in the  
184 protected community, as well as differences in community structure. Relative leopard and prey  
185 abundances were predicted to be lower in the transformed agricultural region, and anthropogenic  
186 factors were expected to negatively influence space-use, by leopards as well as their main prey  
187 species, across the greater landscape.

## 188 **Materials & Methods**

### 189 **Ethical statement**

190 Relevant permissions to conduct our research were granted by the Social, Behavioural and  
191 Education Research Ethics Committee at Stellenbosch University (Project ID #15315),  
192 CapeNature (Permit #CN44-59-12321), and in writing by all landowners involved. Data  
193 collection was performed using camera-traps, which is a non-invasive research method. All data,  
194 including any images captured of human subjects, were treated as strictly confidential.

### 195 **Study area**

196 The Piketberg region (hereafter Piketberg) encompasses a transformed landscape that is  
197 primarily characterised by mixed agricultural practices. Our study area is located approximately  
198 130 to 160 km north of Cape Town, South Africa, and situated southwest of the Cederberg  
199 region (Figure 1). The survey area was approximately 1500 km<sup>2</sup> in size (53 - 864 metres above  
200 sea level), covering 55 privately owned mixed agricultural farms extending north from the town  
201 of Piketberg to Paleisheuwel, with Citrusdal in the east and Aurora on the western boundary  
202 (Figure 1). The area consists of natural vegetation forming a mosaic, highly fragmented by  
203 livestock (e.g. cattle (*Bos taurus*, Linnaeus, 1758), horses (*Equus ferus caballus*, Linnaeus,  
204 1758), sheep (*Ovis aries*, Linnaeus, 1758), goats (*Capra hircus*, Linnaeus, 1758), pigs (*Sus  
205 domesticus*, Erxleben, 1777)), fruit, and other crop farmlands in and around mountainous terrain  
206 (Linder, 1976; Mucina & Rutherford, 2006).

207 The Cederberg region (hereafter Cederberg), known for its rugged remoteness, is a largely  
208 protected area first proclaimed in 1973 and located 200 to 250 km northeast of Cape Town  
209 (Figure 1). This survey area was approximately 1700 km<sup>2</sup> in size (254 - 1455 metres above sea  
210 level) and included the Matjiesrivier Nature Reserve and the Cederberg Wilderness Area. Both  
211 areas are formally protected and managed by the provincial conservation regulation body and  
212 authority in the Western Cape, known as CapeNature (Figure 1). Privately owned areas included  
213 were Bushmans Kloof Wilderness Reserve, community owned land used for the harvesting of  
214 rooibos and limited pastoralism by subsistence farmers, and the Cederberg Conservancy,

215 consisting of pro-conservation farms that are used for ecotourism and largely kept in a natural  
216 ecological state. The two main biomes present are Fynbos and Succulent Karoo in mountainous  
217 terrain (Mucina & Rutherford, 2006).

218 [Insert Figure 1 here]

219 The Western Cape has a Mediterranean type climate characterised by hot, dry summers and cold,  
220 wet winters (Cowling & Holmes, 1992). Localised climatic conditions vary across the greater  
221 study area because of its mountainous nature, and the vastness of the landscape makes it  
222 extremely difficult to describe the climate of the study area in general terms. In essence, average  
223 annual rainfall appears slightly higher, and average summer air temperatures somewhat lower in  
224 Piketberg compared to the Cederberg (Climate-Data.org, 2020). Average winter air temperatures  
225 are more uniform across both regions, but snowfall is more abundant in the Cederberg which is  
226 generally at a higher altitude (Climate-Data.org, 2020).

## 227 **Field sampling methods**

### 228 *Camera-trap surveys*

229 Single season (dry summer – November to March) subsets of photographic data that were  
230 collected in the Cederberg (2017-2018) and Piketberg (2019-2020) were used for our study. The  
231 73 camera-trap stations (n = 146 cameras) in the Cederberg were all located within areas with  
232 protected status, whereas the 64 camera-trap stations (n = 128 cameras) in Piketberg were  
233 situated in non-protected areas nestled between and on farmlands (Figure 1). Paired motion and  
234 heat detecting Cuddeback X-Change series camera-traps were used at each camera station during  
235 both surveys. Our setup procedures followed standard protocols optimised for the detection of  
236 leopards, whereby the landscape across both study regions was divided into 50 km<sup>2</sup> blocks  
237 (Figure 1), based on the minimum estimated home range size recorded for a female leopard with  
238 cubs in the Western Cape (37 km<sup>2</sup>; Martins, 2010; also see Müller et al., 2022a; 2022b). Camera-  
239 trap stations were dispersed across mountainous habitat with mean distances of 2.78 km  
240 (Cederberg) and 3.09 km (Piketberg) between individual stations and two to three stations per  
241 block (Figure 1). Camera-trap locations were selected based on the presence of tracks and signs  
242 of leopards and their main natural prey species found in the nearby vicinity on initial site  
243 investigation. Cameras were mounted ~40 cm above the ground and perpendicular to a game  
244 trail, road, or drainage line. Camera-traps were serviced at an interval of roughly eight weeks to  
245 download images, change batteries, perform site data collection (i.e. recording covariates around  
246 each site), and for general maintenance.

### 247 *Covariate data*

248 Environmental (i.e. altitude, vegetation type, vegetation age, nearest water source type and its  
249 distance) and anthropogenic (i.e. distances to the nearest road and human habitation, evidence of

250 disturbance, livestock, and/or hunting) covariates surrounding each camera-trap station were  
251 recorded during each servicing period (see Supplementary Material, Table S1). Some categorical  
252 and binomial covariates were determined with a repeated physical site inspection of the  
253 surroundings performed by a trained and experienced individual covering a 100 m radius around  
254 each station (Table S1). Other variables were determined by a combination of physical  
255 investigation, with recordings made using a GPS unit (Garmin ETrex 10), and local knowledge  
256 (Table S1). Any further verification was performed using Google Earth (Google, n.d.) and  
257 historical fire records (Table S1). The chosen covariates reflect natural and human-induced  
258 factors that could influence predator and prey space-use or detection at each site.

## 259 **Data analyses**

### 260 *Camera-trap data*

261 Camera Base software (Tobler, 2010) was used to process images and extract meta-image  
262 information from each photograph (image name, date, and time) while correcting for any time  
263 stamp errors. Faunal species and number of individuals in each photograph was identified where  
264 possible. Primary analyses were performed using the Camera Trap Analysis Package (CTAP)  
265 software developed by the Zoological Society of London (Amin & Wacher, 2017). Only  
266 terrestrial mammals > 0.5 kg, including leopard (see Charsley (1977), Steyn & Funston (2006),  
267 and Balme & Hunter (2013) for examples of reported cannibalism), were considered as potential  
268 leopard prey species for analyses. They are the main target group for camera-traps set up in this  
269 manner and are also generally regarded as the main dietary component of leopards (Hayward et  
270 al., 2006; Tobler et al., 2008; Martins et al., 2010; Drouilly, Natrass & O’Riain, 2018; Mann et  
271 al., 2019; Müller et al., 2022a). Relative abundance indices (RAI; i.e. number of events, where  
272 an “event” is defined as any image sequence for a given species occurring after an interval of  $\geq$   
273 60 minutes from a previous sequence of that species, per 100 days of camera trapping; Karanth  
274 & Nichols, 1998; Amin et al., 2018) per camera-trap station were calculated for known main  
275 prey species of leopards in the study area, sympatric meso-carnivores - caracal (*Caracal caracal*,  
276 Schreber, 1776) and black-backed jackal (*Canis mesomelas*, Schreber, 1775) - and leopards, and  
277 used as biotic covariates during occupancy modelling (Table S1). Despite being influenced by  
278 sampling design or species’ behaviour (Sollmann et al., 2013), RAI is still considered a suitable  
279 tool for assessing species occurrence (Hedwig et al., 2018; Palmer et al., 2018).

### 280 *Community structure*

281 Biological communities can differ in species composition, total number of species (richness), and  
282 the relative abundance of species (evenness) (Colwell, 2009). Species sample-based rarefaction  
283 curves were constructed and the terrestrial medium-to-large (> 0.5 kg) mammal species richness  
284 ( $S$ ), representing potential leopard prey species, was estimated for each surveyed community  
285 using a non-parametric incidence-based estimator Jackknife with order one (Bunge &  
286 Fitzpatrick, 1993). Livestock and other domestic species were excluded from analyses. We

287 calculated Simpson's ( $D_s$ ) and Shannon-Wiener ( $H'$ ) diversity indices for each community using  
 288 global RAI values in the package 'vegan' in R statistical software (see Table S2; Oksanen et al.,  
 289 2019). Simpson's diversity index is most sensitive to changes in more common highly abundant  
 290 species, while the Shannon-Wiener diversity index is most sensitive to changes in rare less  
 291 abundant species (Magurran, 2004). Community structure plots representing the RAI as a factor  
 292 of trophic level and mean adult body weight of potential prey species were also constructed.  
 293 Jaccard's Index ( $J$ ) and the Sørensen's Coefficient ( $CC$ ) were calculated as measures of  
 294 similarity, directly comparing Picketberg and the Cederberg, using the following formulae:

$$295 \quad J = \frac{A}{[A + B + C]} \quad CC = \frac{2A}{[2A + B + C]}$$

296  $A$  = Number of species shared by two communities,  
 297  $B$  and  $C$  = Number of species unique to each of the two communities, respectively.

298 The latter places more emphasis on the shared species present rather than the unshared and  
 299 retains sensitivity in more heterogeneous data sets. Sørensen's ecological distance ( $D_{CC} = 1 - CC$ )  
 300 is therefore useful as many species may potentially be present in a community, but not present in  
 301 a sample from that community (Magurran, 2004).

### 302 *Occupancy modelling*

303 Naïve occupancy, defined as the proportion of sites that recorded at least one photograph of the  
 304 target species, was calculated for leopards of each community:

$$305 \quad \psi_{naïve} = \frac{\# \text{ of sites detected}}{\# \text{ of sites sampled}}$$

306 To accurately model occupancy, unique detection histories consisting of 1s (detection) and 0s  
 307 (non-detection) were created for leopards and their main prey species (i.e. baboon, duiker,  
 308 grysbok, hyrax, klipspringer, porcupine, and rhebok) in the Cederberg and Picketberg. The unique  
 309 detection histories reflected the presence or absence of each species at each camera-trap site on  
 310 each occasion (maximum value '1' per 24 hr period) for each region. Original unique detection  
 311 history datasets (Cederberg N occasions = 151; Picketberg N occasions = 132) for each species  
 312 were collapsed into data subsets by merging the occasions into intervals of between five to 11-  
 313 day sampling occasions. This was deemed appropriate as it reduced each species dataset into  
 314 manageable sizes for computational purposes and accurately represented the rarity of the study  
 315 species (Sollmann, 2018).

316 All continuous covariate values were scaled into standardized z-scores (Bruggeman et al., 2016).  
 317 Multi-collinearity was tested for by calculating variance inflation factors (VIF), whereby  
 318 covariates with VIF scores greater than three were removed (Wang et al., 2018). A global

319 occupancy model that included all ecologically relevant covariates (see Table S1) was applied to  
320 the subsets of data for each species and tested for goodness-of-fit (MacKenzie & Bailey, 2004).  
321 Subset data for each species that had the closest over dispersion statistic ( $\hat{c}$ ) to 1 (extreme values  
322 over ( $> 3$ ) or under 1 ( $< 0.90$ ) indicate poor fit of the data) and an insignificant chi-square  
323 probability ( $\chi^2 p > 0.05$ ) was chosen for further occupancy analyses (see Table S3; Mazerolle,  
324 2017). This showed maximum model fit without over compressing statistical power of the data  
325 (Burnham & Anderson, 2004; MacKenzie & Bailey, 2004). Our study violates the assumption of  
326 spatial autocorrelation and independence of camera-trap sites, which means that our results will  
327 be interpreted within the context of area used (i.e. space-use) rather than area occupied  
328 (MacKenzie & Nichols, 2004).

329 For each species, only combinations of covariates that could affect the two modelling parameters  
330 (space-use probability,  $\psi$ , and detection probability,  $p$ ) and that presented ecologically  
331 reasonable hypotheses were included (McDonald et al., 2016). With such a large number of  
332 covariates, the set of candidate models that we might have examined was extremely vast  
333 (Schuette et al., 2013). Therefore, we used a stepwise procedure following Dugger, Anthony &  
334 Andrews (2011), whereby the first step was to model  $p$  by investigating additive combinations of  
335 covariates while treating  $\psi$  as constant (i.e. intercept only). For model selection, the over  
336 dispersion statistic ( $\hat{c}$ ) estimated from the global model for each species was used to compute  
337 quasi-likelihood information criteria (QAICc: for small sample sizes) by scaling the log-  
338 likelihood of each model, for each species, by its corresponding  $\hat{c}$  value (Mazerolle, 2017).  
339 Therefore, QAICc model-selections were used to retain the best  $p$  model for each species to use  
340 in subsequent analyses of factors affecting  $\psi$ . The second step was to model  $\psi$  by investigating  
341 additive combinations of covariates. The package ‘unmarked’ (Fiske & Chandler, 2011) was  
342 used to fit models and to estimate covariate coefficients for each parameter in R (version 4.1.2, R  
343 Development Core Team, 2017). The R package ‘AICcmodavg’ was used for all model selection  
344 computations (Mazerolle, 2017).

345 The lowest  $\Delta$ QAICc scores ( $< 2$ ) and highest QAICc weights ( $w > 0.10$ ) were used to select the  
346 best-approximating models for each species in each community (see Table S4 & S6; Burnham &  
347 Anderson, 2004). We drew conclusions about strength of evidence of relationships between  
348 covariates and parameters based on 95% confidence intervals (CIs) of coefficients and the  
349 direction of relationships (see Table S5 & S7; Arnold, 2010).

## 350 Results

351 A total of 10114 operational camera-trap days (mean 140 days/station) were accumulated in the  
352 Cederberg, with only one station failure (refer to Figure 1). In Piketberg, 6258 operational  
353 camera-trap days (mean 103 days/station) were accumulated, and three camera-trap stations  
354 failed (Figure 1). The outcomes of our study are unlikely to be affected by this difference as  
355 sampling effort across both regions was sufficient (see Figure 2) and indices based on relative

356 abundance values were employed, providing equal weight to both communities, therefore  
357 allowing comparison.

### 358 *Species richness*

359 Piketberg had an estimated potential prey species richness ( $S = 26$ ) similar to that of the  
360 Cederberg ( $S = 27$ ). The rarefied species accumulation curves do however show more species  
361 detected per unit effort in the Cederberg compared to Piketberg (Figure 2). Both the Shannon-  
362 Wiener ( $H'$ ) and Simpson diversity ( $D_s$ ) indices were only marginally higher in the Cederberg  
363 ( $H' = 2.64$ ,  $D_s = 0.90$ ) compared to Piketberg ( $H' = 2.46$ ,  $D_s = 0.89$ ). Thirty potential natural  
364 prey species were photographed across the two regions (Cederberg: 27; Piketberg: 25), with five  
365 species unique to the Cederberg and three to Piketberg (Table S2).

366 [Insert Figure 2 here]

### 367 *Community structure*

368 Differences in community structure were largely complementary, providing a similar pattern  
369 across trophic guilds for both the Cederberg and Piketberg (Figure 3). The same number of  
370 carnivore species were detected in both regions ( $n = 10$ ), but no Cape fox (*Vulpes chama*, Smith,  
371 1833) or large grey mongoose (*Herpestes ichneumon*, Linnaeus, 1758) were recorded in the  
372 Cederberg, whereas black-backed jackal and water mongoose (*Atilax paludinosus*, Cuvier, 1826)  
373 were not detected in Piketberg. Herbivores were the most frequently encountered guild across  
374 both regions; more herbivorous species were encountered in the Cederberg ( $n = 13$ ) than in  
375 Piketberg ( $n = 11$ ). Main leopard prey species (i.e. baboon, duiker, grysbok, hyrax, klipspringer,  
376 porcupine, and rhebok) were all accounted for in both communities (Table S2).

377 Across all guilds, global trap rates (RAIs) for species detected were generally higher in Piketberg  
378 (Figure 3 & Table S2). Noteworthy exceptions included hyrax (Cederberg: 4.05; Piketberg:  
379 3.16), klipspringer (Cederberg: 3.56; Piketberg: 2.41), and rhebok (Cederberg: 0.84; Piketberg:  
380 0.14). A marked difference was the higher RAIs of all carnivores  $> 4$  kg – including leopard  
381 (Cederberg: 3.52; Piketberg: 4.65) – as well as most medium ( $> 0.5$  kg and  $< 100$  kg) herbivores,  
382 in the Piketberg region (Figure 3 & Table S2). Baboons were the most frequently detected  
383 species across both communities (Cederberg: 608 events; Piketberg: 592 events), followed by  
384 hyrax in the Cederberg (410 events) and porcupine in Piketberg (540 events). No single species  
385 dominated (i.e.  $> 50\%$  of total trap rates) in any of the two communities.

386 [Insert Figure 3 here]

387 High levels of similarity between the two study regions were shown by both the Jaccard's Index  
388 ( $J = 0.73$ ) and Sørensen's Coefficient ( $CC = 0.85$ ). The Jaccard's Index suggested that 73%  
389 similarity exists between the contrasting communities. Similarly, the Sørensen Coefficient

390 suggested that the ecological distance that separate the two regions is merely 15%, supporting  
391 close relatedness of ecological make-up in each community.

### 392 *Spatial behaviour*

393 Camera-trap stations were excluded from occupancy (i.e. space-use) analyses when cameras  
394 were operational for < 80% of occasions (see Figure 1). Baboon and rhebok were excluded due  
395 to insufficient model fit (Table S3). Only strong relationships with space-use and detection  
396 probabilities are discussed (see Table 1). In essence, factors that strongly influenced the spatial  
397 dynamics of leopards and their main prey species in the Cederberg were primarily environmental  
398 (56%), whereas anthropogenic (32%) and biotic variables (12%) played a less significant role  
399 (Table 1). In contrast, anthropogenic variables (41%) dominated in Piketberg relative to notable  
400 influences by biotic (36%) and environmental (23%) factors (Table 1).

401 [Insert Table 1 here]

### 402 *Leopard*

403 Leopards occurred across the landscape in both communities and were detected at 55 camera-  
404 trap stations in Piketberg and 60 stations in the Cederberg, providing naïve occupancy estimates  
405 of 0.852 (Piketberg) and 0.833 (Cederberg) respectively. The spatial dynamics of leopards  
406 differed between the Cederberg and Piketberg, except for both leopard populations preferring to  
407 utilise areas further away from human habitations (Table 1; Figures 4A & 5A). In the Cederberg,  
408 leopards also preferred areas in closer proximity to permanent rather than seasonal water sources  
409 (Table 1; Figure 4B) but were more likely to be detected further away from water (Table 1;  
410 Figure 4E). Furthermore, leopards of the Cederberg were generally less likely to be detected in  
411 areas where sympatric meso-carnivores were more abundant (Table 1; Figure 4C) and at higher  
412 altitudes (Table 1; Figure 4D). In Piketberg, leopards were less likely to be detected if present at  
413 sites characterised by Sandveld vegetation and in areas utilised by livestock (Table 1; Figures  
414 5B, 5C, 5D & 5E).

415 [Insert Figure 4 here]

416 [Insert Figure 5 here]

### 417 *Main prey species*

418 The space-use of grysbok, hyrax, klipspringer, and porcupine were influenced by slightly  
419 different factors in the primarily protected Cederberg and agriculturally transformed Piketberg  
420 (Table 1). None of the variables we considered were found to strongly influence duiker space-  
421 use (Table 1). In the Cederberg, grysbok preferred areas farther away from roads, porcupine  
422 preferred areas of older vegetation, while hyrax preferred areas characterised by Karoo  
423 vegetation and seemingly avoided areas where caracal and black-backed jackal were abundant.  
424 In Piketberg, both hyrax and klipspringer avoided areas where caracal were more prevalent

425 (black-backed jackal are absent), but porcupine appeared to prefer areas that had greater caracal  
426 presence.

427 The detection probabilities (i.e. detectability) of these prey species were affected by various  
428 combinations of factors across the greater landscape (Table 1). In both study regions, duiker  
429 were more likely to be detected (if present) nearer to human habitations and at lower altitudes,  
430 grysbok were more likely to be detected in closer proximity to roads, and klipspringer were more  
431 likely to be detected where meso-carnivores were less abundant. Considering only the  
432 Cederberg, detectability of duiker was greater farther away from water sources and lower in  
433 areas consisting of older vegetation. Detection of grysbok was more likely in areas that showed  
434 signs of anthropogenic disturbance, but less likely at sites characterised by Karoo vegetation.  
435 Similarly, the probability of detecting porcupine was also lower in areas of Karoo as well as  
436 older vegetation, and greater in areas closer to roads. By contrast, the detectability of both hyrax  
437 and klipspringer in the Cederberg was greater within the Karoo biome. Furthermore, hyrax were  
438 more likely to be detected at lower altitudes and farther away from roads, whereas the probability  
439 of detecting klipspringer was less at anthropogenically disturbed sites. In Piketberg, detection  
440 probability of klipspringer was greater closer to water, particularly permanent water sources.  
441 Both klipspringer and duiker were also more likely to be detected in the vicinity of roads in this  
442 region. Additionally, duiker, as well as hyrax, were less likely to be detected where leopard RAI  
443 was greater. Instead, hyrax detectability increased as caracal RAI increased. On the other hand,  
444 grysbok in Piketberg were more likely to be detected in areas where leopards were seemingly  
445 more abundant. Their detection probability was also greater at higher altitudes and in areas closer  
446 to human habitations. Detectability of porcupine, however, was lower nearby human habitations.  
447 Yet, porcupine were more likely to be detected in areas that showed other signs of anthropogenic  
448 disturbance across the agriculturally transformed region.

## 449 **Discussion**

### 450 **Prevalence of leopards**

451 Contrary to expectations, our results, in terms of both relative abundance indices (RAI:  
452 Cederberg: 3.52; Piketberg: 4.65) and naïve occupancy ( $\psi_{naïve}$ : Cederberg: 0.833; Piketberg:  
453 0.852), suggest that leopards are at least as relatively widespread across the agriculturally  
454 transformed Piketberg landscape, and potentially even more abundant, than they are in the  
455 primarily protected Cederberg region. We similarly observed greater relative abundances of all  
456 carnivorous species > 4 kg shared between the two communities (Figure 3 & Table S2).  
457 Assuming comparable average activity levels, leopards of Piketberg may therefore occupy  
458 smaller or more overlapping home ranges than leopards found in the Cederberg (refer to Müller  
459 et al., 2022b). Recently, Snider et al. (2021) showed that it is indeed common for free-roaming  
460 leopard home-range size to be smaller (inferring greater density) within areas of greater human  
461 population density. Alternatively, should activity levels greatly differ between the two

462 subpopulations, leopards could also occupy larger home ranges in Piketberg (Neilson et al.,  
463 2018; Rogan et al., 2019). Since the relationship between occupancy (or space-use), abundance,  
464 and density is influenced by the number of individuals, home range size, and the degree of  
465 spatial overlap between individuals, neither relative abundance nor the space-use parameter can  
466 be used to ascertain differences in density with absolute certainty (Rogan et al., 2019).  
467 Nonetheless, greater predator abundances can only be sustained by a greater relative carrying  
468 capacity (i.e. prey availability). Higher RAIs were also noted in Piketberg compared to the  
469 Cederberg for most medium sized ( $> 0.5$  kg and  $< 100$  kg) herbivores (Table S2), which are  
470 regarded as the primary prey component for leopards (Hayward et al., 2006). Therefore, prey  
471 populations in Piketberg appeared sufficient to facilitate and sustain relatively greater, potentially  
472 denser, and at least as equally successful predator populations to those found in the Cederberg.  
473 Notable differences that we observed in the RAIs of main leopard prey species between the two  
474 study regions, however, suggests that leopard diet composition is likely to differ (based on  
475 availability; Hayward et al., 2006) in the agriculturally transformed landscape.

476 The main prey species considered in this study are known to comprise approximately 85% of the  
477 biomass consumed by leopards in the Cederberg (Müller et al., 2022a), while in other areas of  
478 the Western Cape they comprise as much as 91% (Boland) and as little as 57% (Little Karoo) of  
479 leopard diets (Mann et al., 2019). Grey rhebok, klipspringer, and rock hyrax were more abundant  
480 in the Cederberg, while Cape grysbok, Cape porcupine, chacma baboon, and common duiker  
481 were more abundant in Piketberg (Table S2). Leopards in the Cederberg appear heavily reliant  
482 on hyrax and klipspringer in particular, which together constitutes ~61% of biomass consumed  
483 (Martins et al., 2010; Müller et al., 2022a). Despite lower relative abundances recorded for both  
484 these prey species in Piketberg (Table S2), where leopard diet composition remains unknown,  
485 the leopard population here appeared unaffected. Our findings thus suggest the persistence of  
486 leopards in this agriculturally transformed region, highlighting the adaptability, but also the  
487 potential vulnerability, of these large apex predators. Leopards in the Soutpansberg and  
488 Waterberg mountains (Limpopo Province) of South Africa have also been shown to thrive  
489 outside of protected regions (Chase Grey, Kent & Hill, 2013; Swanepoel, Somers & Dalerum,  
490 2015), as is the case across a densely populated agricultural landscape in India (Athreya et al.,  
491 2013). Therefore, together with our results, it is evident that a landscape level approach is needed  
492 to ensure that the appropriate conservation policies, laws, and practices are implemented  
493 (Athreya et al., 2013) to ensure the safeguard of leopards throughout the entirety of their  
494 distributional range and not just in protected areas. The importance of protected regions is,  
495 however, not to be undermined (see Mohammadi et al., 2021).

#### 496 **Natural prey species availability**

497 Our camera surveys appear to have recorded almost all natural potential prey species (mammals  
498  $> 0.5$  kg) present, as the number of species captured was very close or equal to the total number  
499 estimated in both communities. Community composition of potential prey species did differ, but

500 niche composition remained relatively intact across both regions, and each supports complete  
501 communities of carnivores and herbivores (Figure 3). Generally, carnivores do not play a  
502 significant role in leopard diet in the Western Cape (Martins et al., 2010; Drouilly, Nattrass &  
503 O’Riain, 2018; Mann et al., 2019; Müller et al., 2022a), although elsewhere small carnivores are  
504 commonly killed (Palomares & Caro, 1999; Hayward et al., 2006). Herbivores unique to each  
505 community in our study (gemsbok in Cederberg; kudu in Piketberg: Table S2) were both large  
506 antelope species (> 100 kg) which also generally do not constitute a major component of leopard  
507 diet in the Western Cape, except in the Little Karoo (Martins et al., 2010; Drouilly, Nattrass &  
508 O’Riain, 2018; Mann et al., 2019; Müller et al., 2022a). Here, their marked presence in leopard  
509 diet has been attributed to land-use change, characterised by an increase in game farming in  
510 recent years (Mann et al., 2019). It is however improbable that the very low abundances (Table  
511 S2) and limited distributions (detected at only one station each) we recorded for these large  
512 antelopes in Piketberg would effectively support its leopard population. Instead, predation on  
513 these introduced individuals would be likely to ultimately result in farmer-predator conflict and  
514 increase the level of risk that leopards are exposed to (Constant, Bell & Hill, 2015). Hence, the  
515 minor differences observed in potential prey species composition and richness between the  
516 Cederberg and Piketberg are unlikely to substantially influence leopard diet, and consequently  
517 population persistence, in the latter.

#### 518 **Variance of main prey species**

519 Leopards in Piketberg are more likely to rely on alternative main prey species to those primarily  
520 utilised in the Cederberg, based on observed differences in their perceived availability in each  
521 community (Table S2). By considering the factors that strongly affects habitat use of main prey  
522 species (Table 1), we broadly infer some potential underlying drivers of these differences. Due to  
523 the inability to model probabilities of space-use and detection for baboon and rhebok, we did not  
524 speculate on probable causes for differences in their availability (i.e. RAIs). It should also be  
525 noted that our results for hyrax may be unintentionally skewed because of their restricted habitat  
526 (being confined to rocky outcrops; Skinner & Chimimba, 2005) not being accounted for in our  
527 camera set-up procedures; we advise caution in interpretation thereof.

528 Unsurprisingly, the relative impact on prey species by anthropogenic factors accompanying  
529 agricultural practices (e.g. roads, disturbances, habitations) was greater in Piketberg, but not all  
530 species were negatively influenced (Table 1). In essence, anthropogenic drivers were generally  
531 more likely to strongly influence preferred main prey species of the Cederberg (hyrax and  
532 klipspringer) in a negative manner, but alternative main prey species (duiker, grysbok, and  
533 porcupine) appeared less sensitive, some even showing a potential preference for disturbed sites.  
534 These alternative prey species are therefore likely to play a relatively larger role in leopard diet  
535 and facilitation of the leopard population in Piketberg. The greater perceived abundance of  
536 duiker, grysbok, and porcupine in the agriculturally transformed region may further be facilitated  
537 by a preference for readily available crop food resources as these species are known to frequent

538 the fringes of agricultural land (Birss, Relton & Selier, 2016; Bragg & Child, 2016; Palmer et al.,  
539 2016). Elsewhere in the Western Cape, however, it has recently been shown that duiker and  
540 grysbok both remain dependent on natural vegetation even within severely transformed  
541 landscapes (Jansen van Vuuren, Fritz & Venter, 2022). We therefore believe that suitable natural  
542 habitat within the mosaic Piketberg landscape plays a pivotal role for sustaining these species.  
543 Thus, we promote the maintenance of natural vegetative corridors within and between  
544 transformed lands. Remaining natural vegetation in Piketberg can generally be considered denser  
545 than across the Cederberg, thereby having the potential to further cater for grysbok and  
546 porcupine which are both known, and shown by this study, to require sufficient vegetative cover  
547 (Bragg & Child, 2016; Palmer et al., 2016). In contrast, the sparser Karoo vegetation of the  
548 Cederberg appear to be favoured by hyrax and klipspringer (Birss et al., 2016; Visser &  
549 Wimberger, 2016). These two species also appeared to be the most affected by top-down  
550 influences of predators as both species in both communities seemingly avoided areas heavily  
551 utilised by caracal and black-backed jackal, resulting in an indirect spatial overlap with leopards  
552 in the Cederberg. Interestingly, leopard RAI strongly influenced main prey species in Piketberg  
553 only, exhibiting direct overlap with grysbok. Yet again, hyrax and duiker in Piketberg appeared  
554 to be influenced in an opposing manner. In the Cederberg and elsewhere, hyrax are particularly  
555 favoured as prey by both leopard and caracal (Hayward et al., 2006; Müller et al., 2022a). It is  
556 thus also plausible that hyrax may in fact experience significant predation pressure and therefore  
557 their numbers and activity may appear relatively limited in areas shared more frequently with  
558 leopards in Piketberg (Wittmer, Sinclair & Mclellan, 2005).

#### 559 **Livestock – An alternative food source?**

560 Aside from alternative main prey species playing an important role, unnatural prey (i.e. livestock  
561 or domestic species) might also supplement leopard diet in Piketberg. In a national park in  
562 Pakistan and a human-dominated landscape in India for example, leopards have previously been  
563 shown to be almost completely dependent on livestock and other domestic species as prey  
564 (Shehzad et al., 2015; Athreya et al., 2016). Our decision to exclude livestock and other domestic  
565 species from abundance analyses was because the vastly greater use of livestock proof fences in  
566 the Piketberg region prevented accurate and comparable detection of livestock at camera-trap  
567 stations. While fences do not prevent the movement of leopards across a landscape, the energetic  
568 costs to leopards that accompany their presence may be a driving factor for the killing of more  
569 livestock (Wilmers et al., 2017). Müller et al. (2022a) showed that 7% biomass of leopard diet in  
570 the Cederberg was comprised of livestock. Subsequently, we believe a greater proportion can be  
571 expected in Piketberg, which is a conclusion that seems to be supported by higher levels of  
572 livestock predation events reported in recent years (C Luyt - Community Outreach Officer at the  
573 Cape Leopard Trust, 2020, pers. comm.). Although not found to be strongly correlated in either  
574 region, the inverse relationship between space-use by leopards and presence of livestock in the  
575 two contrasting study regions (Table 1), is noteworthy. Leopards in the Cederberg tended to  
576 avoid areas with signs of livestock, while in Piketberg they appear to have shown a greater

577 preference for areas with livestock. This observation could suggest a plausible tendency for  
578 greater reliance on livestock by leopards in Piketberg. In the Cederberg, livestock roam more  
579 freely but tend to be guarded by herders, whereas in Piketberg they are generally fenced and  
580 unguarded. Unguarded, fenced livestock that are not completely predator-proofed may result in  
581 leopards being attracted to livestock as prey, especially when preferred natural prey abundances  
582 are low (Odden, Nilsen & Linnell, 2013; Khorozyan et al., 2015). This may subsequently result  
583 in an increase in illegal retaliatory killings, making the leopard population in Piketberg  
584 particularly vulnerable (Inskip & Zimmerman, 2009; Soofi et al., 2022).

585 Importantly, if livestock serve as regular prey, this has the potential to result in less pressure and  
586 reduced ecological regulation of natural prey species, regarded as agricultural pests (Norton,  
587 1980; Kingdon, 1982; Estes, 1991; Skinner & Chimimba, 2005). Examples of this has been  
588 described with other apex predators like snow leopards (*Panthera uncia*, Schreber, 1775) in  
589 Nepal and dingoes (*Canis lupis dingo*, Meyer, 1793) in Australia (Johnson & Wallach, 2016;  
590 Shrestha, Aihartza & Kindlmann, 2021). Conversely, leopards that are less reliant on livestock as  
591 prey, provided sufficient preventative measures for livestock predation are employed, can  
592 partially limit population explosions of their natural prey species (O'Bryan et al., 2018).  
593 Effective preventative mitigation of conflict with crop pests (i.e. prey species) may also cater for  
594 leopards, offering sufficient natural prey availability in the future which may minimise livestock  
595 losses (Odden, Nilsen & Linnell, 2013; Khorozyan et al., 2015). Hence, leopards and their prey  
596 species can be regarded as assets on a landscape scale, and pro-active (preventative and non-  
597 lethal) measures employed together by livestock and crop farmers in an agricultural community  
598 can thus benefit them both instead of either one indirectly inducing conflict onto the other. We  
599 therefore agree with Du Toit, Cross & Valeix (2017) that a shift in attitude towards asset  
600 management, rather than problem control by means of retaliatory killings, will be advantageous  
601 as the removal of conflict-prone species is likely to be counter-productive for the community  
602 (Conradie & Piesse, 2013; Lennox et al., 2018).

### 603 **Impacts on leopard behaviour**

604 Besides potential for retaliatory killings of leopards, a further direct negative impact due to  
605 humans was reflected by the avoidance of human habitations by leopards in both study regions  
606 (Table 1; Figures 4A & 5A). This reiterates that anthropogenic development is responsible for  
607 habitat loss (Swanepoel et al., 2013; Jacobson et al., 2016). Environmental factors that directly  
608 dictated the spatial dynamics of leopards differed between the two regions (Table 1). Greater  
609 detectability further away from water in the Cederberg, where sources are presumably more  
610 limited, can be explained since leopards are largely independent of water (Bothma, 2005).  
611 Leopards in this region did however show a preference for areas closer to permanent (e.g. rivers;  
612 Table S1) rather than seasonal (e.g. streams; Table S1) water sources, but this is likely to be a  
613 simple consequence of the seasonal water sources being dry and unusable at the time of our  
614 study. The lower detection probability of leopards in Sandveld vegetation and areas presumably

615 used for grazing in Piketberg indicate that fine-scale habitat utilisation by leopards is likely to be  
616 selective and affected by agricultural activities. The influence of altitude observed in the  
617 Cederberg is assumed to be a consequence of the slightly higher density recorded for leopards in  
618 the region during the summer months, which relates to individuals occupying smaller home  
619 ranges on the more accessible lower mountain slopes at this time of year (Müller et al., 2022b).  
620 Finally, the relationship we observed between leopards and meso-carnivores in the Cederberg is  
621 consistent with the conclusions of Müller et al. (2022a): caracal (meso-predator) tend to avoid  
622 leopards (apex predator) in time and space. Interestingly, the availability of natural main prey  
623 species did not directly dictate spatial utilisation by leopards, which is probably because leopards  
624 (and natural prey) occurred widely across the study area. It is important to note that the impacts  
625 we observed on the behaviour of various main prey species, both environmental and  
626 anthropogenic, do have the potential to indirectly affect leopards going forward. Therefore,  
627 continuous monitoring and evaluation of the environmental and anthropogenic factors affecting  
628 the ecology of both leopards and their natural prey is of vital importance to ensure the  
629 persistence of leopards in both protected and unprotected areas.

### 630 **Study limitations**

631 Potential criticisms of our study are that data were collected roughly two years apart, and that we  
632 investigated factors influencing behaviour only at a single spatial scale. We are aware that  
633 community structure could be influenced by weather on a seasonal or annual basis. The Western  
634 Cape experienced a relatively dry year (South African Weather Service, 2021) prior to the  
635 Cederberg survey and recorded precipitation of 212.9 mm below the annual mean (2017; Data  
636 provided by [www.meteoblue.com](http://www.meteoblue.com)) in the region. A precipitation anomaly of 139.9 mm below  
637 the mean (2019; Data provided by [www.meteoblue.com](http://www.meteoblue.com)) was also noted prior to the survey in  
638 the Piketberg region. Nonetheless, Müller et al. (2022b) showed that the leopard population in  
639 the Cederberg remained relatively stable during the decade prior to, and including, our study  
640 period. Currently, the same quantitative insight does not exist for the Piketberg community,  
641 highlighting a need for long-term population monitoring. Ideally, ecological modelling should  
642 aim to incorporate different orders of scale (e.g. Pitman et al., 2017), but this is not always  
643 practical. We concur that spatial scale must, however, be accounted for in conservation decision-  
644 making.

### 645 **Conclusions**

646 Our findings exemplify how severely transformed, commercial agricultural regions have the  
647 potential to facilitate biological diversity – including apex predators – to (at least) the same  
648 standard as analogous protected landscapes (also see Linell, Swenson & Anderson, 2001).  
649 Indeed, no real differences were apparent between the potential prey species composition or  
650 richness, or the prevalence of leopards, in the agriculturally transformed Piketberg and the  
651 primarily protected Cederberg communities. Despite the preferred prey species of leopards in the

652 Cederberg being relatively less abundant in Piketberg, the leopard population here seemingly  
653 persevere. We believe that greater utilisation of alternative main prey species to those preferred  
654 in the Cederberg, likely further subsidised by livestock, facilitates persistence of the Piketberg  
655 leopard population. Consequently, this adaptation is a probable driving factor of high levels of  
656 human-wildlife conflict. Therefore, in the context of mixed-farming communities, we argue that  
657 a holistic multi land-use, multi-species (predator and prey), pro-active management approach,  
658 that encourages co-existence and aims to limit the cascade of ecosystem effects that could follow  
659 human-induced changes to the landscape, can benefit both livestock and crop farmers.  
660 Ultimately, such a collaborative and holistic approach can provide incentive to conserve apex  
661 predators and their prey and is therefore useful to ensure the conservation of apex predators on  
662 working lands worldwide. Furthermore, we also provide insights on the different combinations  
663 of factors influencing the spatial dynamics of leopards and their main prey species. In essence,  
664 this study can be used to inform conservation policies that aim to cater for free-roaming leopards  
665 in commercial agricultural landscapes, and act as a baseline for ecological monitoring of the  
666 Piketberg community, thereby guiding adaptive management going forward. We encourage  
667 further detailed investigation of the leopard population in Piketberg, including density, home-  
668 range, population structure, dietary and human-wildlife (both leopards and their prey) conflict  
669 analyses, to further inform local conservation management decision-making and maintain its  
670 leopard population into the future.

**671 Acknowledgements**

672 We are grateful to the Cape Leopard Trust who provided support and resources to enable this  
673 research. We would like to extend our thanks to all the landowners and to CapeNature for  
674 granting access to their properties and for their collaboration. We would like to extend a special  
675 thank you to Jacobus Smit for providing accommodation and contacts within the Piketberg  
676 community. We are grateful for the field assistance provided by Chavoux Luyt, Mari-Su de  
677 Villiers, Ross de Bruin, Barbara Seele, Christiaan Lochner, Ismail Wambi, Ewan Brennan,  
678 Hannes de Kock and Grant Baker, and contributions to data processing by Mari-Su de Villiers.  
679 Thank you to Kathryn Williams for providing comments on this manuscript.

## 1091 **Figure legends**

1092 **Figure 1:** Maps showing the location of the Western Cape province within South Africa (a), and  
1093 the proximity of the survey areas within the Western Cape (b). Main map shows the location of  
1094 camera-trap stations for both Cederberg and Piketberg. Failed camera-trap stations (because of  
1095 major camera malfunctioning, fire, other damage, or theft) are noted. Formally proclaimed  
1096 protected areas (CapeNature reserves) are also highlighted.

1097 **Figure 2:** Rarefied species accumulation curves for medium-to-large ( $> 0.5$  kg) terrestrial  
1098 mammals (i.e. potential leopard prey species) photographed in the primarily protected Cederberg  
1099 and agriculturally transformed Piketberg regions. Both curves approach an asymptote, indicating  
1100 sufficient sampling effort.

1101 **Figure 3:** Distribution of medium-to-large ( $> 0.5$  kg) terrestrial mammals (i.e. potential leopard  
1102 prey species) in the Cederberg and Piketberg on the basis of body size and trophic category.  
1103 Each circle represents a species in functional space. The size of the circle is proportional to the  
1104 trapping rate (RAI) for that species.

1105 **Table 1:** QAICc weights ( $w$ ) for covariates from well-supported models ( $w > 0.10$  and QAICc  $<$   
1106  $2$ ) for each species (leopard + main prey) in each community. Either the direction of the  
1107 relationship for covariates from the best fit models or the parameter probability estimate ( $\pm$   
1108 standard deviation) for top models are indicated in parentheses.

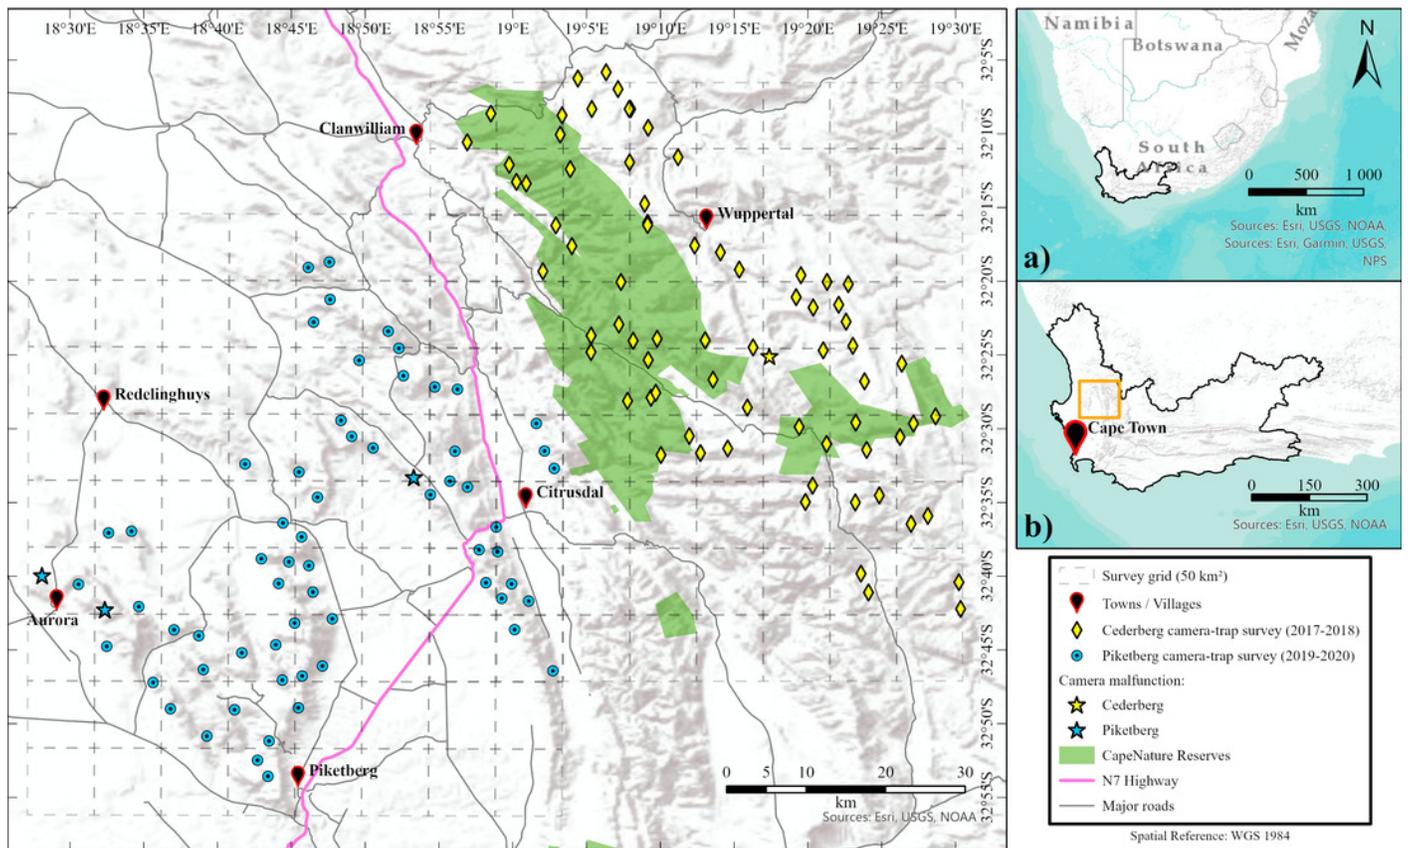

1109 **Figure 4:** Detection and space-use (i.e. occupancy) probabilities for leopards with regards to  
1110 variables with strong associations in the Cederberg.

1111 **Figure 5:** Detection and space-use (i.e. occupancy) probabilities for leopards with regards to  
1112 variables with strong associations in Piketberg.

# Figure 1

Location of survey regions.

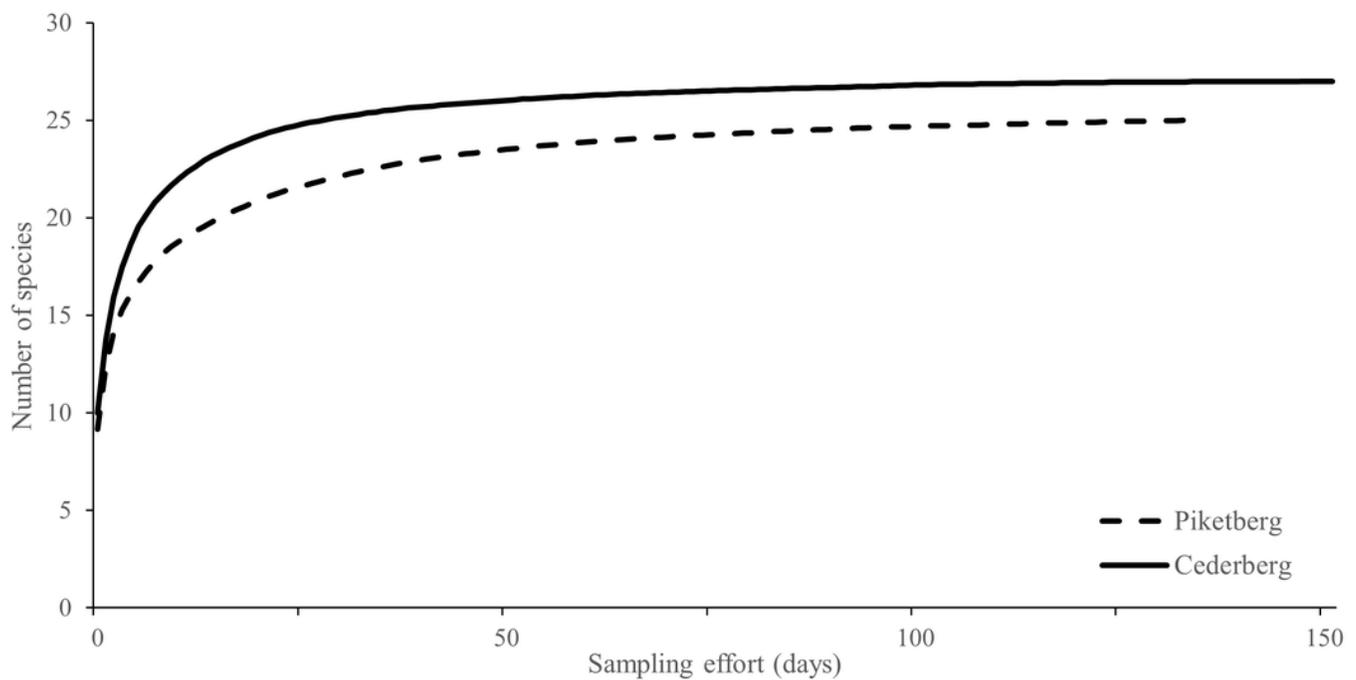

Maps showing the location of the Western Cape province within South Africa (a), and the proximity of the survey areas within the Western Cape (b). Main map shows the location of camera-trap stations for both Cederberg and Piketberg. Failed camera-trap stations (because of major camera malfunctioning, fire, other damage, or theft) are noted. Formally proclaimed protected areas (i.e. CapeNature reserves) are also highlighted.

## Figure 2

Figure 2: Rarefied species accumulation curves for medium-to-large (> 0.5 kg) terrestrial mammals (i.e. potential leopard prey species) photographed in the Cederberg and Piketberg regions.

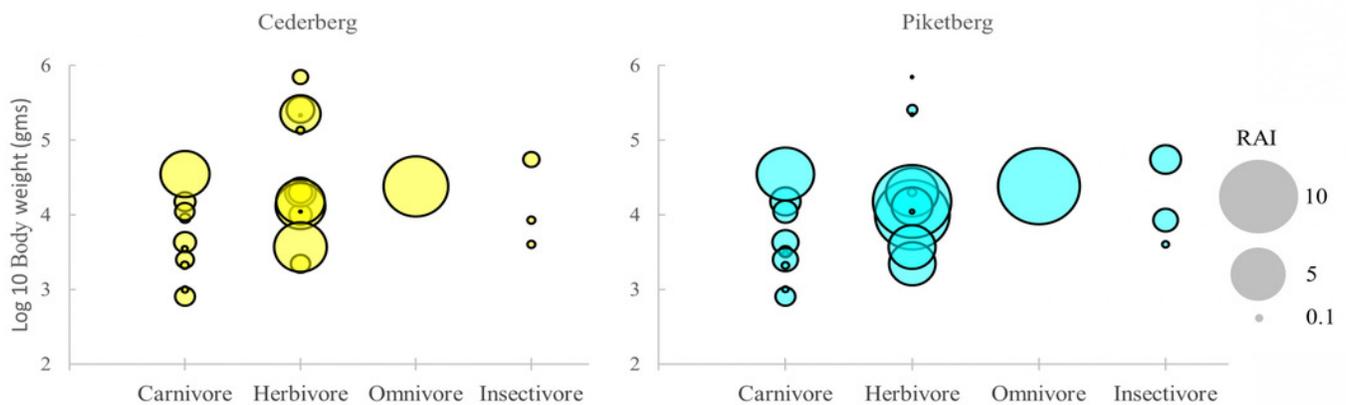

Both curves approach an asymptote, indicating sufficient sampling effort.

## Figure 3

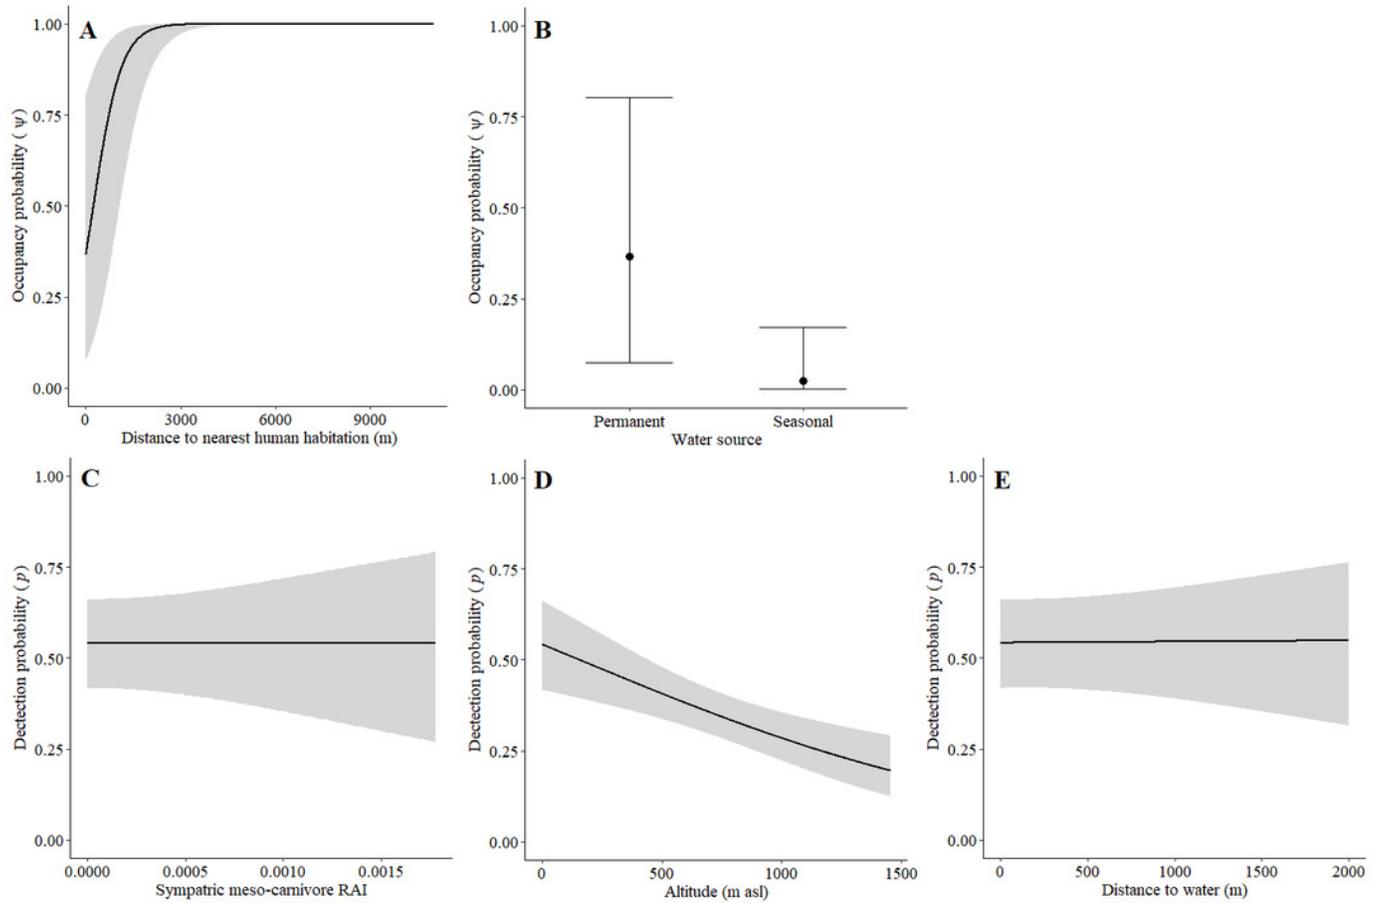

Distribution of medium-to-large (> 0.5 kg) terrestrial mammals (i.e. potential leopard prey species) in the Cederberg and Piketberg on the basis of body size and trophic category.

Each circle represents a species in functional space. The size of the circle is proportional to the trapping rate (RAI) for that species.

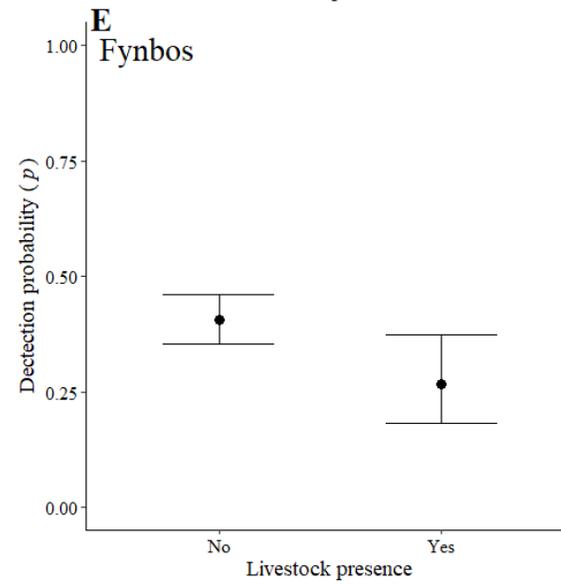

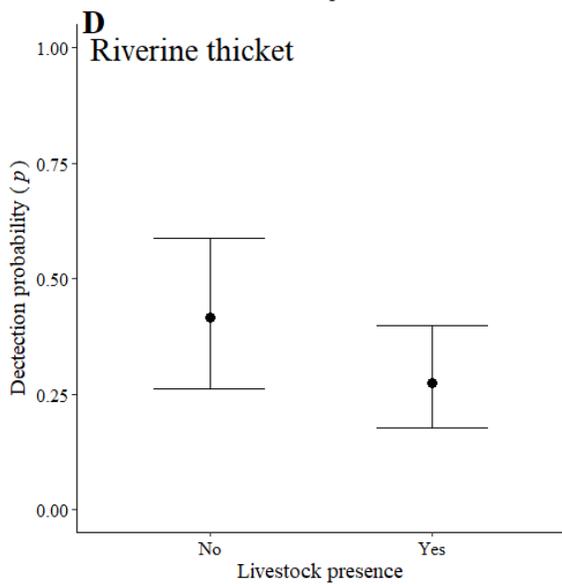

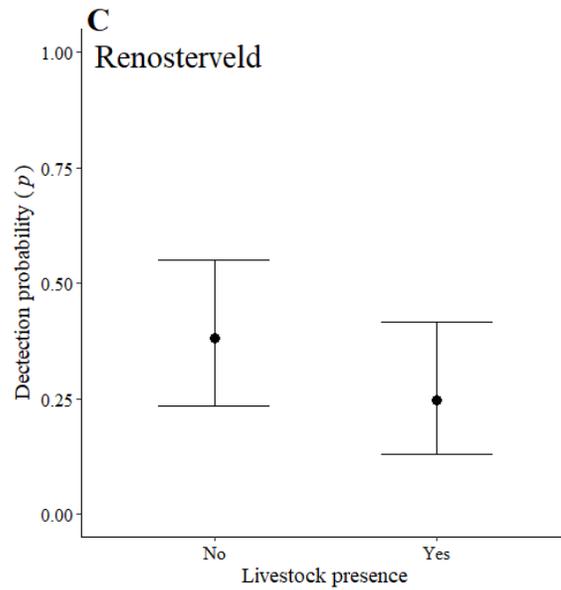

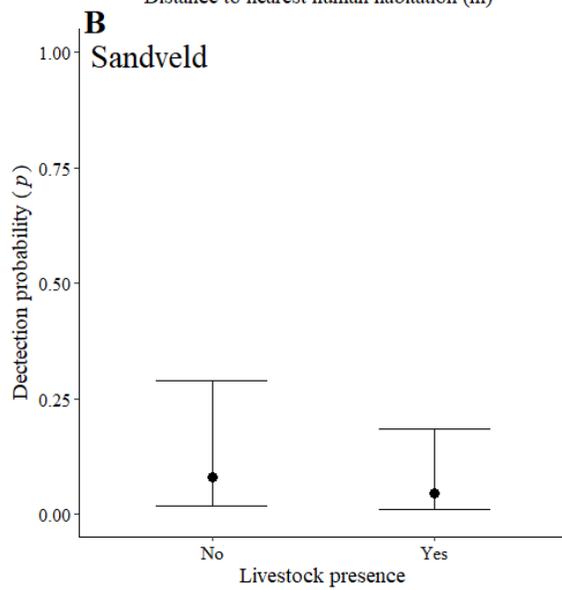

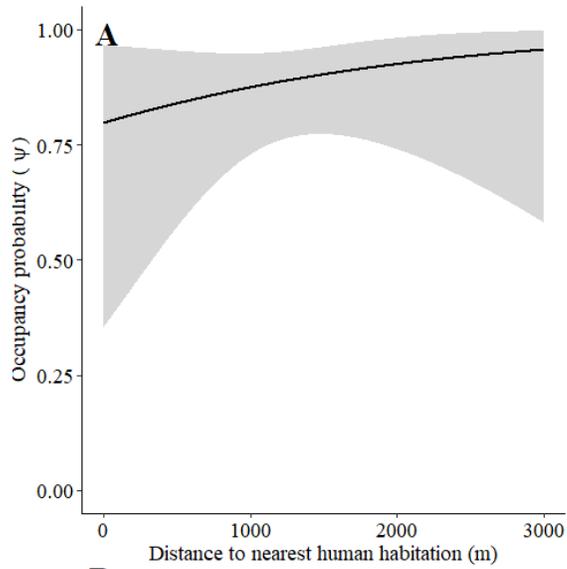

## Figure 4

Detection and space-use (i.e. occupancy) probabilities for leopards with regards to variables with strong associations in the Cederberg.

## Figure 5

Detection and space-use (i.e. occupancy) probabilities for leopards with regards to variables with strong associations in Piketberg.

**Table 1** (on next page)

QAICc weights ( $w$ ) for covariates from well-supported models ( $w > 0.10$  and QAICc  $< 2$ ) for each species (leopard + main prey) in each community.

Either the direction of the relationship for covariates from the best fit models or the parameter probability estimate ( $\pm$  standard deviation) for top models are indicated in parentheses.
