## Abstract

**Background:** We quantified and evaluated the allocation of soil and water resources in the Aksu River Basin to measure the consequences of climate change on an agricultural irrigation system.

**Methods:** We first simulated future climate scenarios in the Aksu River Basin by using a statistical downscaling model (SDSM). We then formulated the optimal allocation scheme of agricultural water as a multiobjective optimization problem and obtained the Pareto optimal solution using the multi-objective grey wolf optimizer (MOGWO). Finally, optimal allocations of water and land resources in the basin at different times were obtained using an analytic hierarchy process (AHP).

**Results:** (1) The SDSM is able to simulate future climate change scenarios in the Aksu River Basin. Evapotranspiration ( $ET_0$ ) will increase significantly with variation as will the amount of available water albeit slightly. (2) To alleviate water pressure, the area of cropland should be reduced by 127.5 km<sup>2</sup> under RCP4.5 and 377.2 km<sup>2</sup> under RCP8.5 scenarios (3) To be sustainable,

the allocation ratio of forest land and water body should increase to 39% of the total water resource in the Aksu River Basin by 2050.

## Introduction

Economic and social development are constrained by various factors, including shortages of available water and land resources, climate change and environmental degradation. (Bai *et al.*, 2015). The IPCC's Sixth Assessment Report (AR6) has made clear that climate change is intensifying the water cycle and affecting rainfall patterns (IPCC, 2021), which will have a significant impact on the global hydrological cycle and water balance (Miller and Belton, 2014). With rapid population and economic growth, it is difficult to reconcile trade-offs among water and land management, ecological environmental protection, and socio-economic development (Mei *et al.*, 2010).

As the world population and consequent demand for food increase, safe water for agricultural use has become increasingly scarce (Summerlin *et al.*, 2021). This phenomenon is pronounced in arid and semiarid regions with irrigation (Rasouli *et al.*, 2012). The total amount of agricultural irrigation is often determined by planting area and planting structure. However, ET is usually calculated using a crop coefficient in irrigation planning with evapotranspiration ( $ET_0$ ) as a key indicator (Wu *et al.*, 2021).

Recent studies have found that  $ET_0$  should change with the effects of climate change, especially where agricultural water consumption accounts for a large proportion of use (Zou *et al.*, 2020). The ability to accurately simulate future climatic scenarios will be the basis for estimating the  $ET_0$ . Although future climate conditions can be roughly estimated using general circulation models (GCMs), meeting requirements for high resolution has been challenging (Wilby *et al.*, 2002). Therefore, it is necessary to use downscaling methods to "shrink" the study area to specific areas or sites for practical application (Hewitson and Crane, 2006).

There are two dominant downscaling approaches: dynamic and statistical. Statistical downscaling is widely used because of its simple operation and low cost (Vallam and Qin, 2018). A statistical downscaling model (SDSM) is used to produce the required high-resolution climate projection by developing a statistical relationship between the large- and local-scale climate variables (Gebrechorkos *et al.*, 2019). As such it is more suitable for climate change simulation at local scales. However, in previous studies, the impact of climate change on

regional inflow and demand and the feedback relationship between supply and demand were ignored (Fu et al., 2014). For example, Sun et al. (2018) have considered the impact of climate change on watershed runoff, but ignored the impact of different climatic conditions on agricultural and ecological water demand. Therefore, how to simultaneously consider changes in water resources and water demand under climate change and realize a balanced allocation of regional water and land resources is a problem that needs to be solved urgently.

However, industrial / domestic and ecological water are considered equally important for regional development. Water and land optimization allocation is also a complex problem that involves many elements (Habibi *et al.*, 2016). How to rationalize planting structure with the effects of climate change is an important consideration in water resource management. The best way to solve this problem is to build a multi-objective model for optimization. Approaches such as evolutionary (EA), genetic (GA), and nondominated sorting genetic algorithms (NSGA-II), linear (LP) and non-linear programming (NLP), among others, have been applied to optimize water and land resources (Keshtkar *et al.*, 2020). These methods provide multiple options for decision makers by finding a model Pareto solution set. However, most have a number of shortcomings, (e.g., local optima traps or slow convergence). The grey wolf optimizer (GWO) algorithm, which was proposed by Mirjalili *et al.* (2014), is a relatively novel population-based metaheuristic algorithm that combines fast convergence and high optimization accuracy (Rashidi *et al.*, 2018). The GWO algorithm utilizes the simulated social leadership and encircling mechanism in order to find the optimal solution for single-objective optimization problems (Mirjalili *et al.*, 2014). For performing multi-objective optimization, the multi-objective GWO (MOGWO) extends the advantages of GWO to more complex scenarios. However, the shortcomings of GWO (initial value effects, local optimum traps) when solving multi-objective problems have been improved (Mirjalili *et al.*, 2016).

Xinjiang province is typical of arid and semi-arid regions in China that lack significant water resources that are primarily generated by glacier meltwater in adjacent mountains (Chen *et al.*, 2020). Water shortages have become a source of conflict in the Tarim River Basin of Southern Xinjiang with intense confrontations between environmental protection and economic development (Lam *et al.*, 2011). As an ecologically fragile area, the Tarim River Basin has experienced a significant decline of its riparian desert forests (Zhang *et al.*, 2019). Additionally, the Tarim River Basin is a major source of cotton and fruit production. Therefore,

it is particularly important to improve water use efficiency and optimize allocation of water resources in this region.

To help decision makers formulate regional resource allocation strategies in future climate change scenarios, we developed a multi-objective water and soil resource allocation model based on MOGWO and AHP. The main contributions of our model lie in the following aspects: (1) forecast regional climate change scenarios using the SDSM model; (2) calculate regional water supply and demand in different climate scenarios; (3) determine water consumption among crops and establish a multi-objective programming model using the MOGWO algorithm to solve water-use conflicts for agricultural production, ecosystems, and drinking water supply; (4) select the most suitable options from the Pareto solutions using an analytic hierarchy process (AHP).

## Materials & Methods

### Study area

The study area was the Aksu Valley ( $75^{\circ} 35' - 82^{\circ} 00' E$ ,  $40^{\circ} 00' - 42^{\circ} 27' N$ , excluding Akqi) in Xinjiang, China. The area is approximately  $3.6 \times 10^4 \text{ km}^2$ , including 6 counties or cities in the Aksu area (Aksu, Wensu, Awati, Wushi, Keping and Alar). It is served by the western upper reaches of the Tarim River Basin (**Error! Reference source not found.**) and sand dunes are the predominant landform (El-Tantawi *et al.*, 2019). The water used for agricultural irrigation makes up more than 95% of the total regional water consumption. The most important irrigated crop is cotton, which has increased in annual planting area (Li *et al.*, 2020).

### Data Sources

Meteorological data were obtained from the China Meteorological Science Data Network (1961–2005) (<http://data.cma.cn/>). Large-scale climate variables (predictors) for the current climate and future scenarios under the RCPs in years 1961 to 2050 obtained from Canadian Climate Data and Scenarios (<http://climate-scenarios.canada.ca/>). We used grid resolution  $2.815^{\circ}$  latitude by  $2.815^{\circ}$  longitude. River discharge data (1961–2005) were from the Aksu Valley Chronicles (Aksu River Basin Management Office, 2006). Socio-economic data were gathered from the Aksu Region Yearbook and Xinjiang Construction Corps Yearbook (Bureau of Statistics of Xinjiang Production and Construction Corps, 2009).

### Simulation of climate scenarios

Statistical downscaling model under two scenarios (RCP 4.5 and RCP 8.5)

RCP 2.6 represents a stringent mitigation scenario, RCPs 4.5 is intermediate mitigation scenarios and RCP 8.5 is low mitigation scenario with very high greenhouse emissions (Carvalho et al., 2019). Due to better representation of actual emissions since 2000 by other RCPs (Peters et al., 2012), we excluded RCP 2.6 in this study. The CanESM2 predictors provide 26 parameters (<https://climate-scenarios.canada.ca/?page=pred-canesm2>). To produce climate data for future analyses, the SDSM model was parameterized by inputting daily observations (Fig. 1) and 26 predictors from CanESM2 (1961–1990 data for model building and 1991–2005 data for the model validation). Five predictors (daily maximum and minimum temperature, daily relative humidity, annual rainfall, and annual sunlight) were selected based on the correlation matrix, partial correlation, and P-value (Fowler et al., 2007) (Supplementary Table 1). Final model accuracy was examined using both the coefficient of determination ( $R^2$ ) and Root Mean Square Error (RMSE) (Wood et al., 2004) (Supplementary Table 1).

# **Estimation of water demand and supply in Aksu River basin**

## **(1) Total water demand**

### **a. Agricultural water demand**

The Hargreaves equation and downscaling simulation results were used to calculate the reference crop evapotranspiration ( $ET_0$ ). Previous research showed that Hargreaves equation had good applicability in arid and semi-arid regions (Wang, et al., 2013)

$$ET_0 = \frac{K}{\lambda} (T_{max} + T_{min})^n \cdot (T_{mean} + T_{off}) \cdot R_a \quad (1)$$

$$T_{mean} = (T_{max} + T_{min})/2 \quad (2)$$

Where K is the conversion coefficient (recommended value=0.0023),  $\lambda$  is the latent heat of water vaporization (recommended value=2.45 MJ/kg),  $T_{max}$ ,  $T_{min}$  are the highest and lowest temperature ( $^{\circ}C$ ), n is the exponential coefficient (recommended value=0.5),  $T_{mean}$  is the average temperature ( $^{\circ}C$ ),  $T_{off}$  is the temperature constant (recommended value=17.8), and  $R_a$  is the solar insolation at the top of the atmosphere MJ/( $m^2$ /d)(Bautista, et al., 2009). The water requirement of the main crops in the study area was calculated as:

$$W_{GD} = \sum_{i=1}^n \sum_{j=1}^m P_i (ET_{0ij} K_{cij} - 0.52 T_{ij}) \quad (3)$$

where  $W_{GD}$  is the water requirement per unit area of arable land ( $10^4 m^3/km^2$ ),  $P_i$  is the proportion of crop i per unit area of arable land,  $ET_{0ij}$  is the reference crop water requirement for crop i in

month  $j$  (growing season),  $K_{cij}$  is month  $j$  (growing season) of crop  $i$ ,  $T_{ij}$  is month  $j$  (growing season) of crop  $i$  rainfall, and 0.52 is the rainfall utilization coefficient (Rahman *et al.*, 2008).

Irrigation water requirement per unit area:

$$W_{GDi} = W_{GD} * a_i / b_{i1} + W_{GD} * (1 - a_i) / b_{i2} \quad (4)$$

where  $W_{GDi}$  is the amount of irrigation water per unit of arable land,  $a_i$  is the proportion of water-saving irrigation area in year  $i$ , and  $b_{i1}$  and  $b_{i2}$  are respectively the conventional and water-saving irrigation water utilization coefficients in year  $i$ .

#### b. Industrial and domestic water demand ( $W_{IDi}$ )

According to 2018 statistics data, industrial water consumption per  $\text{km}^2$  was calculated by dividing the total industrial outputs with total industrial water consumption in Aksu. The water consumption of the industrial added value of ten-thousand yuan was approximately  $110 \text{ m}^3$ . Residential water consumption per unit area is calculated using the resident population and the water consumption per municipality. According to the Plan for Reform and Development of the Aksu Region (2020-2050), and these are summed for the Aksu River Basin (**Table 1**).

#### c. Ecological water demand

We consider water for the forests and water bodies as ecological. The formula for the calculation of forest demand is:

$$W_{LD} = K_s \sum_{j=1}^m (ET_{0j} K_{cj} - 0.52 T_j) \quad (5)$$

where  $W_{LD}$  is the water demand per unit area of woodland in the watershed ( $10^4 \text{ m}^3 / \text{km}^2$ ),  $K_s$  is the soil moisture limitation coefficient,  $ET_{0j}$  is month  $j$  of the forest land (growing season) reference crop water demand,  $K_{cj}$  is the crop coefficient of forest land in month  $j$ , and  $T_j$  is the rainfall of forest land in month  $j$ .

$$W_{LDi} = W_{LD} / b_{i2} \quad (6)$$

Here,  $W_{LDi}$  is the amount of irrigation water per unit of woodland, and  $b_{i2}$  is the water-saving irrigation water utilization coefficient in decade  $i$ .

The water demand for the water bodies:

$$W_{WA} = 0.58 * E_0 \quad (7)$$

$$ET_0 = 0.556 * E_0 \quad (8)$$

where  $W_{WA}$  is water demand per unit of water area. Xi and Cheng (2002) estimated the conversion coefficient between a  $20 \text{ cm}^2$  dish and a  $20 \text{ m}^2$  evaporating pool was 0.58.  $ET_0$  was

estimated by multiplying  $E_0$  by a coefficient 0.556 (Xi and Cheng, 2002). We assume that grasslands are not irrigated in this study.

**Total water demand = total agricultural water demand + total industrial and domestic water demand + total ecological water demand**

(2) Total water supply in the future climate

**Total water supply = available surface water + available groundwater resources**

The sum of river flow of two hydrological stations (Sahliguilanke and Xiehela) was used as water resource input and the river flow at the Alar station was used as the residual amount of water resource (**Fig. 1**). The difference between the two flows was computed as **the amount of available surface water** in the study basin. A neural networks model was used to estimate runoff data for the hydrometric station.

The specific analysis we used followed Zarghami *et al.* (2011). Using the runoff and meteorological data from 1958–1995, the feedforward neural network models between runoff and meteorological factors were parameterized. Data from 1996–2003 were selected for verification and the fluctuation and precision judgment indices were set to evaluate neural network performance. Because the number of network layers was 20, the two indexes reach the minimum value by trial-and-error. The following data were used in the models: runoff (R), precipitation (P), relative water content (RWC), minimum temperature ( $T_{\min}$ ), maximum temperature ( $T_{\max}$ ), average daily sunshine hours (ADS), mean temperature ( $T_{\text{mean}}$ ) and  $ET_0$ , all indexed to time (years). The resulting model is:

$$R(t)=f(P(t), RWC(t), T_{\max}(t), T_{\min}(t), T_{\text{mean}}(t)ADS(t)ET_0(t)) \quad (9)$$

The modeling process was performed using the ANN toolbox in the MATLAB environment. Annual average meteorological values predicted by SDSM under RCP4.5 and RCP8.5 scenarios were entered into the neural network model to estimate the annual runoff at the hydrological station. Finally, an expected future amount of water resources could be calculated from the estimated hydrological station data. The **available amount of groundwater** in Aksu River Basin was considered as unchanged.

### **Multi-objective optimal allocation model of water and soil resources**

The multi-objective optimal allocation model must cover the balance of the economic, social and ecological benefits. We used the gross national product (GDP) as the economic indicator, the

maximum benefit of water per cubic meter as the social indicator and ecological green equivalent as the ecological indicator. The computational formula is:

$$F_1(X) = \max \sum_{i=1}^n \sum_{j=1}^m a_{ij} X_{ij} \quad (10)$$

$$F_2(X) = \max \frac{\sum_{i=1}^n \sum_{j=1}^m a_{ij} X_{ij}}{\sum_{i=1}^n \sum_{j=1}^m b_{ij} X_{ij}} \quad (11)$$

$$F_3(X) = \max \sum_{i=1}^n \sum_{j=1}^m c_{ij} X_{ij} \quad (12)$$

$$\sum_{i=1}^n b_{ij} X_{ij} \leq W_s \quad (13)$$

$$\sum_{i=1}^n X_{ij} = T \quad (14)$$

$$\sum_{j=1}^n X_{1j} \geq PL_{\min} \quad (15)$$

$$\sum_{j=1}^n X_{2j} \geq FL_{\text{now}} \quad (16)$$

$$\sum_{j=1}^n X_{3j} \geq CL_{\text{now}} \quad (17)$$

$$\sum_{j=1}^n X_{4j} \geq WL_{\text{now}} \quad (18)$$

$$\sum_{j=1}^n X_{5j} = NL_{\text{now}} \quad (19)$$

where  $F_1(X)$  is total GDP,  $F_2(X)$  is the utilization of maximum benefits per cubic meter of water,  $F_3(X)$  is the ecological green equivalent of the river basin,  $X_{ij}$  is the area of land types in each area ( $\text{km}^2$ ),  $a_i$  is gross national product per unit area of each land type (10,000 yuan/ $\text{km}^2$ ),  $b_i$  is the water demand per unit area of each land use type ( $\text{m}^3$ ), and  $c_i$  is the green equivalent value of each area of each land type.  $T$  is the total area ( $\text{km}^2$ ),  $PL_{\min}$  is the red line of cultivated land in the study area ( $\text{km}^2$ ),  $FL_{\text{now}}$  is the current forest area ( $\text{km}^2$ ),  $BL_{\text{now}}$  is the current construction land area,  $WL_{\text{now}}$  is the current water area, and  $NL_{\text{now}}$  is the current unused land area.

## The MOGWO algorithm and the optimal solution

### (1) Design of MOGWO algorithm

We modified the grey wolf algorithm (GWO) to incorporate two new components (storing non-dominated Pareto optimal solutions archive and a leader selection strategy) to comprise the MOGWO (Mirjalili *et al.*, 2016). The detailed procedures are described in **Fig. 2**.

We obtained a set of non-dominated solutions for the multi-objective model. The parameter settings were number of wolves=100, achieve=100, range=20% and iterations=100.

### (2) The best optimal value for multi-objective model based on analytic hierarchy process method (AHP)

The AHP is introduced to transform the process into hierarchical problems. To establish a judgment matrix, the relative weight of each target is determined. At the same time, the consistency index of the judgment matrix is calculated to verify the validity of the weight. The consistency of the matrix is considered acceptable when the consistency ratio (CR) is less than 0.1. We determined importance indicators for establishing the judgment matrix (**Table 2**) and the proportions and test indicators of the three planning goals calculated by the analytic hierarchy process (**Table 3**).

## Results

### Projected future climate and water resource change

We projected temperatures and precipitation at the Aksu Basin using the downscaled global climate models (GCMs) (**Fig. 3**). Warming was predicted for this area's subregions. By the year 2050 (starting in 2020), the projected temperature could increase up to 1.3, 0.9, 0.8, and 0.2 °C, at Aksu, Keping, Alar, and Akqi under RCP4.5, respectively. Under the RCP8.5 climate scenarios, the temperatures were predicted to increase at a faster rate. As opposed to temperature trends, the precipitation showed decreasing trends except at the Keping station.

The minimum and maximum temperatures predicted by SDSM from 2006 to 2050 change over the whole basin's  $ET_0$  (**Fig. 4, Fig. 5**).  $ET_0$  values of the four weather stations showed an upward trend during the period 2010–2050. There was no significant difference between the RCP4.5 and RCP8.5 climate scenarios during the first years, but  $ET_0$  has an increasingly higher value under RCP8.5 scenarios relative to RCP4.5 after 2035. The difference value is expected to be as high as 50 mm by 2050.

By using the neural network model to estimate the runoff flow of the hydrological station, the available surface water in the basin gives a trend of slow future increase (**Fig. 6**). Until 2050, the annual average runoff is predicted to increase  $7.963 \times 10^8 \text{ m}^3$  and  $10.41 \times 10^8 \text{ m}^3$  under RCP4.5 and RCP8.5, respectively. The amount of runoff was higher under the RCP8.5 scenario than the RCP4.5 scenario (**Table 4**).

### The optimal allocation of the water and land resources

Future water shortage is predicted to be about  $5.83 \times 10^8 \text{ m}^3$  in the basin (**Table 5**). The Pareto frontier under the five scenarios obtained by MOGWO is shown in **Supplementary Fig. 1**; the specific values of water and soil resource allocation in the basin are shown in **Supplementary Table 2-7**. Due to the high emission concentration (RCP8.5), with the exception of construction land, the water demand per unit area of the other land types is higher compared to

the low emission concentration (RCP4.5). Although the total cultivated area in the basin under the two climate scenarios is similar, the change of cultivation in each region of the basin differs. Water and land resource allocation in the Recent-term (2020), medium-term (2035), and long-term (2050) plan under two emission concentrations show, in general, a trend of decreasing arable land and grassland and increasing other land (**Fig. 7**). The arable land areas of Awati, Aksu, and Alar exhibited a continuous downward trend as the result of the policy for restoring farmland to save water, but the arable land areas is likely to continue to increase in Wushi County (**Fig. 8**). In addition, the area of grassland in the Wushi and Wensu regions is trending downward, while the Alar is increasing (**Fig. 9**).

## Discussion

We found that SDSM had higher predictive accuracy for temperature relative to rainfall using a formal accuracy index. This may mimic the model's limitations in simulating rainfall (Wilby *et al.*, 2002). Downscaled climate change model scenarios suggest that the warm-wet climate trend will continue in the semi-arid region. Rainfall shows a declining trend (except for Keping station) in the region during 2021–2050, which has been also found in other studies (Chu *et al.*, 2010; Wilby and Dawson, 2013; Zhu *et al.*, 2019).

The change of  $ET_0$  caused by climate change will have a significant impact on agricultural and ecological water demand (Guo and Shen, 2016; Hadinia *et al.*, 2016).  $ET_0$  values in the Aksu River basin trend upward in the future (Figure 6) as in other areas of China such as the Tibetan Plateau, Haihe River Basin and Hetao Irrigation District (Wang *et al.*, 2013; Xing *et al.*, 2014; Zhou *et al.*, 2017). The increasing  $ET_0$  rate was also inversely related to elevation (Zou *et al.*, 2020), therefore  $ET_0$  of the Akqi station had the lowest increasing rate in Aksu River basin.

Because of the hydrology of Xinjiang under future climate change scenarios (Li *et al.*, 2020; Shen *et al.*, 2020; Xu *et al.*, 2010), we suggest that surface runoff in the basin will trend upward in the future. We suspect that the main reason for increased runoff will be an increase in temperature leading to amplified loss of seasonal snow cover, glacier and ice sheet melting (IPCC, 2021). In the past 30 years, ice and snow melt water has been increasing and will continue to increase until 2050 in the Aksu River Basin (Wang, 2018; Zhang, 2010), which also supports our model results. Ding and Reng (2007) reported that glacier melt water around the

Tarim Basin would continually grow potentially reaching a level of  $10^8 \text{ m}^3/\text{a}$  (Xia Jun, 2011).

The upward trend in runoff is also predicted to be greater under RCP 8.5 than RCP4.5 (**Fig. 6**).

Water scarcity continues to be a major crisis in the Aksu River Basin. With the  $\text{ET}_0$  increase water demand from agricultural production and ecological protection has increased annually. The multi-objective allocation of soil and water resources to economic, societal, and ecological goals, compel us to recommend reducing the area of cultivated land to alleviate the current water shortage (Xu *et al.*, 2010). Currently, the Aksu River Basin is facing a shortage of water resources estimated to be  $5.83 \times 10^8 \text{ m}^3$  (**Table 5**). To balance water supply and demand, the Aksu River Basin needs to reduce agricultural water use as a measure to protect the environment. The most effective mitigation action is to reduce the arable land area. Forests and water bodies should be expanded to strengthen ecological protection and improve ecosystem services. Therefore, regions should adopt alternative allocation strategies to achieve the optimal comprehensive benefits for the whole basin. Decision makers should enact recommended configurations according to their own conditions under a changing climate and in different regions.

Notably, the change of cultivation in each region of the basin differs. The arable land areas of Awati, Aksu, and Alar exhibited a continuous downward trend as the result of the policy for restoring farmland to save water, but the arable land areas is likely to continue to increase in Wushi County (**Fig. 8**). The cause of this heterogeneity may be the different water requirements per unit area of arable land in each county under the two scenarios. The output value per unit area of Wushi County is lower than other regions due to the large proportion of crops planted on arable land. As well, water demand per unit area is smaller than in other regions. If water shortages constrain watershed development and are red line constraint of arable land, then lower water use in Wushi will have a greater impact on the overall benefits of the entire watershed than a low output value. We provide the following policy recommendations: To cope with this shortage in the basin and measure including strictly following the “red line” restriction of cultivated land, the area of the cropland should be reduced by  $127.5 \text{ km}^2$  under RCP4.5 or  $377.2 \text{ km}^2$  under RCP8.5 models. For the sake of ecological sustainability, the allocation ratio of forest and water bodies should increase to 39% of the total water volume in the Aksu River Basin by 2050.

There is some limitation in this study, and the model could still be improved. For example, due to the lack of data on future the cultivated land planting structure, we used current cultivated planting structure for calculating future water demand per unit area. And in the AHP method, the interconnection between the factors in the criterion level was ignored and considered as independent of each other, and the factors could be refined in the later study to make the results closer to the actual situation.

## Conclusions

In the future, the  $ET_0$  of the Aksu River Basin will increase variably according to climate predictions of an SDSM model. Our study indicated that the water resources, mainly generated by glacier/snow meltwater, increased according to the neural network model. Climate change may have beneficial effects on agriculture in Aksu River Basin. This outcome may force governments to find new and sustainable adaptation strategies to rescue the future water supply. The water governance in this region should be more flexible and decentralized to cope with climate change.

## Acknowledgements

We are very thankful to Dr. John Wilmshurst for carefully reading and polishing the manuscript.
