

Real-life experience with personally familiar faces enhances discrimination based on global information

Meike Ramon, Goedeke Van Belle

Despite the agreement that experience with faces leads to more efficient processing, the underlying mechanisms remain largely unknown. Building on empirical evidence from unfamiliar face processing in healthy populations and neuropsychological patients, the present experiment tested the hypothesis that personal familiarity is associated with superior discrimination when identity information is derived based on global, as opposed to local facial information. Diagnosticity and availability of local and global information was manipulated through varied physical similarity and spatial resolution of morph faces created from personally familiar, or unfamiliar faces. We found that discrimination of subtle changes between highly similar morph faces was unaffected by familiarity. Contrariwise, relatively more pronounced physical (i.e., identity) differences were more efficiently discriminated for personally familiar faces, indicating more efficient holistic processing of facial information through real-life experience.

Real-life experience with personally familiar faces enhances discrimination based on global information

1 **Abstract**

2 Despite the agreement that experience with faces leads to more efficient processing, the
 3 underlying mechanisms remain largely unknown. Building on empirical evidence from
 4 unfamiliar face processing in healthy populations and neuropsychological patients, the present
 5 experiment tested the hypothesis that personal familiarity is associated with superior
 6 discrimination when identity information is derived based on global, as opposed to local facial
 7 information. Diagnosticity and availability of local and global information was manipulated
 8 through varied physical similarity and spatial resolution of morph faces created from
 9 personally familiar, or unfamiliar faces. We found that discrimination of subtle changes
 10 between highly similar morph faces was unaffected by familiarity. Contrariwise, relatively
 11 more pronounced physical (i.e., identity) differences were more efficiently discriminated for
 12 personally familiar faces, indicating more efficient holistic processing of facial information
 13 through real-life experience.

1 Introduction

2 Humans are highly efficient at processing faces of conspecifics. Within a few hundred
3 milliseconds, we can categorize faces according to their gender, expression, race and
4 familiarity, as well as identify them. The social importance of face processing, and its
5 complexity as a perceptual and cognitive process has motivated numerous investigations of
6 the underlying mechanisms. Several lines of research indicate that processing of identity
7 information is linked to observers ability to integrate global facial information, also referred to
8 as holistic processing, a hallmark of adult's face processing expertise (McKone, Kanwisher, &
9 Duchaine, 2007; Mondloch, Pathman, Maurer, Le Grand & de Schonen, 2007; Richler &
10 Gauthier, 2013). Neuropsychological studies have demonstrated that face processing deficits
11 observed in prosopagnosia can be accounted for by patients' impairment of holistic processing
12 (e.g., Ramon, Busigny & Rossion, 2010; for a review see Rossion, 2014). Furthermore, recent
13 evidence suggests a direct relation between the extent of holistic processing and healthy
14 observers' face processing efficiency (Wang et al., 2012).

15 While the most impressive demonstration of humans' face processing ability is
16 observed for *familiar* faces, the bulk of empirical evidence regarding its determinants stems
17 from experiments involving *unfamiliar* face stimuli. Several studies indicate that personally
18 familiar faces are processed more efficiently than their unfamiliar counterparts (e.g., Bruce,
19 Henderson, Greenwood, Hancock, Burton & Miller, 1999; Burton, Wilson, Cowan & Bruce,
20 1999; Ramon, Caharel & Rossion, 2011). Familiar identities can be behaviorally categorized
21 as such significantly faster than unfamiliar faces, within as little as 310 ms (Ramon, Caharel
22 & Rossion, 2010; see also Busigny, Bled, Besson & Barbeau, 2012), with differential
23 electrophysiological responses occurring 100 ms prior (Caharel, Ramon & Rossion, 2014).
24 Moreover, the presence of an underlying facial representation stored in memory makes
25 perceptual processing more robust to variations in the input characteristics. For instance, we
26 can easily recognize a famous or personally familiar face based on their eyes alone (Sadr,
27 Jarudi & Sinha, 2003; Ramon, Busigny, Gosselin & Rossion, in preparation), or from a highly

degraded image (Watier & Collin, 2009; Loftus & Harley, 2005; Ramon et al., in preparation), and even after considerable time periods (Bahrick, Bahrick & Wittingler, 1975). Contrariwise, identity processing in unfamiliar faces is highly dependent on the visual characteristics of the stimulus input, i.e., availability of color, texture, and surface reflectance (Russell, Sinha, Biederman & Nederhouser, 2006; Jiang, Blanz & Rossion, 2011), and is hence more prone to error given superficial image variations (e.g., viewpoint or image quality; Bruce 1986; Roberts and Bruce 1989; Bruce, Henderson, Newman & Burton, 2001).

Together, these observations support the general consensus that unfamiliar and personally familiar faces are processed differently (cf., Tong & Nakayama, 1999; Megreya & Burton, 2006; Carbon, 2008; Gobbini et al., 2013). However, there is little understanding of the underlying mechanisms promoting such differential processing. While early studies using famous faces have suggested that familiarity affects processing of internal facial information in general (Ellis, Shepherd & Davies, 1979; Young, Hay, McWeeny, Flude & Ellis, 1985; Brooks & Kemp, 2007), other investigations have provided inconsistent results regarding whether or not its effects are restricted to processing of the eyes only (O'Donnell & Bruce, 2001), or extends to the less salient mouth region (Barton, Radcliffe, Cherkasova, Edelman & Intriligator, 2006; Van Belle, Ramon, Lefèvre & Rossion, 2010). However, more recent findings may reconcile these seemingly conflicting findings. Ramon (2015a,b) reported that personal familiarity affects discrimination of vertical displacements of the eyes and the mouth, as well as changes of the overall configuration between these two sources of information. These findings suggest that personal familiarity may not affect processing of specific *types* of facial information, but rather modulate the *processing style* engaged in.

The present study sought to extend these previous findings by varying the degree to which local or global information was diagnostic for identity discrimination. The underlying idea is that personal familiarity facilitates perceptual processing, and thus discrimination of faces through the presence of a facial representation in memory. Given the relationship between holistic processing and processing of identity (Sergent, 1984; Tanaka & Farah, 1993,

2003), our hypothesis was that such enhanced perceptual processing for familiar compared to unfamiliar faces would be observed along with decreased reliance on local, piecemeal information.

In a delayed matching paradigm, observers performed forced-choice decisions of facial identity. The face stimuli used to this end were derived from morph continua similar to those used in investigations of categorical perception of identity, or expression (Beale and Keil, 1995 ; Gilaie-Dotan & Malach, 2005; Fox, Moon, Iaria & Barton, 2009; Ramon, Dricot & Rossion, 2010). The parametric variations in identity-related physical information offered a means to manipulate the perceptual similarity and hence ambiguity of information supporting discriminative decisions.¹ While dissimilar stimuli could be more easily discriminated based on global information, discrimination of more similar ones would be comparably less efficient and require more local distinctive feature sampling. Hence, our experimental conditions differed in the extent to which discrimination would be based on global, or holistic processing (defined here as the fast and automatic process leading to an internal representation of the face as a whole; Galton, 1883; Rossion, 2013).

Importantly, to investigate whether personal familiarity selectively affects global processing, or leads to a general processing advantage, two groups of observers completed the same task. Control subjects were unfamiliar with *all* of the identities depicted. The experimental group comprised subjects who were highly personally familiar with *half* of the identities, which represented their classmates.

Thus, contrary to previous studies, we varied two aspects that are considered to modulate observers face processing efficiency. On the one hand, the physical similarity of face stimuli (which co-varies with discrimination efficiency based on global information), as well as observers' familiarity with face stimuli. In line with the high discrimination

¹ Previous studies have demonstrated that increased physical similarity is associated with decreased discriminability and therefore more piecemeal processing of local cues (e.g. pixel-based intensity, or color differences; Barton et al., 2006; Orban de Xivry, Ramon, Lefèvre & Rossion, 2008; Busigny, Graf, Mayer & Rossion, 2010; Van Belle, Lefèvre & Rossion, 2012), i.e. decreased reliance on initial holistic or global processing. Note that other authors have applied the same morphing techniques to e.g. identities differing merely in regard to a single feature (Goffaux, 2012) or a metric relation between features (Gilad-Gutnik, Yovel & Sinha, 2012).

performance reported for familiar vs. unfamiliar face discrimination, a beneficial effect of familiarity was anticipated for conditions of low similarity considered to involve reliance on global information. Contrariwise, no such familiarity-related advantage was expected for discrimination of highly similar faces, which would rely on observers' ability to identify locally circumscribed details.

Naturally, local details are also available in conditions of low similarity, and thus could be used for face discrimination. Therefore, we incorporated a third condition involving low similarity. Here, the local, high resolution information was made unavailable through stimulus blurring (Sergent, 1986; Collishaw & Hole, 2000; Schwaninger, Wallraven, Cunningham & Chiller-Glaus, 2006; Gilad-Gutnick et al., 2012). Thus, we removed high spatial frequency information typically used for piecemeal analytic processing (Goffaux, 2009; Goffaux & Rossion, 2006).

In sum, we manipulated stimulus similarity, availability of high resolution local details, as well as personal familiarity to directly test—for the first time to our knowledge—the hypothesis that familiarity leads to an advantage in global/holistic, but not local processing. Two possible outcomes were anticipated. First, if familiarity were associated with an advantage at processing local discriminative information, we should observe a familiarity advantage across both conditions involving high resolution images enabling the use of said information. Alternatively, if familiarity is advantageous for automatic global processing, we should observe an experience-related benefit for conditions involving low stimulus similarity—regardless of whether high spatial information used for local information processing is available.

Methods

Procedure and apparatus

Participants performed a two to one alternative forced-choice delayed matching task. Each trial started with a centrally presented fixation cross. Upon fixation of the central

fixation cross, two probe faces (distance between the inner borders: 5° of visual angle) were presented side by side for 2.5s. This pair of probe faces was followed by a single test face, which was identical to one of the two probes (sides counterbalanced) and remained on screen until participants indicated to which of the probes the test face corresponded by pressing the corresponding left or right arrow button on the keyboard. The next trial was initiated immediately after each response.

The experiment consisted of six blocks of 40 trials in total. There were 3 blocks for familiar, and 3 blocks for unfamiliar face stimuli, respectively. Each block, consisted of trials of one of the three experimental conditions (Full 20%, full 50%, blur 50%; see below). The order of the blocks in terms of familiarity and similarity condition was counterbalanced across participants (note that control subjects were unfamiliar with all faces used as stimuli; see below). Within each block there was an equal amount of left and right correct response sides and both faces from each of the 10 stimulus pairs appeared twice as the test stimulus. This procedure ensured equal likelihood of perceiving either identity (see Ramon et al., 2010).

To become familiar with the task, participants completed 5 practice trials prior to the main experiment. These practice trials contained faces that were not used in the main experiment and were excluded from analysis. Stimuli were displayed using Presentation or Eprime software, on a 22" Sony Trinitron monitor (58cm viewing distance, 1400 x 1050 pixel resolution, 85 Hz refresh rate). Probe and test faces' height comprised 10.3 and 11.5° of visual angle, respectively. This roughly corresponds to the size of a real face viewed at normal conversational distance of 90 cm (Hall, 1966). Both stimulus display and response registration was controlled by an Intel Centrino vPro.

Stimuli

Two different sets of stimuli were used in the main experiment. The first was taken from a previous study (Ramon et al., 2010) and involved 10 morph continua, the extremes of which were unfamiliar to all participants. An additional set of 10 morph continua were created between pairs of faces with which half of the participants were personally familiar: their

classmates. To this end full-front photographs of 26 students of the same class were taken under identical conditions (distance, lighting). The photographs of five male and one female student were excluded from the final set of familiar faces used, due to the presence of facial hair or make-up at the time the photographs were taken. Using Adobe Photoshop, the remaining 20 familiar face stimuli were cropped of external features and hair (see Figure 1a) and morph continua were created with Photo Morpher v3.10 (Morpheus, Santa Barbara, CA, USA) following the same procedure as used by Ramon et al. (2010). Specifically, face pairs were selected based on eye color, shape and overall luminosity of the face. For each face, 350 points were placed on the critical features (encompassing the pupils, iris, eye bulbs, eye lids, eye brows, mouth, nose and overall facial contour) to allow smooth transitions between the stimuli created per morph continuum (two original faces representing the extremes, with 10% increments; see Figure 1a).

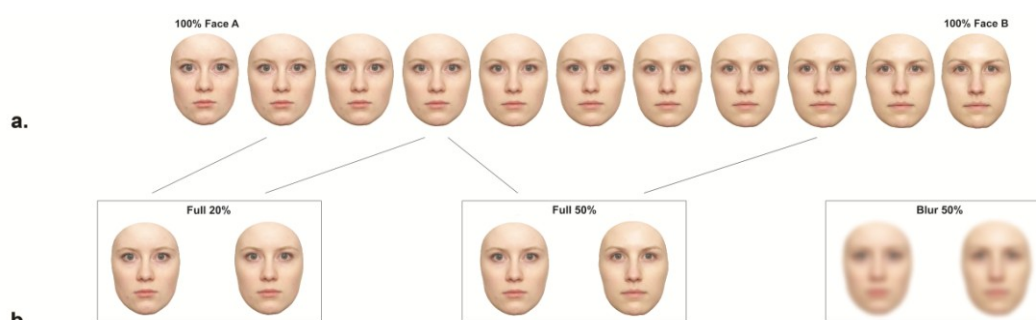

Figure 1. Stimuli discriminated in the delayed matching task. a. An example of an unfamiliar face morph continuum. Unfamiliar stimuli were those used by Ramon et al. (2010), which were unfamiliar to all subjects tested. Familiar morph continua were created from pairs of classmates of experimental subjects tested, and were unfamiliar to control subjects. **b.** Examples of stimulus pairs to be discriminated in the 2AFC delayed matching task (pairs were taken from either side of a continuum; see Ramon et al., 2010).

As described above, our hypothesis states that personal familiarity would facilitate discrimination of faces by an amount *depending on their physical similarity*. We therefore created 3 conditions resulting in three degrees of reliance on local distinctive features, and therefore three different degrees at which performance is determined by global processing. The first condition involved probe face pairs of stimuli differing by 20% (physically similar pairs, *Full 20%*) that were located on the same side of the categorical boundary of the morph continua (i.e., the point where both identities would be perceived with equal likelihood; see e.g. Beale & Keil, 1995; Gilaie-Dotan & Malach, 2007; Ramon et al., 2010; Rotshtein,

Henson, Treves & Driver & Dolan, 2005). The second condition involved pairs of stimuli which differed by 50% (physically dissimilar pairs, *Full 50%*) and were located on opposite sides of the categorical boundary of the morph continua. Note that the distance of these more dissimilar items relative to both extremes (i.e., original faces) and the categorical boundary was identical to the physical difference between *Full 20%* pairs (see Figure 1).² In the full 20% condition the faces are more similar than in the Full 50% condition, making the comparison more ambiguous, and comparably more dependent on local information. A third condition involved the same dissimilar pairs (*Full 50%*), to which a Gaussian blur (30 pixel radius; see e.g., Gilad-Gutnick et al., 2012) was applied in order to make high resolution information (e.g., freckles, wrinkles, etc.) less available (physically dissimilar pairs of blurred faces, *Blur 50%*). As described above, this was done to disable to the use of local features in conditions of low similarity.

Participants

Twelve participants (mean age: 23±1; 3 male), who were personally familiar with half of the individuals depicted in the stimuli (from here on referred to as ‘experimental group’, were financially compensated for their participation. They were all senior year psychology master students who had been following classes in the same group of ~30 students for about 2 years at the time of testing; some knew each other for a maximum of 5 years (data collection occurred while students were still in the cohort). The control group comprised 12 participants (mean age: 25±4; 4 male), who were unfamiliar with the entire set of individuals used to create the face images used, and were also financially compensated for participation. The experiments were undertaken with the understanding and written consent of each subject, and conform to The Code of Ethics of the World Medical Association (Declaration of Helsinki).

² For trials on which probe stimuli differed by 20% (*Full 20%*, see Figure 1a), probes were selected to depict a given identity by 90% and 70% (test stimuli always depicted a given identity by 90%). For trials on which probe stimuli differed by 50% (*Full 50%*, *Blurred 50%*), the probes represented a given identity by 70% and 20%; test stimuli always depicted a given identity by 20%.

Analyses

The analyses were conducted separately on accuracy scores and correct RTs as individual subjects may differ in terms of the measure they exhibit performance differences (Pachella, 1974; Meyer, Irwin, Osman & Kounios, 1988). For each subject and condition separately, familiarity indexes $((\text{familiar} - \text{unfamiliar}) / (\text{familiar} + \text{unfamiliar}))$ were computed for accuracy and correct RTs to capture potential effects of stimulus familiarity (which in the case of the control group would capture any perceptual differences between the sets of stimuli, which were both unfamiliar to them). These familiarity indexes will further be referred to as ‘*the familiarity advantage*’. Using SPSS, we conducted a mixed model repeated measures ANOVA on the familiarity advantage with one between-subjects factor (group: *experimental vs. control*), and one within-subject factor (condition: *Full 50%, Full 20%, Blur 50%*). Post-hoc contrasts between individual factor level combinations were Bonferroni corrected. Raw accuracy and RT values per group and condition, as well as 95% bootstrapped confidence intervals can be found in the supplemental material (Table S1). None of the conditions was associated with performance at chance or ceiling level.

Results

The analyses conducted on the familiarity indexes (reflecting potentially beneficial effects of stimulus familiarity assumed for the experimental group, as controls were unfamiliar with both stimulus sets used; see Methods) revealed a main effect of condition for accuracy scores ($F(2,44)=16.11, p<.01, \eta_p^2=.42$), as well as for normalized RTs ($F(2,44)=3.65, p<.05, \eta_p^2=.14$). There was also a main effect of group, with generally larger familiarity advantages for the experimental, than the control group for accuracy ($F(1,22)=5.39, p<.05, \eta_p^2=.20$), but not for RTs ($F(1,22)=.25, p=.62, \eta_p^2=.01$). Most importantly, for accuracy scores we observed a significant interaction between group and condition ($F(1,22)=3.76, p<.01, \eta_p^2=.15$), which was again not significant for RTs

1 (F(2,44)=1.63, $p=.21$, $\eta_p^2=.07$). Group means of the familiarity advantage for accuracy across
2 conditions are displayed in Figure 2.

3
4 **Figure 2. Familiarity advantage in the 2AFC delayed matching task with personally familiar and unfamiliar**
5 **morph stimuli.** Mean familiarity advantage ((familiar – unfamiliar) / (familiar + unfamiliar)) for accuracy scores
6 per condition observed for control, as well as experimental subjects. Error bars represent standard errors for both
7 measures. Note that for control subjects, all faces were unfamiliar.

8 Further investigation of the interaction effect for accuracy revealed that the familiarity
9 advantage was larger for the experimental group than for the control group in the Full 50%
10 condition ($t=3.08$, $p<.01$) and in the Blur 50% condition ($t=3.41$, $p<.01$), but not in the Full
11 20% condition ($t=.66$, $p=.52$). Furthermore, all differences between conditions in the
12 experimental group were significant, with a smaller familiarity advantage in the Full 20% than
13 Full 50% ($t=2.75$, $p<.05$) condition, and even larger in the Blur 50% ($t=4.16$, $p<.01$) than the
14 Full 50% condition. In the control group, the difference between familiar and unfamiliar
15 stimuli did not significantly vary across conditions ($ps>.05$).

16 Discussion

17 Several lines of empirical evidence suggest a relationship between face processing
18 efficiency and the ability to process faces holistically, i.e., the ability to rapidly integrate
19 information from across the entire face into a unified percept. Some studies indicate a direct
20 association between the degree of holistic processing exhibited by healthy observers, and the
21 efficiency with which upright faces are processed (e.g., Wang et al., 2012). Experimental

manipulations utilized to disrupt holistic processing include stimulus inversion, as well as increased physical stimulus similarity. Both lead to reliable decreases in face processing performance and have been associated with employment of a more local/featural processing style (Barton et al., 2006; Orban de Xivry et al., 2008, Van Belle, De Graef, Verfaillie, Busigny & Rossion, 2010), a phenomenon also observed in patients with prosopagnosia (i.e., the face selective recognition deficit due to brain damage), who have lost the ability to process faces holistically (e.g., Bukach, Le grand, Kaiser, Bub & Tanaka, 2008; Busigny & Rossion, 2010; Ramon et al., 2010a; Van Belle, Busigny, Lefèvre, Joubert, Felician, Gentile, Rossion, 2011; Van Belle, De Graef, Verfaillie, Busigny & Rossion, 2010; Van Belle, Lefèvre, Laguesse, Busigny, De Graef & Verfaillie, 2010; Rossion, 2014).

The present study aimed to investigate the effect of repeated, real-life experience with personally familiar individuals on perceptual processing of faces. Naturally, healthy observers have no difficulty in determining the identity of familiar individuals (see also e.g., Jenkins, White, Van Montfort & Burton, 2011; Ramon et al., in preparation)—a task for which ceiling effects can be expected. To manipulate the relative reliance on global versus local information processing for face discrimination, the stimulus material used here involved morph faces of varied physical similarity (e.g. Beale & Keil, 1995; Gilaie-Dotan & Malach, 2007; Ramon et al., 2010b; Rotshtein et al., 2005). Following previous research, discrimination of highly similar faces was assumed to be less efficient and rely more on processing of local details (Barton et al., 2006; Orban de Xivry et al., 2008). Contrariwise, dissimilar faces were anticipated to be distinguished more efficiently given automatic extraction of global information from across the entire face.

Most importantly, the experimental subjects tested here were personally familiar with half of the individuals used to create the morph stimuli presented. That is, not only did the face stimuli differ in their respective physical similarity, but also regarding the presence of a facial representation stored in memory. Replicating previous findings (e.g., Bruce et al., 1999; Burton et al., 1999; Ramon et al., 2011; Ramon, 2015a,b), we found that personal familiarity

was associated with enhanced face discrimination performance. Using morph stimuli differing in physical similarity and subjects' familiarity, we sought to determine whether this enhancement is due to more efficient global, as opposed to local processing; two potential outcomes were anticipated. First, selectively increased performance for familiar versus unfamiliar faces for high resolution images only (i.e., irrespective of physical (dis)similarity) would indicate higher efficiency at selecting discriminative local features for familiar than for unfamiliar faces. Alternatively, a familiarity-dependent advantage for discrimination of *dissimilar* faces only (i.e., for both high resolution and blurred images) would support the idea of experience-related increased efficiency for processing facial identity based on global or holistic processing.

The performance profiles observed for the discrimination of morph stimuli created from *personally familiar faces* was markedly different from that of unfamiliar faces. First, discrimination of highly similar (*Full 20%*) face morphs, which highly relies on local/featural processing (e.g., Barton et al., 2006; Orban de Xivry et al., 2008), was unaffected by familiarity. This finding, which cannot be accounted for in terms of floor effects, indicates that familiarity, i.e., extensive prior real-life experience does not lead to more proficient performance when processing relies on local information. Note that this coincides with Barton et al.'s (2006) findings that higher ambiguity and lack of familiarity lead to an increase in difficulty of perceptually based decisions as well as the need to accumulate more data (in their study: more fixations, longer durations; see also Althoff & Cohen, 1999). Second, mirroring the high efficiency with which personally familiar faces are generally processed, performance increased when discrimination of high-resolution, dissimilar faces (*Full 50%*) was required. Moreover, performance at discriminating the same level of similarity was superior for familiar relative to unfamiliar stimuli *despite* the unavailability of high-resolution, local information (*Blur 50%*).

These results are interpreted as a clear indication that facial representations stored in memory, as is the case for personally familiar faces, lead to enhanced global processing and

less reliance on high resolution local information for face discrimination. This is consistent with Rossion's (2013) description of the role of visual experience for holistic processing. Indeed, previous studies exploring the effects of cross-cultural and cohort-dependent exposure have reported increased holistic processing and superior face discrimination for faces with which subjects had extensive exposure, e.g., own-race (Michel, Rossion, Han, Chung & Caldara, 2006; Michel, Corneille & Rossion, 2007), own-age faces (de Heering & Rossion, 2008; Kuefner, Macchi Cassia, Picozzi & Bricolo, 2008), and faces presented in their canonical orientation (Van Belle et al., 2010b). The present findings thus add to a body of evidence suggesting a direct relationship between experience, increased holistic processing and face processing efficiency (see also e.g. Crookes, Favelle & Hayward, 2013; Degutis, Mercado, Wilmer & Rosenblatt, 2013; Susilo, Crookes, McKone & Turner, 2009; Proietti, Pisacane & Macchi Cassia, 2013). In fact, the present findings go even further, by showing that holistic processing is modulated not only by visual experience with the face category, but also by visual experience with individual faces, i.e. specific exemplars. Based on our findings we suggest that the global percept of an individual face can be influenced by an underlying representation obtained through real-life interactions and stored in memory. In keeping with the observation that personally familiar face identification is robust across viewing distances (Ramon, 2015b) and therefore efficient even provided only low spatial frequency information, we observed that familiarity was associated with a decreased reliance on local details for discrimination of facial identity.

In sum, these observations demonstrate that personal familiarity acquired through repeated, real-life interactions facilitates face discrimination through enhanced holistic processing. As such, they expand our current knowledge about the role of experience for holistic processing by demonstrating that not only experience with categories of faces, but also with individual faces can modulate their perceptual processing.

Supplemental material

Table S1 provides the accuracy scores and correct RTs per condition along with 95% bootstrapped confidence intervals. These were obtained per condition and group by randomly sampling subjects with replacement; this process was repeated 999 times, leading to a distribution of bootstrapped estimates of the mean accuracy and RT for each condition. Accuracy scores were considered above chance and below ceiling if the confidence intervals did not contain .5 nor 1, which was the case across groups and experimental conditions.

Table S1. Average accuracy scores and RTs in msec along with 95% bootstrap confidence intervals for each condition.

Group	Stimuli	Condition	Accuracy [95% CI]	RTs [95% CI]		
Experimental	Familiar	Full 20%	.62 [.57; .67]	1007 [916; 1101]		
		Full 50%	.98 [.96; .99]	769 [697; 849]		
		Blur 50%	.88 [.81; .94]	856 [811; 902]		
	Unfamiliar	Full 20%	0.65 [.58; .72]	1029 [926; 1138]		
		Full 50%	.86 [.83; .90]	870 [798; 940]		
		Blur 50%	.64 [.58; .70]	863 [797; 936]		
		Control	Familiar	Full 20%	.77 [.73; .81]	1037 [905; 1184]
				Full 50%	.91 [.87; .94]	870 [751; 1007]
Blur 50%	0.77 [.72; .81]			894 [783; 1021]		
Unfamiliar	Full 20%		.76 [.71; .81]	975 [803; 1169]
