20 ABSTRACT

21 Introduction of organisms to new range may impose detrimental effects on local organisms,
22 especially when closely related species are involved. Species delimitation employing an
23 integrative taxonomy approach may provide a quick assessment for the species status between
24 taxa of interest, and to infer ecological competition and/or introgression that may be the
25 associated with the introduction. A nymphalid butterfly, *Symbrenthia lilaea lunica*, was recently
26 introduced to Taiwan, where a closely related local taxon, *S. l. formosanus*, can be found. We
27 employed multiple species delimitation methods to study the species status between the two taxa,
28 and the results revealed that they can be recognized as two distinct species. We further
29 performed a niche modeling approach to investigate the ecological interaction between the two
30 species. The taxonomic status of the two taxa, now elevated to species, has been revised and
31 conservation facing rapid expansion of the introduced species discussed.

35

36 Introduction

37 Biological invasions and range expansion of organisms usually impose unfavorable effects on

38 local organisms that share similar ecological requirements (*Mooney & Cleland, 2001*),
39 particularly when the expanding form is of continental origin and entering insular areas (*Sax &*
40 *Gaines, 2008*). Competition may occur between native taxa and the invading one, notably when
41 the counter taxa are closely related, where they are expected to share resource requirements
42 (*Zwerschke et al, 2018*). This kind of scenarios have been well-documented in various
43 organisms, such as ants (*von Aesch & Cherix, 2005*), birds (*Koenig, 2003*), molluscs (*Zwerschke*
44 *et al, 2018*), plants (*Leger & Espeland, 2010; Cuda et. al., 2015; Sheppard & Brendel, 2021*),
45 etc., and even inspired E. O. Wilson to coin in his “taxon cycles” hypothesis (*Wilson, 1961*).
46 Alternatively, if the involved taxa were previously allopatric populations or subspecies, gene
47 flow may occur between taxa, resulting in changes in the genetic make-up of the local population
48 (*Rhymer & Simberloff, 1996*). Consequently, whether the exotic taxon represents interspecific or
49 intraspecific entity to the local taxon may lead to different types of ecological and evolutionary
50 impacts to local community. Species delimitation employing an integrative taxonomy approach
51 has becoming popular to help with taxonomic treatments/decisions among closely related taxa
52 and to detect cryptic species (*Moraes et al., 2021*). This approach can also help with assessing
53 whether an invading taxon is conspecific or not to the local taxon.

54 A case of recent invasion, either by anthropogenic introduction or by natural means such as
55 wind, of a nymphalid butterfly currently recognized as *Symbrenthia lilaea lunica* (Fig. 1A–1D)

56 into Taiwan has been reported (*Lu & Chen 2014; Hsu et al. 2022*). In Taiwan, there is a local
57 native *Symbrenthia* taxon, *S. l. formosanus* (Fig. 1E–1H; *Shirôzu & Ueda, 1992; Hsu et al.*
58 *2022*). *S. l. lunica* from continental Asia was first documented in 2004 in Taiwan (*Lu & Chen*
59 *2014*). Natural observations in Taiwan on immature biology and hostplant usage of both *S. l.*
60 *lunica* and *S. l. formosanus* have documented that the two taxa use the same larval hostplants (*Lu*
61 *& Chen, 2014*). The invading or introduction event represents a ‘natural experiment’ in which to
62 examine whether these two taxa are conspecific as current classification suggests, or if they
63 represent distinct biological species. The answer to this natural experiment may help clarify what
64 ecological effect the introduced taxon may impose on the native taxa. If they turn out to
65 represent distinct species, competition between them may occur as they do not differ in larval
66 hostplant usage. If they turn out to be conspecific, gene introgression may occur since
67 hybridization is liable to occur.

68 We investigated the species status between the two now sympatric taxa in Taiwan using
69 multiple coalescent model based species delimitation methods and distance based species
70 delineation, under a scheme for testing hypothesis of taxonomic status developed by *Braby et al.*
71 (*2012*), following by a niche modeling survey to understand the ecological interaction between
72 two taxa.

73

74 **Materials and Methods**

75 **Sampling**

76 The mitochondrial cytochrome oxidase subunit I (*COI*) gene has been successfully applied as a
77 helpful marker with which to delimit closely related species (*Hebert et al., 2003*). We included a
78 total of 13 specimens collected from various localities in our *COI*-based study. Four specimens
79 of *Symbrenthia lilaea formosanus* were collected around Taiwan, and six specimens of *S. l.*
80 *lunica* were collected in Taiwan (mainland and Matsu archipelago), China, and Thailand. located
81 in the Northwest of Taiwan. All samples were preserved in 70% ethanol and kept at -20°C for the
82 subsequent molecular study. Moreover, additional *COI* sequences of *S. l. formosanus*
83 (AY788679) from Taiwan, *S. l. lunica* (EU368155, KJ649017, KX300094) from China,
84 Vietnam, Myanmar respectively, and the nominate subspecies *S. l. lilaea* (KP644228,
85 KP644229) from India were obtained from GenBank. For the phylogenetic analyses, we used
86 one sequence of *S. brabira* (EU368154) as an outgroup.

87

88 **DNA extraction, PCR amplification and DNA sequencing**

89 Genomic DNA was extracted from one leg of specimens using the Gentra Puregen tissue kit
90 form QIAGEN (QIAGEN, Maryland, USA), following the manufacturer's protocol. A partial
91 fragment from the *COI* gene was targeted for amplification by polymerase chain reaction (PCR).

92 The *COI* gene was amplified using the universal primers COX-J-1460 (5'-
93 TACAATTTATCGCCTAAACTTCAGCC-3') and COX-N-2191 (5'-
94 CCCGGTAAAATTAAAATATAAACTTC). PCR reactions were performed in a 30 μ L volume
95 eppendorf, containing 1 μ L of extracted DNA, 23.5 μ L of ddH₂O, 3 μ L of 10X PCR reaction
96 buffer, 0.6 μ L of each primer and 0.3 μ L of Power Taq (Genomics Biosci & Tech, Taiwan). The
97 following PCR protocol was used: an initial denaturation at 95°C for 5 min, followed by 40
98 cycles of 30s denaturation at 95°C, 30s annealing at 50°C and 45s extension at 72°C, and a final
99 extension at 72°C for 10 min. Automatic sequencing was performed using an ABI 3730XL DNA
100 Analyzer (Applied Biosystems).

101

102 **Sequence Analyses and Phylogenetic Reconstruction**

103 Sequences were edited and assembled using Sequencher 4.10.1 (Gene Codes Corporation, Ann
104 Arbor, USA), and sequence alignments were performed using MUSCLE in MEGA 11 (*Tamura et*
105 *al.*, 2021), and pairwise genetic distances between different populations of *S. l. formosanus* and
106 *S. l. lunica* were also measured using MEGA 11 with the Kimura 2-parameter model.

107 The best-fit nucleotide substitution model for phylogenetic analysis was inferred using
108 jModelTest 2.1.10 (*Posada, 2008*) based on Akaike information criterion (AIC). Phylogenetic
109 trees were reconstructed under maximum likelihood (ML) and Bayesian inference (BI). ML

110 analysis was performed using RAxML v8.2.10 (*Stamatakis, 2014*) with 1000 bootstrap replicates
111 to assess the reliability of the tree. BI analysis was performed using MrBayes 3.2.6 (*Ronquist et*
112 *al., 2012*). For MrBayes, the substitution model inferred from jModelTest was applied. The
113 Bayesian Markov Chain Monte Carlo (MCMC) analysis for 10^9 generations with sampling every
114 1000 generations was run to ensure the average standard deviation of split frequencies were
115 below 0.01. The first 30% of trees were discarded as burn-in. FigTree v1.4.4 was used to
116 visualize the consensus tree.

117

118 **Molecular species delimitation analyses**

119 Many molecular species delimitation programs have been proposed and broadly applied in
120 speciation studies, which provides important evidence for integrative taxonomy. Among
121 molecular species delimitation programs, the Poisson Tree Processes model (PTP) (*Zhang et al.,*
122 *2013*), the Automatic Barcode Gap Discovery (ABGD) (*Puillandre et al., 2012*), and the
123 Generalized Mixed Yule Coalescent model (GMYC) (*Fujisawa & Barraclough, 2013*) were
124 developed as single locus-based approaches for species delimitation. Therefore, we delineated
125 species limits among *S. l. formosanus*, *S. l. lunica*, and *S. l. lilaea* by employing the Molecular
126 Operational Taxonomic Unit concept set by these three programs.

127 For PTP, we used the tree inferred by MrBayes as input tree on the web server

128 (<https://species.h-its.org/ptp/>), with 100000 MCMC generations and 100 thinning. Subsequently,
129 PhyloMap was used to visualize the results of PTP. For ABGD, we performed the analyses on
130 the web version of ABGD (<https://bioinfo.mnhn.fr/abi/public/abgd/>), with default settings of
131 relative gap width ($X=1.5$) and the Kimura two-parameter (K2P) model for nucleotide
132 substitution. For GMYC, we used the phylogenetic tree inferred by MrBayes 3.2.6. The results
133 from MrBayes were forced bifurcated by the “multi2di” and “chronos” function in the package
134 “ape” in R 4.1.2. A single-threshold GMYC analysis was performed in the R package splits
135 v1.0-20. We chose the single-threshold model because of the limited improvements of multiple-
136 threshold model.

137

138 **Species distribution model of *S. l. formosanus* and *S. l. lunica* in Taiwan**

139 *S. l. lunica* was not known to occur in Taiwan until recently, although it inhabits Matzu and
140 Kinmen, which are small outlying islands of Taiwan and close to mainland Asia. However, *S. l.*
141 *lunica* arrived to the main island of Taiwan due to anthropogenic activities or via natural
142 dispersal, with the first credible record found in Xinzhu in northwestern Taiwan in 2004 (*Lu &*
143 *Chen, 2014*). Since then, the range of *S. l. lunica* has expanded quickly, and is currently found in
144 lowland areas throughout Taiwan (*Lu & Chen, 2014; Hsu et al., 2022*). It is an interesting issue
145 whether competitive exclusion has happened between *S. l. lunica* and native *S. l. formosanus*,

146 especially if the species delimitation analyses decide they represent different species.

147

148 The occurrence data of *S. l. formosanus* and *S. l. lunica* were obtained from the Global
149 Biodiversity Information Facility (GBIF) (<https://gbif.org/>, access 26 July 2021), Taiwan Moth
150 Information Center (<https://twmoth.terrsi.gov.tw/>, access 26 July 2021), and the specimen
151 collection at National Taiwan Normal University. To test the interaction between these two
152 species, we separated the occurrence data into two stages based on year. The early invasion was
153 defined as the data recorded from 1911—2012, and the late invasion was defined as the data
154 recorded from 2013—2021. Repeated data was excluded using R 4.1.2, and we ensured the
155 presences of only one presenting point in each raster, as shown in Fig. 1, to avoid overfitting. In
156 total, 48 and 43 localities were obtained during the early invasion stage for *S. l. formosanus* and
157 *S. l. lunica*, respectively (Fig. 2A), and 132 and 192 localities were obtained during the later
158 invasion stage for *S. l. formosanus* and *S. l. lunica*, respectively (Fig. 2B). These data were
159 organized using Microsoft Excel for the subsequent analyses.

160 A total 19 bioclimate variables (period: 1979—2013) were collected from CHELSA ([https://](https://chelsa-climate.org/)
161 chelsa-climate.org/, accessed on 14 July 2021) at a spatial resolution of 30 arc-seconds (1km²).
162 These bioclimate variables were derived from temperature and precipitation, which are
163 considered to be related to the distribution and survival of small arthropods and have been

164 widely used in the prediction of species distribution (*De Meyer et al., 2010; Xu et al., 2020*). In
165 order to avoid the effect of multicollinearity, these 19 variables were selected by the “vifstep”
166 and “vifcor” function with the threshold of 10 and 0.6 separately in “usdm” package in R 4.1.2
167 (selected variables shown in Fig. 7).

168 MaxEnt (3.4.4) (*Phillips et al., 2006*) was applied to predict the habitat suitability of *S. l.*
169 *formosanus* and *S. l. lunica* based on the occurrence data. 10% of the data were selected to run a
170 random test and the remaining data were run following the default settings. Presence-only data
171 were generated pseudo-absences and 10000 random background points were randomly selected
172 by the MaxEnt model. The results were output after 10 cross-validation replicates.

173 The predictions generated from MaxEnt modeling were evaluated according to the
174 threshold independent area under the ROC curve (AUC) values. Receiver operating
175 characteristic (ROC) curves were used to plot the true-positive rate against the false-positive rate
176 and the AUC was used as a measure of the goodness of fit of the model. The AUC value ranges
177 from 0 to 1, with higher values indicating higher predictive performance. The logistic output was
178 chosen as an estimate of the probability of presence conditioned by bio-environmental variables
179 per grid cell. Jackknifing was used to screen for the contribution of each bio-environmental
180 variable used in the model.

181 We performed principal component analyses (PCA) to test the niche overlap of these two

182 species in each of the two stages. The 19 bioclimatic variables were obtained from the CHELSA
183 database based on the GPS of each observation point. The analyses were conducted in R 4.1.2
184 using the function “prcomp”, with scatterplots built using the function “ggbiplot”. Additionally,
185 in order to evaluate the niche shift pattern between the two *Symbrenthia* species in Taiwan, we
186 apply methods modified from *Bates et al., 2020* to quantify the niche shift between *S. l.*
187 *formosanus* and *S. l. lunica* by calculating niche overlap, presented by Schoener’s D, and niche
188 expansion of *S. l. lunica*.

189

190 **Results**

191 **Taxonomic decisions**

192 Phylogenetic reconstruction of *Symbrenthia* COI samples (Fig. 5) revealed that all samples of
193 *lunica+lilaea* form a monophyletic group sister to *formosanus* samples, which also formed a
194 monophyletic group. The p-distance was 0.0017 between *lunica* and *lilaea* and 0.0505–0.0525
195 between *lunica+lilaea* and *formosanus*. PTP, ABGD and GMYC all recognize a two species
196 scenario, with *lunica+lilaea* and *formosanus* each representing a distinct species. Therefore,
197 *formosanus* is recognized as a species distinct from *lunica+lilaea*, with the combination as
198 *Symbrenthia formosanus* Fruhstorfer, 1908 (**stat. rev.**). The taxon *lunica* Bascombe, Johnston &
199 Bascombe, 1999 is proposed to be lumped with *lilaea*, Hewitson, 1864 (**syn. nov.**) herein as the

200 two may not be distinguished by COI barcode nor adult and immature morphology. We thus will
201 call them *S. formosanus* and *S. lilaea* respectively in the remaining text of this article.

202

203 **Environmental factors which contribute to the distribution of *Symbrenthia* species in**

204 **question**

205 After applying "usdm" package to remove those highly correlated factors, "bio 2", "bio 8", "bio
206 12" (Fig. 7A & 7B) are used to construct the species distribution model of "early invasive stage",
207 while "bio 7", "bio 8", "bio 9", "bio 12", "bio 18" (Fig. 7C & 7D) are used to construct the
208 species distribution model of "late invasive stage". According to the results of the jackknife test,
209 the factors show different contribution patterns in the early invasive stage. In the early invasive
210 stage, "bio 2" (annual precipitation) and "bio 12" (air temperature) contribute reversely between
211 these two species; annual precipitation contributes more than mean diurnal air temperature range
212 in the distribution model of *S. formosanus*, whereas mean diurnal air temperature range
213 contributes more than annual precipitation amount in the model of *S. lilaea*.

214 Comparing the jackknife results of both species between the two invasive stages, "bio 8"
215 contributes the most among all models. According to this, the mean daily air temperatures of the
216 wettest quarter may play a key role in the distribution of these two *Symbrenthia* species in
217 Taiwan.

218

219 **The species distribution model and niche shifting of the two *Symbrenthia* species in**
220 **different time stages**

221 According to the species distribution model results, *S. formosanus* does not show an obvious
222 change between the early and late invasive stages (Fig. 6A & 6C). For both invasive stages, the
223 presence probability of *S. formosanus* seems to be higher in the suburban areas and places with
224 less human activity. For *S. lilaea*, the distribution model presents different results between the
225 two time stages (Fig. 6B & 6D). Particularly, presence probability in the southwest part of
226 Taiwan is higher in the later invasive stage (Fig. 6D). The SDM results of both species show that
227 the presence probability decreases in the Pingtung area, the southernmost county of Taiwan.
228 Although there may be biological importance to this observation, it is most likely a result of
229 uneven presence observation point density in the later stage. Most of the presence points for the
230 late invasive stage SDM are from northern Taiwan.

231 From the results of the early and late invasive stages (Fig 8), the niche overlap value
232 increased during the recent years (past-2012 D: 0.48; 2013-2021 D: 0.64), and the niche
233 expansion value of *S. lilaea* remained zero between the two different time stages. Together, these
234 mean that, during these two periods of time, the niche of this alien species did not extend beyond
235 the niche of the native species. According to the ENM model and the niche shift results,

236 competitive exclusion seems to not be occurring between these two species over these 18 years.

237

238 **Discussion**

239 **Taxonomic status of the introduced and native *Symbrenthia* butterflies**

240 The introduced and native *Symbrenthia* butterflies in question of the study were regarded as

241 conspecific subspecies prior to the present study (e. g. *Hsu et al., 2022; Fric et al. 2022*). It has

242 been argued that species delimitation is difficult for allopatric populations or subspecies of

243 similar forms (*King, 1993; Braby et al., 2012*), but in the present case, the introduction of

244 continental *S. lilaea* to Taiwan has proven that insular *S. formosanus* ought to represent a species

245 endemic to the island, instead of being a geographical race of the former. Distinctions between

246 them include: 1) distal band on hindwing uppersides of both sexes form a continuous orange

247 stripe in *S. lilaea* (Fig. 1A & 1C), whereas it is interrupted by darkened veins in *S. formosanus*

248 (Fig. 1E & 1G); 2) distal tip of uncus is acute in *S. lilaea* (Fig. 3A), whereas it is blunt in *S.*

249 *formosanus* (Fig. 3D); 3) distal margin of harpe+sacculus is rounded in *S. lilaea* (Fig. 3A),

250 whereas it is angled, somewhat squared in *S. formosanus* (Fig. 3D); 4) ampulla is stout, slightly

251 down-curved in *S. lilaea* (Fig. 3A), whereas it is slender, strongly bent downwards in *S.*

252 *formosanus* (Fig. 3D); 5) posterior margin of sterigma is concave in *S. lilaea* (Fig. 3C), whereas

253 it is truncate in *S. formosanus* (Fig. 3F); 6) yellow eggs are laid in cluster in *S. lilaea* (Fig. 4A),

254 in contrast to green eggs laid singly in *S. formosanus* (Fig. 4D); 7) larvae are gregarious in *S.*

255 *lilaea* (Fig. 4B-4C), but solitary in *S. formosanus* (Fig. 4E–4F).

349

350 **Niche overlap between two *Symbrenthia* species in Taiwan**

351 Many studies have reported that when a newly introduced species is present, competitive
352 exclusion could be observed between the alien and similar native species (*Mooney &*
353 *Cleland., 2001; Paine et al., 2008; Muthukrishnan et al., 2018*). However, our study presents a
354 different aspect of this interaction. Both the SDM and the niche overlap results showed that the
355 degree of overlap of the presenting area between these two species increases over time (Fig. 8).
356 This means that competitive exclusion may not be present between the alien and the native
357 species. This result may be explained by the following two alternative scenarios:

358 Firstly, obvious competition for the two species may not be observed due to insufficient
359 time of introduction of the alien species. *S. lilaea* was first found on the main island of Taiwan as
360 recently as 2004, and thus may still be in the process of population establishment and early
361 growing stages (*McGeoch et al., 2019*). Consequently, the competitive exclusion effect between

362 these two species may have not yet occurred or not yet occurred to a level observable by our
363 available data.

364 Secondly, perhaps no competitive exclusion will occur between the two *Symbrenthia*
365 species due to abundant host plant resources. Some studies have shown that host plants are much
366 more important for the distribution of herbivorous insects when compared with the abiotic
367 environmental factors (*Wiens et al., 2010; Simões & Peterson., 2018*). These two butterfly
368 species feed on several species in the family Urticaceae, and most of these host plants are
369 common and abundant in Taiwan (*Yang et al., 1996*). The food supply to the caterpillars of
370 *Symbrenthia* may therefore be beyond the demand of both species combined, resulting in the
371 absence of interspecific competition.

372 It awaits to be seen which scenario is more likely to occur, but it may be worthwhile to
373 notice that *S. formosanus* was abundant in the Yangmingshan National Park of northern Taiwan
374 (*Chang, 1994*), but in a butterfly survey conducted with sampling on monthly basis there from
375 the beginning of 2021 to date, only *S. lilaea* has been recorded (*Hsu et al., unpublished data*).
376 This observation suggests competition between the two species may actually have initiated.

377

378 **Distribution difference of *S. lilaea* between two different invasive stage**

379 The SDM of *S. lilaea* shows different result patterns between the early and late invasive time

380 stages (Fig. 6B & 6D). Especially in southwest portion of Taiwan, the presence probability
381 increases significantly in the late invasive stages. This phenomenon can be the result of the
382 expansion of the distribution area of this alien species. The first record of *S. lilaea* is in Xinzhu
383 county located in the northwest part of Taiwan. The distribution area of this species gradually
384 expanded during the 18 years since it was first observed in Taiwan, and this butterfly species can
385 today be observed in nearly all lowland areas around Taiwan.

386 The species distribution model (SDM) has been widely used as a tool to detect the potential
387 invasive area of invasive species (*Wiens et al., 2010; Ahmed et al., 2020*). Based on the niche
388 conservatism of the invasive species, we are usually able to predict the invasive area based on
389 areas in the invaded region with similar environment to the source area from which the species
390 originated. However, the SDM difference of *S. lilaea* between two different invasive stages
391 suggests that the SDM may have inaccurately predicted potential areas of invasive species
392 presence. The niche may be hard to quantify, even though some studies have suggested methods
393 to measure it (*Framiout & Monnet et al., 2018; Lei et al., 2019*), but introduced species usually
394 still undergo niche expansion in the newly invaded area (*Datta et al., 2019; Bates et al., 2020*).
395 Although SDM is still a widely used tool to evaluate potential impact of invasive species, the
396 inaccuracy of the model is inevitable due to the reasons addressed above. We suggest to include
397 more biotic factors of the invasive species when predicting potential invasive regions rather than

398 relying on the SDM results alone. By combining the biotic variables with the SDM constructed
399 by the abiotic variables, the results should be closer to the realistic distribution pattern.

400

401 **CONCLUSIONS**

402 Species delimitation employing an integrative taxonomy approach has helped to clarify
403 taxonomic entities of an introduced and a native *Symbrenthia* butterfly taxa regarded conspecific
404 to date, leading to a decision to recognize each as a distinct species. This result suggests that
405 interspecific competition may occur by the introduction of the alien species, rather than gene
406 introgression. Subsequently, a niche modeling investigation was following, and the result
407 showed that competition between the two species interest has not yet occurred or just initiated.

408

409 **ACKNOWLEDGEMENTS**

410 We are grateful to Dr. Jen-Pan Huang, Mr. Ming-Hsun Chou (both from Academia Sinica) and
411 Mr. Trevor Padgett (Academia Sinica & Tunghai University) for reading and improving the
412 manuscript of this article. We also thank Dr. Masaya Yago (The University Museum, University
413 of Tokyo) for helping us with valuable literatures. Also, we express our gratitude for the DNA
414 Sequencing Core Facility of the Institute of Biomedical Sciences of Academia Sinica, Taipei, for
415 providing DNA sequencing service.

416

417 **Data Availability**

418 The following information was supplied regarding data availability:

419 Voucher specimens are housed at Department of Life Science, National Taiwan University,

420 Taipei, R. O. C. and Biodiversity Research Center, Academia Sinica, Taiwan, R. O. C.
