Background. Animal conservation often requires intensive management actions to improve reproductive output, yet any adverse effects of these may not be immediately apparent, particularly in threatened species with small populations and long lifespans. Hand-rearing is an example of a conservation management strategy which, while boosting populations, can cause long-term demographic and behavioural problems. It is used in the recovery of the critically endangered kākāpō (*Strigops habroptilus*), a flightless parrot endemic to New Zealand, to improve the slow population growth that is due to infrequent breeding, low fertility and low hatching success.

Methods. We applied Bayesian mixed models to examine whether hand-rearing and other factors were associated with clutch fertility in kākāpō. We used projection predictive variable selection to compare the relative contributions to fertility from the parents' rearing environment, their age and previous mating experience, the parental kinship, and the number of mates and copulations for each clutch. We also explored how the incidence of repeated copulations and multiple mates varied with kākāpō density.

Results. The rearing status of the clutch father and the number of mates and copulations of the clutch mother were the dominant factors in predicting fertility. Clutches were less likely to be fertile if the father was hand-reared compared to wild-reared, but there was no similar effect for mothers. Clutches produced by females copulating with different males were more likely to be fertile than those from repeated copulations with one male, which in turn had a higher probability of fertility than those from a single copulation. The likelihood of multiple copulations and mates increased with female:male adult sex ratio, perhaps as a result of mate guarding by females. Parental kinship, mating experience and age all had negligible associations with clutch fertility.

Conclusions. These results provide a rare assessment of factors affecting fertility in a wild threatened bird species, with implications for conservation management. The increased fertility due to multiple mates and copulations, combined with the evidence for mate guarding and previous results of kākāpō sperm morphology, suggests that an evolutionary mechanism exists to optimise fertility through sperm competition in kākāpō. The high frequency of clutches produced from single copulations in the contemporary population may therefore represent an unnatural state, perhaps due to too few females. This suggests that opportunity for sperm competition should be maximised by increasing population densities, optimising sex ratios, and using artificial insemination. The lower fertility of hand-reared males may result from behavioural defects due to lack of exposure to conspecifics at critical development stages, as seen in other taxa. This potential negative impact of hand-rearing must be balanced against the short-term benefits it provides.

24 **ABSTRACT**

25 **Background.** Animal conservation often requires intensive management actions to improve reproductive
26 output, yet any adverse effects of these may not be immediately apparent, particularly in threatened
27 species with small populations and long lifespans. Hand-rearing is an example of a conservation man-
28 agement strategy which, while boosting populations, can cause long-term demographic and behavioural
29 problems. It is used in the recovery of the critically endangered kākāpō (*Strigops habroptilus*), a flightless
30 parrot endemic to New Zealand, to improve the slow population growth that is a result of infrequent
31 breeding, low fertility and low hatching success.

32 **Methods.** We applied Bayesian mixed models to examine whether hand-rearing and other factors were
33 associated with clutch fertility in kākāpō. We used projection predictive variable selection to compare
34 the relative contributions to fertility from the parents' rearing environment, their age and previous mating
35 experience, the parental kinship, and the number of mates and copulations for each clutch. We also
36 explored how the incidence of repeated copulations and multiple mates varied with kākāpō density.

37 **Results.** The rearing status of the clutch father and the number of mates and copulations of the clutch
38 mother were the dominant factors in predicting fertility. Clutches were less likely to be fertile if the
39 father was hand-reared compared to wild-reared, but there was no similar effect for mothers. Clutches
40 produced by females copulating with different males were more likely to be fertile than those from
41 repeated copulations with one male, which in turn had a higher probability of fertility than those from a
42 single copulation. The likelihood of multiple copulations and mates increased with female:male adult sex
43 ratio, perhaps as a result of mate guarding by females. Parental kinship, previous mating experience and
44 parent age all had negligible associations with clutch fertility.

45 **Conclusions.** These results provide a rare assessment of factors affecting fertility in a wild, threatened
46 bird species, with implications for conservation management. The increased fertility due to multiple
47 mates and copulations, combined with the evidence for mate guarding and previous results of kākāpō
48 sperm morphology, suggests that an evolutionary mechanism exists to optimise fertility through sperm
49 competition in kākāpō. The high frequency of clutches produced from single copulations in the contem-
50 porary population may therefore represent an unnatural state, perhaps due to too few females. This
51 suggests that opportunity for sperm competition should be maximised by increasing population densities,
52 optimising sex ratios, and using artificial insemination. The lower fertility of hand-reared males may result
53 from behavioural defects due to lack of exposure to conspecifics at critical development stages, as seen
54 in other taxa. This potential negative impact of hand-rearing must be balanced against the short-term
55 benefits it provides.

56 INTRODUCTION

57 Factors affecting fertility in conservation-managed populations

58 Conservation strategies for wild-living threatened species rely on improving survival and productivity to
59 increase population growth. Methods such as habitat restoration and predator control are used to enhance
60 survival, but it is often problems with reproductive output which most limit recovery (Bunin et al., 1997;
61 Gage et al., 2006; Comizzoli and Holt, 2019) and can have wide-ranging implications (Findlay et al.,
62 2019). Management techniques used to address these problems include translocations, supplementary
63 feeding and artificial insemination (Lloyd and Powlesland, 1994; Castro et al., 2003; Houston et al., 2007;
64 Armstrong and Seddon, 2008; Blanco et al., 2009; Heber et al., 2012; Dogliero et al., 2017; Schneider
65 et al., 2019). However, there has been little study of whether the conservation actions used to promote
66 population growth of threatened species can in fact themselves impact productivity. This is at least partially
67 due to any unintended consequences not being immediately apparent, especially in threatened species
68 for which the ability to recognise significant trends is hampered by small sample sizes (Garamszegi,
69 2016). Here we consider factors which can affect fertility in conservation-dependent species, including
70 the conservation management actions intended to improve population growth.

71 Hand-rearing, in which animals are raised in captivity by humans, is often used in threatened species
72 conservation programmes (Klusener et al., 2018), primarily to increase productivity by improving survival
73 during development to maturity (Alagona, 2004; Heezik et al., 2005). However, this intervention can have
74 negative impacts, mainly by reducing long-term survival (Aourir et al., 2013; Hampson and Schwitzer,
75 2016; Farquharson et al., 2021) and introducing behavioural issues (Utt et al., 2008; Jones, 2008; Pacheco
76 and Madden, 2021) which may cause hand-raised individuals to be unsuited to life in the wild (Meretsky
77 et al., 2000). These behavioural differences appear to affect productivity in some taxa (King and Mellen,
78 1994; Beck and Power, 1988; Hampson and Schwitzer, 2016), although the impacts are poorly understood

79 in wild bird species (Assersohn et al., 2021a).

80 Mating behaviour, in terms of the number of mates and copulations, can directly affect fertility in
81 birds. Females can increase the likelihood of egg fertilisation through polyandry — the ‘fertility assurance
82 hypothesis’ (Birkhead et al., 1987; Reding, 2014; Rivers and DuVal, 2019; Santema et al., 2020) — and
83 by copulating repeatedly with a single male (Zhang et al., 2019). These behaviours are influenced by
84 adult sex ratio (Grant and Grant, 2019; Birkhead and Montgomerie, 2020): when competition is high,
85 females in some species use repeated copulations to ‘guard’ preferred males and copulate with alternative
86 males when their preferred choice is not available (Petrie et al., 1992).

87 Age affects reproductive output in some bird species (Murgatroyd et al., 2018; Brown et al., 2019),
88 but not others (Zhang et al., 2014; Fay et al., 2020) and in general is poorly studied in wild birds. Mating
89 experience can also affect reproductive output: evidence suggests that both males and females with a
90 greater number of previous breeding attempts may have higher reproductive success (Kokko, 1997; DuVal,
91 2012; Assersohn et al., 2021a), and so are preferred as mates (Kokko et al., 1999; Jouventin et al., 1999).
92 Diet is also an important factor in avian reproductive output (Selman and Houston, 1996; Klasing, 1998),
93 but this has also not been studied in most wild bird species (Klasing, 1998; Assersohn et al., 2021a).
94 Fertilisation failure and very early embryo death can also result from increased homozygosity due to
95 matings between closely-related individuals (Hemmings et al., 2012; Assersohn et al., 2021b).

96 **Kākāpō**

97 Low productivity limits population recovery of the kākāpō (*Strigops habroptilus*), a critically endangered,
98 nocturnal and flightless parrot which is endemic to Aotearoa/New Zealand. Infrequent breeding, high
99 infertility and low hatching success have hampered conservation efforts (Clout, 2006), although intensive
100 management increased the population from 51 in 1995 to approximately 200 individuals in 2022. Remnant
101 populations of kākāpō were translocated to predator-free island sanctuaries in the 1980s (Powlesland
102 et al., 1995), and breeding has since occurred on five refuge sites: Whenua Hou/Codfish Island, Te
103 Hauturu-o-Toi/Little Barrier Island, Te Hoiere/Maud Island, Pearl Island and Pukenui/Anchor Island
104 (Elliott et al., 2006). All kākāpō are free-living in the wild, except during hospitalisation or rearing for
105 some individuals.

106 Kākāpō breeding occurs irregularly, synchronised with the mass-fruiting (masting) of certain tree
107 species, particularly the rimu tree (*Dacrydium cupressinum*). Rimu masts every 2–4 years (Harper et al.,
108 2006) and is the predominant food fed to chicks when available (Cottam, 2010). The kākāpō is the only
109 parrot species with a lek mating system (Merton et al., 1984): females visit leks to choose and copulate
110 with displaying males (Eason and Moorhouse, 2006), and both sexes often copulate with multiple partners.
111 Females typically lay 2–3 eggs per clutch (range = 1–5). Males do not contribute to incubation or care
112 of offspring. We refer to males as ‘mates’ if they have copulated with a female; it does not imply a pair
113 association.

114 **Low fertility in kākāpō**

115 A primary reason for low productivity in kākāpō is the high rate of infertility. Approximately 40% of
116 kākāpō eggs are considered infertile from visual inspection (‘candling’), although a recent fluorescence
117 microscope study showed that 72% of these ‘apparently infertile’ kākāpō eggs were actually fertile, and
118 instead failed due to very early embryo death (Savage et al., 2021).

119 There are a number of factors which may contribute to low fertility in kākāpō. With a small founding
120 breeding population of 35 individuals and low levels of genetic diversity, inbreeding may be an important
121 contributor (Bergner et al., 2016; Dussex et al., 2018, 2021; Guhlin et al., 2022). Decreased female
122 heterozygosity is correlated with lower hatching success and smaller clutch size in kākāpō (White et al.,
123 2014), but male heterozygosity has no apparent effect on fertility, perhaps because males with the lowest
124 heterozygosity may not mate at all (White, 2012).

125 Rearing environment may also influence fertility in kākāpō. All copulations occur in the wild, but eggs
126 are often incubated artificially to maximise hatching success, and chicks are removed for hand-rearing
127 if their life is at risk. This hand-rearing has caused behavioural issues, with two male chicks reared
128 individually in 1997 and 1998 displaying imprinting on humans (Eason and Moorhouse, 2006).

129 Repeated copulations and multiple mates could affect fertility in kākāpō, as it does in other species
130 (Torok et al., 2003; Santema et al., 2020). Repeated copulation in lekking species can also provide a
131 strong test of theories for polyandry (Parker and Birkhead, 2012; Rivers and DuVal, 2019).

132 As a long-lived species with a life expectancy of several decades, kākāpō might experience age-related
133 changes in reproductive output. Young age is a barrier to fertility: both sexes can mate from five years old,
134 but no males younger than eight have produced fertile clutches. Impacts towards the end of life are less
135 clear, since the age of kākāpō discovered as adults cannot be determined (Horn et al., 2011), but White
136 (2012) found no impact of male age on egg fertility.

137 As a lek-breeding species, there is a high skew in kākāpō reproductive success, with a small number of
138 males dominating copulations (Eason et al., 2006). The subsequent large variation in mating experience
139 may also affect fertility.

140 Kākāpō are provided with supplementary food during breeding years to optimise productivity (Elliott
141 et al., 2001; Clout et al., 2002) and improve chick survival. Feeding increases clutch size and the
142 proportion of females nesting and leads to a higher likelihood of mothers successfully rearing chicks,
143 but there is no evidence that it affects fertility (Elliott et al., 2001; Houston et al., 2007). Diet is not
144 considered in this study because supplementary food contributes a low proportion of daily metabolised
145 energy (Bryant and Bryant, 2006), and incomplete feeding records and sharing of food stations makes it
146 difficult to determine individual consumption over many years.

147 Other factors which can affect productivity in birds include injury, disease, stress, hormonal disruption,
148 pollution and climate change (Assersohn et al., 2021a,b). These were not included in the current study
149 since they were not considered important in wild kākāpō living on remote islands, and because the diseases
150 which affect kākāpō do not appear to impact reproduction (Gartrell et al., 2005; Jakob-Hoff et al., 2009;
151 Jakob-Hoff and Gartrell, 2010).

152 Despite low fertility being one of the primary reasons for slow growth in the kākāpō population (Elliott
153 et al., 2006), few studies have investigated its causes, and none have been multi-factorial. This study
154 presents the first assessment of the relative impacts of multiple factors on kākāpō fertility, including life
155 history, genetic and behavioural components. Our investigation focuses solely on fertility rather than other
156 measures of productivity such as fledging rates because kākāpō eggs and chicks are subject to intensive
157 management.

158 MATERIALS AND METHODS

159 Kākāpō management

160 *Copulation and nesting detection*

161 Kākāpō are intensively monitored in order to maximise survival and productivity, with nearly every kākāpō
162 fitted with a VHF radio transmitter since 1995. Initially these transmitters only allowed determination of
163 location, so breeding behaviour was assessed manually. Copulation was detected by checking for sign at
164 lek sites (feathers shed by the female during copulation), and nesting was inferred by daily triangulation
165 (if adult females were repeatedly in the same location they were assumed to be incubating). Remote
166 sensing methods improved the efficiency of collecting copulation data and their quality. Proximity sensors
167 were installed at lek sites from 1997 to record male and female presence, and from 2012 the transmitters
168 were fitted with activity sensors to provide copulation and nesting behaviour. The activity data were
169 initially transmitted via coded VHF pulses to telemetry receivers used by field observers or mounted in
170 an aircraft. Then from 2016, the activity data on the main breeding islands of Whenua Hou and Anchor
171 Island were transmitted via a radio frequency data network connected to the island base and internet.

172 The use of VHF transmitters ensured that all nesting attempts since 1994 were detected, except for a
173 very small number of cases when a female's transmitter failed. The addition of activity sensors in 2014
174 ensured that nearly all subsequent copulations were recorded. A small number of copulations were not
175 detected by the transmitters due to hardware failure or unusual copulation activity, but subsequent nesting
176 was detected. In addition, paternity of all offspring since 1997 was determined, first from microsatellite
177 genetic testing (Robertson et al., 2000) and later from genotyping-by-sequencing of blood samples taken
178 from fertile eggs or chicks.

179 Artificial insemination has been attempted in kākāpō during every breeding season since 2008,
180 primarily to override genetically-unsuitable copulations. This is subject to significant logistical challenges,
181 but in 2009 three chicks were produced by artificial insemination in two clutches — a first for a free-living
182 wild bird species. Subsequent attempts failed, until three successful inseminations produced three chicks
183 in 2019, of which one fledged (KRT, 2021, personal observations).

184 **Fertility assessment**

185 Fertility of eggs was assessed by trained observers using ‘candling’: a hand-held torch was used to
186 illuminate the egg and inspect for signs of development (e.g. embryo or blood vessels visible). This was
187 conducted either in the nest or in an incubation facility, and was sufficient for detecting development from
188 approximately four days after laying. Microscopic methods can detect earlier development (Savage et al.,
189 2021), but these have only been conducted for a single breeding season for kākāpō, and so could not be
190 used in the current study which spans multiple years. As a result of using ‘apparent’ rather than true
191 fertility in our analyses, approximately a quarter of the eggs in which embryos died at a very young age
192 (before four days) will have instead been classed as infertile (Savage et al., 2021).

193 **Nest management**

194 From 1997–2019, most eggs (73%) were removed for artificial incubation, to increase hatching success,
195 and replaced with ‘dummy’ eggs. A day or two before or after hatching, the eggs or chicks were returned
196 to nests where possible, and closely monitored. Chicks were frequently cross-fostered among nests to
197 increase the number and growth of chicks in nests. As a result, each chick may have had multiple foster
198 mothers and often was not raised by its biological mother. Chicks fledged from nests at a mean of 73 days,
199 but were still checked regularly until they were independent at around 219 days (Farrimond et al., 2006).

200 **Hand-rearing**

201 Artificial hand-rearing of kākāpō chicks was required due to health issues or if there were insufficient
202 numbers of nests available (Eason and Moorhouse, 2006). In years when there was scarce natural food due
203 to the rimu fruit not ripening, each nesting female could usually support only one chick, and surplus chicks
204 were hand-reared. Between 1981 and 2019, 52% of chicks hatched were hand-reared for at least 10 days.
205 To avoid imprinting on humans, chicks were not reared individually where feasible, and were usually kept
206 in groups of 2–6 (Eason and Moorhouse, 2006). Where possible, chicks were reared on islands and then
207 returned to nests, but some chicks required longer periods of hand-rearing. This long-term hand-rearing
208 took place at a mainland facility, before the chicks were returned to islands at an age of approximately 80
209 days. Here they were weaned in large outdoor pens before being released into the wild at an approximate
210 age of 120 days. Following fledging from the nest or from hand-rearing, most chicks were supported by
211 supplementary feeding.

212 **Data collation**

213 **Clutch data**

214 Clutch data were collated from the Kākāpō Recovery Programme database for the breeding years between
215 1981 and 2019 (Table 1 and Data S1). The database contains all observed events for each individual,
216 including transmitter activity data, captures, health checks, feeding records and copulations. These were
217 combined with a dataset for each clutch since management began in 1981, containing clutch size, number
218 of fertile eggs (apparent fertility), number of eggs hatched, and the number of chicks fledged, as well
219 as paternity assumed from transmitter data and confirmed by genetic testing. Data prior to 1990 were
220 excluded from the analysis since there was insufficient information for each nesting attempt. This yielded
221 an initial data set of 237 clutches.

222 This data set contained first ($n = 197$), second ($n = 39$) and third ($n = 1$) clutches. Kākāpō will
223 naturally re-nest if a nest fails early enough, and double clutching is used as a management method to
224 improve productivity.

225 **Paternity assignment**

226 Confirmation of paternity from genetic testing was available for 120 out of all 237 clutches laid from
227 1990–2019. Of the 117 clutches which did not have confirmed genetic paternity, it was necessary to
228 identify the male which ‘fathered’ the clutch, so that its hand-rearing status, age, copulation experience
229 and the parental kinship could be compared to clutch fertility. Four clutches were excluded for which an
230 unknown number of males copulated with the female, leaving 113 clutches without confirmed genetic
231 paternity and 233 in total. In 92 clutches without genetic paternity confirmation, only one male copulated
232 with the female, so assigning the ‘father’ was straightforward.

233 For a further 21 clutches (14 infertile, 7 fertile) with unconfirmed genetic paternity, different identified
234 males were confirmed or assumed to have copulated with the female. These clutches could not be excluded
235 since doing so would remove the entire set (14) of infertile clutches produced by copulations with different
236 males, biasing the clutches from multiple males to higher fertility by only leaving the fertile clutches. So

Year	Island	Clutches	Recorded copulations	Fertile eggs	Infertile eggs	Hatched	Fledged
1981	Rakiura	2	0	4	0	4	3
1985	Rakiura	3	0	3	6	2	0
1990	Hauturu	2	2	2	1	2	0
1991	Hauturu	4	3	6	2	4	2
1992	Whenua Hou	4	1	9	2	6	1
1993	Hauturu	2	3	1	3	1	0
1995	Hauturu	2	2	0	5	0	0
1997	Whenua Hou	6	6	7	5	4	3
1998	Maud	1	1	3	0	3	3
1999	Pearl	8	8	11	5	8	6
2002	Whenua Hou	24	34	42	25	26	24
2005	Whenua Hou	10	16	11	15	6	4
2008	Whenua Hou	5	12	10	0	8	6
2009	Whenua Hou	28	52	54	18	36	33
2011	Anchor	1	0	2	0	0	0
2011	Whenua Hou	8	13	14	4	11	11
2014	Hauturu	1	3	3	0	2	2
2014	Whenua Hou	7	14	6	9	5	4
2016	Anchor	22	32	32	38	21	15
2016	Hauturu	2	4	1	2	0	0
2016	Whenua Hou	20	31	30	19	26	20
2019	Anchor	37	60	56	67	42	37
2019	Whenua Hou	43	64	63	66	44	36
Total		242	361	370	292	261	210

Table 1. Breeding attempts since modern records began in 1981. Only data after 1990 were used in this study because data between 1981 and 1990 were incomplete. Note that for some clutches no copulations were recorded, and that fertility reported here is apparent fertility determined from ‘candling’; not true fertility from microscopic analysis. This is the full data set; some of these clutches were excluded from the fertility model. See text for further details.

237 to retain these 21 clutches, a ‘father’ was assigned from the 2–3 males identified to have copulated with
 238 the female, based on a likelihood of paternity from male copulation order. This likelihood of paternity
 239 was determined from clutches with confirmed genetic paternity, calculated as the proportion of clutches
 240 fathered by a male copulating first, last, middle, or first and last out of all the males which copulated with
 241 the female (Table S1). These probabilities were then used to select a ‘father’ from the candidate males
 242 using weighted sampling.

243 This method of selecting a clutch ‘father’ will have introduced errors due to the incorrect male being
 244 chosen in some cases, but these instances would have been few compared to the overall number of clutches.
 245 Moreover, this method would have caused less bias to the measured impact on fertility of copulations with
 246 multiple males compared to omitting the 21 clutches without genetic paternity confirmation. Furthermore,
 247 reducing the sample of clutches from multiple males would have greatly reduced the ability to assess the
 248 effect of sperm competition on fertility, which may be greater than the influence of the characteristics of
 249 the male which fathered the clutch. We acknowledge that the term ‘father’ cannot strictly be applied to an
 250 infertile clutch, but use it to signify the copulating male which had the highest likelihood of fertilising
 251 the eggs — and noting that in many cases, the eggs of these apparently infertile clutches were in fact
 252 fertilised.

253 A further seven clutches with mixed paternity and/or produced by artificial insemination were excluded,
 254 because these were not the product of a single male and female. The resulting 226 clutches were therefore
 255 the product of a single identified female and a male designated as the clutch ‘father’. A further nesting
 256 attempt without any eggs was also removed, leaving 225 clutches from a total of 60 females and 51 males.

257 Rearing status

258 For each clutch, the hand-rearing history of the mother and father was established from database records.
259 Kākāpō were assigned as hand-reared if they had spent more than 10 days being hand-reared, at any
260 period of their development; otherwise they were classed as wild-reared. A binary hand-rearing variable
261 was chosen over a continuous one as it is more practicable to apply to management and because it
262 simplified the statistical analysis. The binary variable was also more suited to the bimodal distribution of
263 hand-rearing periods, with kākāpō chicks tending to be hand-reared for either a short period or for most of
264 their development (Figure S1). Many chicks are hand-reared for just a few days to enable them to recover
265 from ill health or weight loss, particularly between the ages of two to three weeks, when chicks fed by
266 mothers receiving supplementary food often require removal to hand-rearing for a change of diet for up to
267 five days. Alternatively, prolonged ill-health or lack of available nests means that they are hand-reared
268 until they reach weaning age. Of the 111 adult kākāpō which contributed to the 225 clutches, 59 were
269 hatched after intensive management and hand-rearing began. Of these, 21 (36%) were hand-reared for
270 up to 10 days and 38 (63%) for more than 10 days, with only four hand-reared for between 10 and 60
271 days (Figure S1). Hand-rearing could start at any chick age, so the number of days hand-reared was not
272 necessarily the same as the age of the chick.

273 Age assignment

274 The ages of the male and the female producing the clutch were calculated from hatch dates if these were
275 known. Kākāpō of unknown age comprised 17 of the 60 females and 22 of the 51 males which contributed
276 to the 225 clutches. These were assigned a minimum age of 10 years at discovery, which is a typical age
277 of first breeding for males and females. Although the inclusion of the kākāpō of unknown age will have
278 introduced errors due to inaccuracies in these estimated ages, these were likely to have been relatively
279 small compared to the absolute ages at breeding, and the alternative of omitting these individuals would
280 have resulted in greater model uncertainty due to the smaller sample size. This age assumption results
281 in the oldest kākāpō breeding at 48.5 years of age (Fig. S2), which is younger than the presumed mean
282 life expectancy in the contemporary managed population. However, the remnant populations from which
283 the kākāpō of unknown age were sourced were under extreme predation pressure (Karl and Best, 1982;
284 Atkinson and Merton, 2006), so would have had shorter life expectancies than the current protected
285 population.

286 Previous copulations

287 The previous copulation experience for each kākāpō was obtained from recorded copulation attempts and
288 genetic paternity analysis. This provided an estimated cumulative number of copulations for the clutch
289 mother and father prior to the clutch, summed over the lifetime of each individual, or since recordings
290 began. The paternity analysis gave evidence of at least one copulation in cases when none were recorded.
291 This estimated number of copulations was a lower limit, since not all copulations were detected — even
292 with the electronic mating detection system — and since it was assumed that all founder individuals had
293 not previously copulated at the time of their discovery. This underestimate was unavoidable given the lack
294 of observational data prior to their discovery.

295 Parental kinship

296 Pairwise kinship for all male-female combinations of living and recently-deceased kākāpō were obtained
297 from a pedigree generated from the kākāpō studbook in PMx (Lacy et al., 2012). To address the assumption
298 of founders being equally unrelated to one another (Ballou, 1983), founder relatedness was incorporated
299 into the kākāpō studbook using genomic-based estimates of relatedness. In this process whole genome
300 resequencing data from 169 birds was used to discover SNPs using the reference-guided Deep-Variant
301 pipeline (Poplin et al., 2018). A stringent filtering protocol using BCFTools (Li et al., 2009) and
302 VCFTools (Danecek et al., 2011) was applied to include biallelic SNPs with a minimum coverage of
303 three, a maximum coverage of 100, a minimum Phred quality score of 10, a genotyping rate $> 90\%$, a
304 minor allele frequency of 0.05, and pruning for linkage disequilibrium with an r^2 of 0.8 and a sliding
305 window of 1000 sites. This filtering resulted in 8,407 high confidence markers with high depth (average
306 = $19.88 \pm 8.08SD$) and low missing data (average = $0.0002 \pm 0.0001 SD$) across individuals. Initial
307 testing was performed to evaluate estimators for accuracy and precision with mother-offspring relatedness,
308 including: KING (Waples et al., 2019), estimated through the package NGSrelateV2, Hanghøj et al.
309 2019), KGD (Dodds et al., 2015), KGD with a correction for self-relatedness (as per Galla et al. 2020, Rxy

310 (Hedrick and Lacy 2015, estimated through NGSrelateV2), and TrioML (Wang 2007, estimated through
311 the R program *related*, Pew et al. 2015). R_{xy} was chosen as the best relatedness estimator, given
312 its high accuracy for mother-offspring relatedness and the benefit of bounding between 0–1 for ease of
313 entry into PM_x (Lacy et al., 2012). Final relatedness estimators were calculated between the 35 founders
314 identified in the kākāpō studbook and were incorporated into PM_x as kinship (half of the relatedness
315 value). Parental kinship for the clutches in this study were produced in PM_x using the founder-corrected
316 studbook. These values were in the range 0–0.265, with a median of 0.0074 and a distribution that was
317 positively skewed (Fig. S2).

318 **Statistical analyses**

319 ***Bayesian model structure***

320 A Bayesian generalised linear mixed model was used to assess factors contributing to clutch fertility.
321 The explanatory variables considered to have potential effects on clutch fertility were chosen from data
322 exploration and knowledge of kākāpō ecology. These were: the age, hand-reared status and previous
323 mating experience (number of previous copulations) of both clutch mother and father; the copulation
324 behaviour of the clutch mother, in terms of the number of copulations and the number of different males
325 the female copulated with to produce the clutch; and the parental kinship.

326 The hand-rearing status of the clutch mother and father was set to a binary variable: one if the
327 individual had been hand-reared for more than 10 days and zero otherwise. The female copulation
328 behaviour was a categorical variable with three levels: one copulation with one male, more than one
329 copulation with the same male, and copulations with different males. This latter category contained
330 clutches in which a female copulated more than once with at least one of the multiple males ($n = 17$).
331 Parental kinship was a continuous variable in the range 0 – 0.265. Mating experience was defined as the
332 number of previous copulations detected prior to those which yielded the clutch, since records began.
333 This was calculated for both the female and male which produced the clutch.

334 The numeric explanatory variables were scaled and centred to have mean of one and standard deviation
335 of 0.5 (Gelman et al., 2008); the categorical variables were defined as factors. No interactions of the
336 covariates were considered relevant. Collinearity of predictors was examined with correlation plots and
337 paired posterior plots: no significant correlation among predictors were found, so none were excluded.

338 The response variable was the binary fertility status of each clutch (0/1), with a Bernoulli error
339 distribution. This was used instead of the proportion of eggs in a clutch that were fertile, because the
340 fertility of each egg was not independent of the fertility status of others in the clutch (Fisher exact test
341 for association between categorical variables, $p < 0.001$, odds ratio = 0.0153, [0.00833, 0.0270] 95%
342 confidence interval). Of 602 eggs in clutches with more than one egg, 313/332 fertile eggs were in a
343 clutch with other fertile eggs, and 216/270 infertile eggs were in infertile clutches (Supplementary Data
344 S1).

345 Random effects were included for clutch mother and father identity to account for pseudo-replication,
346 and for year, to account for unmeasured environmental variation. No effect was included for island, since
347 this predictor was highly imbalanced, with two of the five breeding islands dominating the number of
348 clutches: Whenua Hou (145) and Anchor Island (59) produced 91% of the 225 clutches.

349 Observations with missing values for any of the predictors were excluded. From the initial set of 225
350 clutches, the final model data contained 217 clutches with complete values for all eleven input variables
351 (Table 2). This resulted in a mean of 19.7 events per variable, which was greater than the minimum of
352 10–15 recommended for linear regression modelling (Heinze et al., 2018).

353 ***Bayesian model variable selection***

354 Small datasets are common in threatened species research, leading to statistical challenges such as low
355 precision, low accuracy and instability masking true relationships between variables (Garamszegi, 2016).
356 To prevent the model from overfitting to the data due to the large ratio between number of parameters
357 and number of observations, it is often necessary to limit the number of variables in the model (Heinze
358 et al., 2018). Methods such as penalized regression and shrinkage priors are commonly used to this effect
359 (Piironen and Vehtari, 2017b; Vehtari et al., 2017; Erp et al., 2019; Carvalho et al., 2010; Hastie et al.,
360 2015; Narisetty and He, 2014). However, these methods do not really produce truly sparse solutions, as
361 every variable has a non-zero probability of inclusion. Instead, we applied projection predictive variable
362 selection (Piironen et al., 2020; Catalina et al., 2020), which effectively selects a subset of variables from
363 a previously fitted reference model. This method ranks the variables in order of their contribution to the

Component	Variable	Type	Values (frequency)
Response	Clutch fertility	Binary	0 (80) / 1 (137)
Fixed	Mother hand-reared	Logical	true (64 clutches; 26 females) / false (153 clutches; 34 females)
	Father hand-reared	Logical	true (43 clutches; 12 males) / false (174 clutches; 38 males)
	Mother age (years)	Continuous	range = 4.8 – 48.5, mean = 20.9, median = 17.8
	Father age(years)	Continuous	range = 4.8 – 43.4, mean = 22.7, median = 20.8
	Mother copulation behaviour	Categorical	1 copulation (104) / 1 male, > 1 copulation (50) / Different males (6)
	Mother previous copulations	Integer	range = 0 – 17, mean = 4.4, median = 4
	Father previous copulations	Integer	range = 0 – 33, mean = 6.5, median = 4
Random	Mother/father kinship	Continuous	range = 0 – 0.265, mean = 0.021, med = 0.0074
	Mother	Categorical	60 individuals, 1 – 9 repeats, mean = 3.6, median = 3
	Father	Categorical	50 individuals, 1 – 16 repeats, mean = 4.3, median = 4
	Year	Categorical	range = 1990 – 2019, 16 levels

Table 2. Model predictors. Parameters for the 217 clutches used in the Bayesian model relating clutch fertility to the characteristics of the clutch mother and clutch father (the male and female which produced the clutch). See Fig. S2 for distributions of the numeric variables.

364 model predictions, replacing the posterior of the model with a constrained projection which provides
 365 predictive performance equivalent to the full model (Piironen et al., 2020; Catalina et al., 2020), as
 366 measured by the Kullback-Leibler divergence of their predictions (Goutis, 1998). Projection predictive
 367 variable selection has been shown to outperform other more established variable selection methods
 368 (Piironen and Vehtari, 2017a). Furthermore, it can be applied not only to generalised linear models, but
 369 also to generalised linear and additive multilevel models, allowing the projection of random (additive)
 370 effects.

371 In order to rank the variables during model search, projection predictive variable selection uses forward
 372 search for multilevel or additive models and a faster L1-like heuristic for generalised linear models. Since
 373 the model structure included random effects per individual in the sample, we restricted the search to first
 374 select the fixed effects, and only then added the random effects. This was to ensure that the predictive
 375 variance would not be completely saturated by the individual random effects and properly measure the
 376 effect of the biologically-relevant terms.

377 **Bayesian model execution and validation**

378 All analyses were conducted in R (version 4.1.2; R Core Team 2020), with the Bayesian model imple-
 379 mented in R package `brms` version 2.16.3 (Bürkner, 2017) and projection predictive variable selection
 380 applied with package `projpred` version 2.0.5.9 (Piironen et al., 2020). A regularised horseshoe prior
 381 was used (Piironen and Vehtari, 2017b), with one degree of freedom for the student-T prior for the local
 382 and global shrinkage parameters, and a scale of one for the global shrinkage and regularisation parameter
 383 (Bürkner, 2017). The model was run with four chains, with 15,000 iterations and 15,000 warm-up
 384 iterations per chain. Model code and results are available in Data S1.

385 Projection predictive variable selection was then used to provide a reduced model with equivalent
 386 predictive performance to the full model. The variables included in the reduced model were selected by
 387 the improvement they provided to the model. As criteria for the selection of variables we checked the
 388 ELPD improvement and each variable's marginal posterior, and selected those whose posterior mass was
 389 clearly non-zero and whose ELPD improvement was significant.

390 Model validity was assessed by Pareto k estimates (Vehtari et al., 2017, 2019), and by graphical
 391 residual and posterior predictive checks using the `bayestestR` package (Makowski et al., 2019b). The
 392 relative influence of each predictor on clutch fertility was assessed by Bayesian indices of effect existence
 393 and significance (Makowski et al., 2019a). Effect existence was measured by the probability of direction
 394 (p.d.), which is the proportion of the posterior that is of the same sign as the median and is interpreted as
 395 the probability that a variable is positive or negative (Makowski et al., 2019a). The effect 'significance'
 396 was assessed from the amount of intersection of the full posterior distribution of the constrained projection
 397 with the region of practical equivalence (ROPE; Makowski et al. 2019a). This region of 'practically no
 398 effect' provides a measure of the 'importance' of a parameter, based on the proportion of the posterior
 399 which overlaps the ROPE. It is quantified by the probability of significance (p.s.): the proportion of the

400 distribution outside the ROPE. If there were values of the distribution both above and below the ROPE,
401 the probability of significance was reported as the higher probability of a value being outside the ROPE. A
402 range of [-0.18, 0.18] was used for the ROPE, as recommended for logistic models (Kruschke and Liddell,
403 2018).

404 ***Multiple copulations and population density***

405 In addition to the Bayesian fertility model, we also investigated the incidence of multiple copulations
406 with kākāpō abundance. We merged repeated copulations with one male and copulations with different
407 males into a single category of ‘multiple copulations’, in order to achieve sufficient sample sizes. We
408 correlated the proportion of clutches produced by multiple copulations with the total number of adult
409 female and male kākāpō, and the adult sex ratio, on Whenua Hou for each year since 1990. This analysis
410 was confined to a single island to avoid inter-island effects, and Whenua Hou was chosen as it produced a
411 large proportion of all clutches from 1990–2019 (64%). Due to the size of the island and the lek breeding
412 system of kākāpō, there is opportunity for copulation between all breeding-aged males and females.
413 Correlations were assessed using the `correlation` package (Makowski et al., 2020) in R, using the
414 Pearson correlation coefficient and Holm adjustment method (Holm, 1979).

415 **RESULTS**

416 **Factors affecting fertility**

417 Projection predictive variable selection in the Bayesian mixed model showed that of the fixed terms,
418 the hand-rearing status of the clutch father explained most of the variance in the model, followed by
419 the copulation behaviour of the mother (Fig. 1, Supplementary Data S2). These two fixed terms made
420 the biggest change in expected log predictive density (ELPD) difference, contributing 15% and 11%
421 respectively of the total difference in ELPD; all other fixed terms contributed just 5% combined. These
422 proportions should only be used as a guide to the relative contribution to the model variance, since the
423 ELPD depends on the order of the projected terms. Clutch father hand-rearing status and mother copulation
424 behaviour were the only two fixed terms which had projected posterior distributions distinguishable from
425 zero (Fig. 2). All other fixed terms had negligible impact on the model fit, and had projected posterior
426 distributions indistinguishable from zero (Figs. 1 and 2). Of the random terms, clutch father and mother
427 identity contributed most to the variance (50% and 12% of the total ELPD variation, compared to 8%
428 for the year random term), with father identity the most important of all fixed and random parameters.
429 Random effects dominating fixed effects is common in mixed models, and can obscure the underlying
430 fixed model structure. It suggests that there was substantial variation in the model due to individual effects
431 which were not captured by the fixed variables. A reduced model containing mother copulation behaviour,
432 clutch father hand-rearing status and random terms for clutch father, mother and year provided predictive
433 performance equivalent to the full model (Fig. 3). This reduced projected model explained approximately
434 31% (estimated $R^2 = 0.031$) of the total observed variation in clutch fertility.

435 Clutches from hand-reared fathers were associated with the highest change in clutch fertility, with a
436 strongly significant negative effect (probability of direction, p.d. = 0.98, probability of significance, p.s.
437 = 0.93 in the reduced model). The effect of females copulating with different males had similarly high
438 importance, associated with a strongly positive and significant increase in fertility compared to single
439 copulations (p.d. = 0.97; p.s. = 0.92). Clutches in which females copulated repeatedly with the same
440 male were also highly likely to be more fertile than single copulations, but with lower significance (p.d. =
441 0.81, p.s. = 0.60; Fig. 3). The remaining fixed terms of clutch mother rearing status, clutch mother and
442 father age, parental kinship, and clutch mother and father copulation experience were not included in the
443 reduced model as they all had a very low impact on clutch fertility compared to hand-rearing status of the
444 clutch father and the copulation behaviour of the clutch mother.

445 Model predictions (Fig. 4) showed that females copulating with multiple males had a high probability
446 of producing a fertile clutch, especially if the clutch father was wild-reared (84% for a wild-reared
447 father and 66% for a hand-reared father). Females copulating repeatedly with a single male had a higher
448 likelihood of clutch fertility than those copulating just once (72% vs 64% for a wild-reared mate, and
449 50% vs 39% for a hand-reared mate). Irrespective of the number of copulations and mates, copulating
450 with a hand-reared male decreased the likelihood of clutch fertility compared to a wild-reared male.

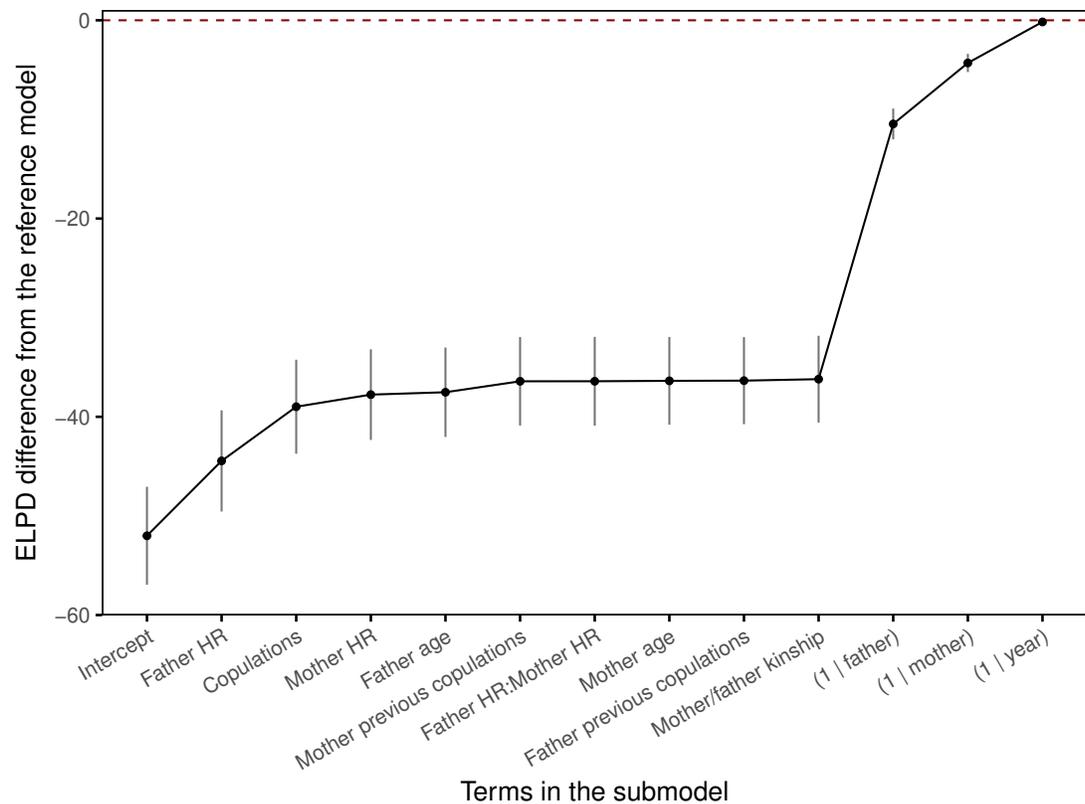

Figure 1. Projection predictive variable selection results. Variables ranked by their contribution to the fertility model's predictive ability, measured by the change each makes to the expected log predictive density (ELPD). As each variable is added from left, the change in ELPD difference from the previous term shows the change in the model's performance, relative to the full model. Fixed terms are ordered in their contribution to the model variance, with random terms selected last. The dashed line shows the ELPD for the full model. The reduced model containing the fixed variables of clutch father rearing status and mother copulation behaviour, with random terms for clutch father, mother and year, provided equivalent predictive performance to the full model. HR = hand-rearing.

451 **Multiple copulations and kākāpō density**

452 The likelihood of females engaging in multiple copulations (either with the same male or different males)
 453 was strongly positively correlated (Pearson correlation, $r = 0.93$, 95% CI = [0.74, 0.98], $p < 0.001$, $t =$
 454 7.44, d.f. = 8) with the size of the adult female population on Whenua Hou from 1990–2019 (Fig. 5). The
 455 association between multiple copulations and male abundance was much weaker (Pearson correlation,
 456 $r = 0.61$, 95% CI = [-0.02, 0.90], $p = 0.059$, $t = 2.20$, d.f. = 8), but there was a strong correlation
 457 between multiple copulations and the female:male sex ratio (Pearson correlation, $r = 0.92$, 95% CI
 458 = [0.71, 0.98], $p < 0.001$, $t = 6.88$, d.f. = 8).

459 There was substantial variation in multiple copulation behaviour among females. Of the 60 females in
 460 the model data set, 38 (63%) copulated with different males in at least one breeding season, 27 (45%)
 461 had repeated copulations with the same male at least once, and 52 (87%) produced at least one clutch
 462 following a single copulation.

463 **DISCUSSION**

464 Low hatching success, particularly due to egg infertility or very early embryo death, is one of the main
 465 obstacles to recovery for the critically endangered kākāpō. Using all available reproductive data for the
 466 species, this study shows that of those assessed, the dominant factors affecting clutch fertility are male
 467 hand-rearing status and female copulation behaviour, in terms of the number of copulations and number

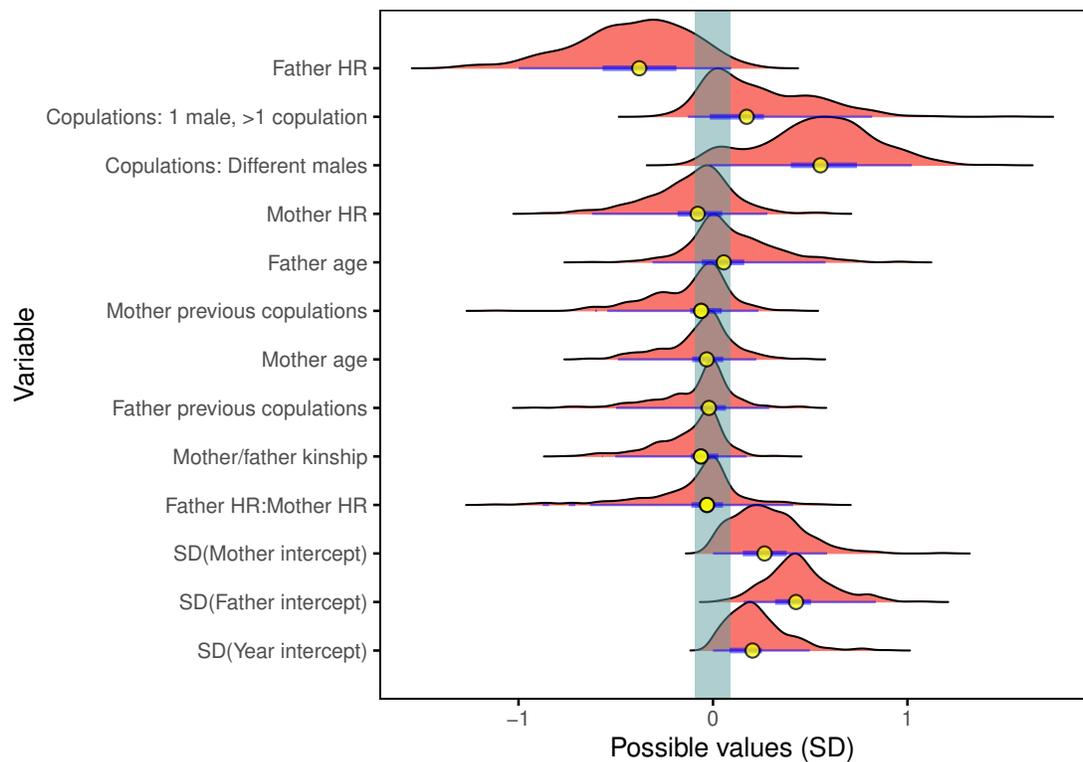

Figure 2. Posterior coefficient distributions of the coefficients for the full projected model. The effect of each variable on predicted clutch fertility in the full model. The less a posterior distribution intersects the ROPE (region of practical equivalence, denoted by the shaded vertical bar), the stronger the association of that variable with fertility (see Statistical Analyses for details.) Distributions to the right of the ROPE indicate a positive impact on clutch fertility, and those to the left a negative impact. Posterior medians are shown by filled yellow circles, with thick and thin horizontal blue bars denoting the 50th and 95th percentiles respectively. Of the fixed effects, only the clutch mother copulation behaviour and clutch father hand-rearing variables had posteriors likely to be non-zero. The mother copulation behaviour variable is split into its factor levels, with the reference level a single copulation. For rearing status, wild-reared is the reference level. Considering the posteriors and the projection predictive variable selection results, only these two fixed variables were retained in the reduced model. HR = hand-rearing.

468 of mates. Fertility was reduced in clutches produced by a hand-reared father compared to a wild-reared
 469 father, increased if the mother copulated repeatedly with one male compared to a single mating, and
 470 increased further still if the mother copulated with more than one male.

471 **Small samples sizes and longitudinal data**

472 The sample size of 217 clutches in this study is statistically small, but represents a substantial and long-
 473 term monitoring effort utilising advanced technologies. Few wild species are monitored as intensively
 474 as the kākāpō, with individuals closely followed over decades and nearly all copulations recorded. This
 475 longitudinal data set has enabled analysis of potential impacts on fertility, highlighting the importance of
 476 adequate monitoring to assess effects of management methods which may not be immediately apparent,
 477 as well as the importance of long-term, individual-based studies (Clutton-Brock and Sheldon, 2010).

478 Despite this effort, the impact of small data sets must be considered when evaluating these results.
 479 Small sample sizes are often unavoidable in threatened species analyses, which can lead to imprecise,
 480 inaccurate or unstable results, and important effects being missed due to apparently non-significant results
 481 arising from high uncertainty (Garamszegi, 2016). This is why for small data sets it is important to use
 482 robust statistical methods which provide reliable uncertainty measures and can rank predictors by their

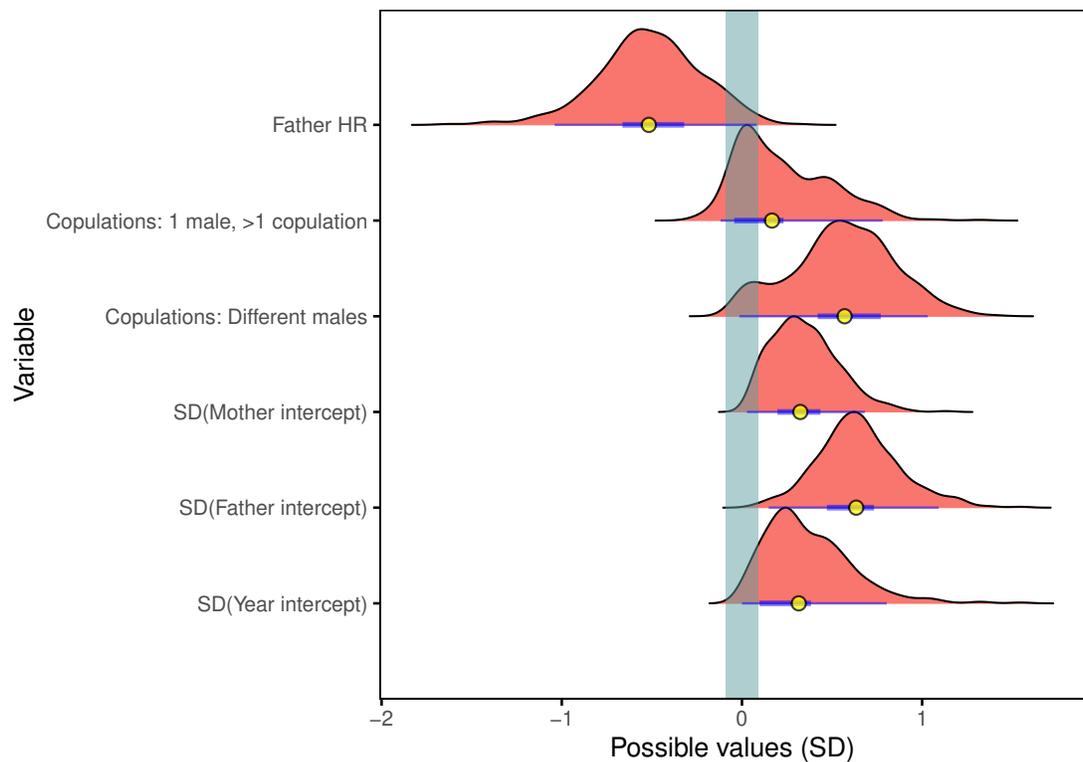

Figure 3. Posterior distributions of the coefficients for the projected reduced model. The effect on predicted clutch fertility of the subset of variables in the reduced model, which had predictive performance equivalent to the full model containing all terms. The reduced model contained all three random effects and the two fixed effects with the highest variance contribution: clutch father hand-rearing status and clutch mother copulation behaviour. Description and symbols as in Fig. 2.

483 contribution to the response, such as the Bayesian predictive projection variable selection utilised here.
 484 Even with these methods, the impact on fertility of the effects we report is likely to be underestimated.
 485 This must be considered when using these results to make conservation management decisions, and
 486 emphasises the importance of reanalysis when data sets become larger with further monitoring. A further
 487 benefit of the Bayesian methods employed here is that they make such reanalysis straightforward.

488 Rearing environment

489 The model showed a strong impact of father hand-rearing status on clutch fertility, with a 98% probability
 490 that a hand-reared father had a negative effect on clutch fertility compared to a wild-reared father and a
 491 93% probability that this effect was significant. This result provides a rare demonstration of hand-rearing
 492 affecting productivity in a bird species. In fact, evidence of similar effects across *any* taxa is extremely
 493 limited, in contrast to examples of the impact of captivity or rearing method on other traits such as survival
 494 (Farquharson et al., 2018). This is likely a result of the difficulty of measuring these effects, which usually
 495 requires longitudinal data of reproductive success across several generations (Clutton-Brock and Sheldon,
 496 2010), and which is compounded by a strong bias in fertility studies towards commercial bird species and
 497 a tendency to focus on male reproductive issues (Assersohn et al., 2021a).

498 Limitations

499 We used a binary hand-rearing variable, but this does not mean that kākāpō hand-reared for fewer than the
 500 10 day cut-off were immune from impacts of hand-rearing. Inclusion of these hand-reared individuals
 501 (albeit hand-raised for a very short period) may have reduced the influence of hand-rearing in the model,
 502 but we would expect this effect to be small, given that nearly all of these (20/21; Supplementary Data

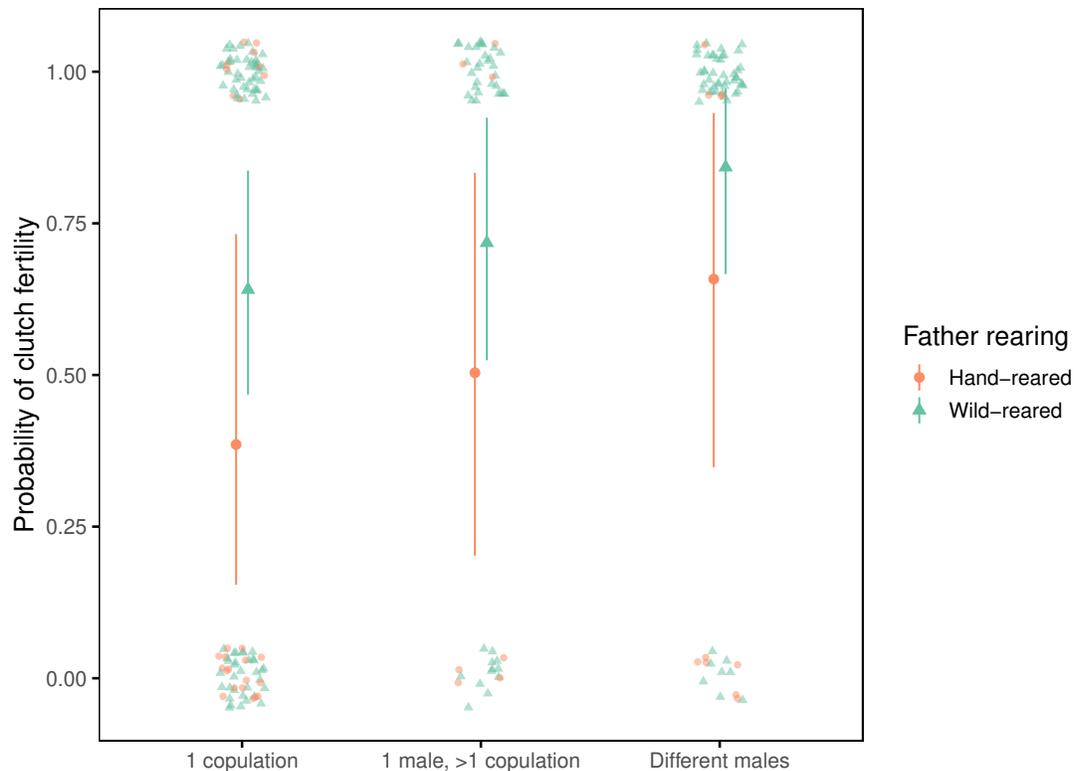

Figure 4. Fertility model predictions for the interaction of clutch mother copulation behaviour and clutch father rearing status. Predictions from the reduced model for how the likelihood of clutch fertility varied with the number of mates and copulations of the clutch mother, and with the rearing environment of the clutch father. A clutch is considered fertile if at least one egg is fertile and infertile if all eggs are infertile. Model predictions are shown as large filled circles, with 95% highest posterior density intervals denoted by vertical bars. Small filled symbols denote the observational data, with circles for hand-reared fathers, and triangles for wild-reared fathers. The data are jittered along both axes for clarity.

503 S1) were hand-reared for 5 days or less. An individual was defined as having been hand-reared if it was
 504 hand-raised for at least 10 days at any stage during development. When the hand-rearing occurs may be
 505 as important as its duration, but this could not be assessed with the available data. Examples from other
 506 species demonstrate that the timing of imprinting varies among species, and that even a short hand-rearing
 507 period may influence behaviour (Jones, 2008). Male falcons reproduce less effectively if reared by hand
 508 for more than the first week of their life (Lierz, 2019), and in raptors imprinting or even partial imprinting
 509 can affect pair behaviour and therefore reduce egg fertility (Jones, 2008; Lierz, 2008). Whereas it is clear
 510 that a fully hand-raised bird might not be able to reproduce with conspecifics, there is uncertainty over the
 511 impact of shorter hand-rearing periods. It is feasible that any time during the development period that an
 512 individual is not raised by conspecifics might later lead to behavioural alterations (Irwin and Price, 1999).
 513 Assessing whether there is a particular period during development when the impact of hand-rearing is
 514 most pronounced should be a focus for future analyses when sufficient data are available.

515 **Implications**

516 Examples from other taxa suggest that the reason for hand-rearing affecting clutch fertility in kākāpō is
 517 likely to be behavioural. In primates, lack of access to conspecifics lowers reproductive output through
 518 suspected behavioural mechanisms (King and Mellen, 1994; Beck and Power, 1988; Hampson and
 519 Schwitzer, 2016). We suggest that hand-reared male kākāpō have a lower ability to copulate successfully
 520 than their wild-reared counterparts as a result of sexual imprinting (Irwin and Price, 1999). Sexual

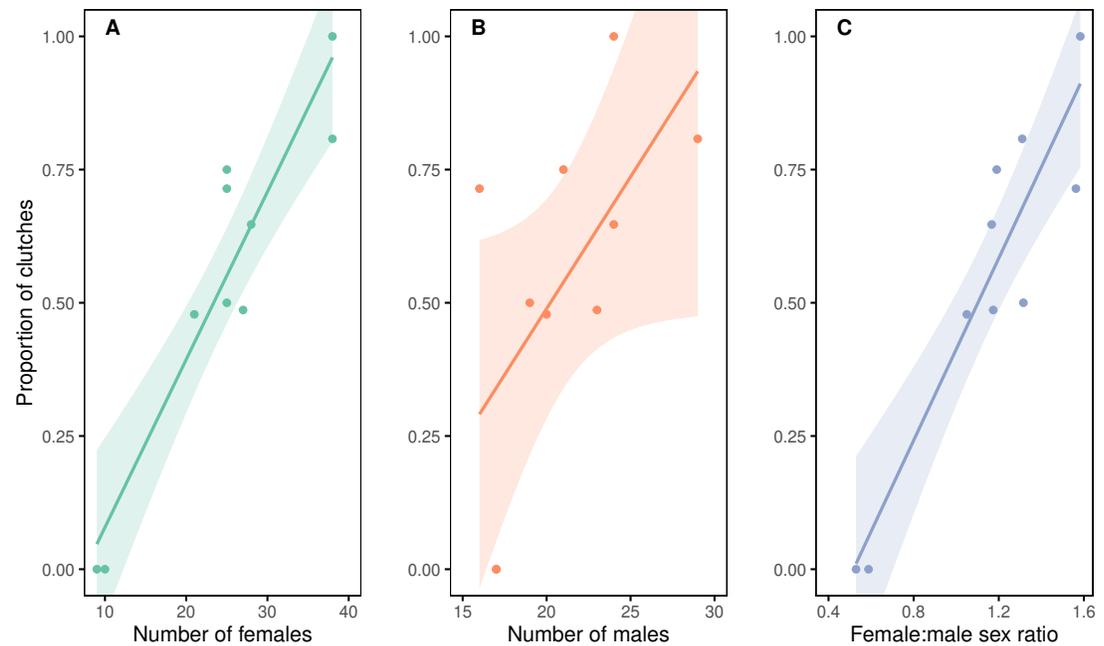

Figure 5. Proportions of clutches with multiple copulations in relation to the number and sex ratio of adult kākāpō. The association between the incidence of clutches produced by multiple copulations with (A) female and (B) male kākāpō abundance and (C) female:male sex ratio, on Whenua Hou over ten breeding seasons from 1990–2019. Clutches from multiple copulations are those produced by a female repeatedly copulating with a single male or copulating with multiple males. Lines and shading show linear regression fits with 95% confidence intervals. The scales for the number of kākāpō in panels (A) and (B) are different.

521 imprinting on humans is known in other species such as falcons, with imprinted males showing no interest
 522 in mating with female birds (Lierz, 2008). There is qualitative evidence of this in kākāpō, with one
 523 individual hand-reared alone in 1997 (from three to 15 weeks of age) apparently unable to mate as a
 524 result of strong imprinting on humans (Eason and Moorhouse, 2006). Another male hatched in 1998
 525 was also hand-reared alone for a similar period and is partially sexually imprinted on humans. Although
 526 this individual has mated with female kākāpō, it has not yet (to 2019) naturally produced fertile eggs.
 527 These imprinting behaviours appear to most strongly affect male chicks reared alone: females have been
 528 similarly hand-reared alone without any observed negative reproductive impacts, although these may be
 529 less immediately apparent (Eason and Moorhouse, 2006; Harper and Joice, 2006). The relative impact of
 530 hand-rearing birds individually rather than with conspecifics is demonstrated in other species. In falcons,
 531 for example, chicks hand-reared alone tend to be less successful breeders and have more behavioural
 532 problems than those reared in a cohort (Jones, 2008). As a consequence, kākāpō chicks are no longer
 533 hand-reared separately from other individuals, unless it is unavoidable due to particular health issues, in
 534 which case the time that they are hand-reared without conspecifics is minimised (Eason and Moorhouse,
 535 2006).

536 Hand-rearing has been shown to reduce reproductive output — although not fertility — in takahē
 537 (*Porphyrio hochstetteri*), a threatened rail endemic to New Zealand. Hand-raised takahē fledge approxi-
 538 mately 50% fewer offspring than their wild-reared counterparts, even though egg fertility is similar (G.
 539 Greaves, New Zealand Department of Conservation, 2015, pers. comm.). This suggests that hand-reared
 540 takahē have reduced chick-rearing ability and that a behavioural mechanism is responsible. While this
 541 does not directly support our hypothesis that hand-rearing affects male copulation ability in kākāpō, it
 542 does demonstrate that hand-rearing can strongly affect reproductive behaviour.

543 The evidence for negative impacts of hand-rearing on kākāpō reproductive output may have profound
 544 consequences for the conservation of the species. Hand-rearing is a key part of management, used to
 545 prevent loss of chicks which would naturally have died through starvation or ill health. More than half of

546 the 261 chicks hatched from 1981–2019 were hand-raised for at least 10 days, usually in the first four
547 weeks after hatching. Hand-rearing has made a stronger contribution to population growth than perhaps
548 any other management method. There have been no other apparent negative effects of this practice: from
549 32 hand-reared females which bred up to 2019, 25 (78%) hatched chicks, and all of these fledged at least
550 one chick.

551 Steps are already taken to avoid imprinting in kākāpō: chicks are not reared alone, are only hand-reared
552 if there is no alternative and are released from captivity soon after weaning. But the additional impact
553 on fertility identified here adds greater pressure to avoid hand-rearing of males. This is at odds with
554 the current management policy which prioritises leaving female rather than male chicks in nests when
555 there is insufficient capacity. This has been applied as it was assumed to be more important to produce
556 high-quality, naturally-raised females, the availability of which was thought to be one of the primary
557 factors limiting population growth.

558 **Female copulation behaviour**

559 This study shows that female copulation behaviour — in terms of the number of copulations and mates —
560 has a significant effect on clutch fertility in kākāpō. The mother copulation behaviour variable contributed
561 more to the model variance and had a higher importance than any other fixed term except for the hand-
562 rearing status of the clutch father. The model predictions showed a clear trend in the likelihood of clutch
563 fertility with female copulation behaviour: lowest for clutches produced by a single copulation, higher for
564 those from repeated copulations with one male, and highest for clutches produced by females copulating
565 with multiple males. The effect of copulating with multiple males had a strongly positive and significant
566 impact on clutch fertility (97% probability that it was positive and a 92% probability of significance).
567 Furthermore, our results demonstrate that this female copulation behaviour was strongly influenced by the
568 number and sex ratio of kākāpō in a population. With more females and a higher female:male sex ratio,
569 an increasing number of clutches were produced by multiple copulations, either with the same or different
570 males.

571 **Limitations**

572 Before assessing the implications of these findings, it is important to consider the limitations of the
573 evidence. First, the estimated effect on fertility from copulation with multiple males would have been
574 subject to errors from assigning a putative clutch ‘father’ to the 21 such clutches which had no genetic
575 paternity confirmation. This would have most influence on the clutch father variables, because some
576 infertile clutches may have been assigned the incorrect ‘father’ and therefore the incorrect hand-rearing
577 status, age, copulation experience or parental kinship. However, omitting these clutches would instead
578 have created a much larger impact on the multiple copulation effect by removing a greater proportion
579 of infertile clutches (14/14 infertile clutches compared to 7/53 fertile clutches; Figure 4), therefore
580 overestimating the fertility increase from copulating with different males. Furthermore, this method made
581 use of the available information of the identity of the 2–3 candidate fathers known to have copulated
582 with the female (for example, in three infertile clutches all potential fathers had the same rearing status),
583 which the alternative method of imputing missing values (van Buuren and Groothuis-Oudshoorn, 2011)
584 would not. That this process affected less than 10% of all clutches also suggests that the impact of any
585 incorrectly-assigned paternity was relatively small. This was confirmed by a comparison of model results
586 with and without these clutches included, which showed that the overall conclusions were preserved.

587 There were other limitations due to the size and nature of the data. One is that the clutches from
588 multiple mates included those with repeated copulations with at least one of the males, so that any effect
589 attributed to multiple mates could at least partially be due to repeated copulations. The number of mates
590 and number of copulations could be decoupled with a larger data set in future, and a continuous rather
591 than categorical parameter used for the number of copulations. The use of a binary variable for clutch
592 fertility, rather than the proportion of fertile eggs per clutch, similarly results in a loss of information, but
593 is unavoidable given the non-independence of egg fertility within a clutch. The timings of copulations
594 relative to egg laying and the stage of the breeding period were not considered in our analyses, but may be
595 important predictors of fertility. It is also possible that the incidence of repeated copulations and multiple
596 mates was a function of female condition, with those in better condition able to visit and copulate with
597 more males. However, we did not include this effect since there were sparse data on female condition,
598 and it is unlikely to have a strong impact because most breeding females were maintained within a narrow
599 weight range by supplementary feeding (Clout et al., 2002).

600 The strong correlation of the proportion of clutches from multiple copulations with adult sex ratio
601 could potentially be influenced by an unmeasured co-correlate, particularly one which has changed over
602 time. The sex ratio has changed on Whenua Hou since 1990 (Supplementary Data S3), largely due to an
603 increase in the early 2000s which can be attributed to the optimisation of supplementary feeding resulting
604 in more female chicks (Clout et al., 2002) However, we do not consider it feasible that this change in
605 supplementary feeding could have similarly affected female copulation behaviour. Temporal changes in
606 spatial partitioning of the males and females on Whenua Hou is also unlikely to have contributed to the
607 observed correlation, since females have always had access to all displaying males.

608 **Fertility assurance**

609 The kākāpō reproductive data provide a rare opportunity to assess fertility benefits of females copulating
610 repeatedly with the same male. Close observation of individual mating behaviour is rare in wild bird
611 species, so there have been limited opportunities to assess the impact of repeated copulations to help
612 determine the reason for this behaviour. Some of the hypotheses for repeated copulations require a pair
613 bond or paternal investment, which are not present in kākāpō (Hunter et al., 1993). Other explanations
614 are that repeated copulations could reduce the likelihood of the male copulating successfully with other
615 females; could devalue the sperm from an inferior male; or could increase fertility through a higher
616 likelihood of the female receiving sufficient sperm (Petrie, 1992; Heeb, 2001; Hunter et al., 1993). The
617 first of these hypotheses is less likely to apply to kākāpō, because males copulate relatively infrequently,
618 despite apparently having the capacity to do so more often (Eason et al., 2006). The second explanation
619 is not supported by clutches in which the female kākāpō copulated only with one male (48% of the
620 217 clutches used in the model) or with one male before and after a second (9% of the 63 clutches
621 with multiple mates). The final explanation, the increased fertility hypothesis (Birkhead et al., 1987), is
622 supported in flycatchers, in which repeated inseminations from the same individual increased the number
623 of sperm reaching the perivitelline layer (PVL; Torok et al. 2003). Savage et al. (2021) provided evidence
624 that multiple copulations increase the number of sperm reaching the PVL in kākāpō. However, Birkhead
625 et al. (1987) concluded that there was no evidence that copulation frequency limited fertilisation across
626 multiple species, and Hunter et al. (1993) suggested that the hypothesis could not explain cases where
627 there were high numbers of repeated copulations. Nevertheless, our observed association of higher kākāpō
628 clutch fertility with repeated copulations, together with the results of Savage et al. (2021), suggests that
629 the fertility assurance hypotheses for repeated copulations applies to kākāpō.

630 The fertility assurance hypothesis is also supported by the result of increased clutch fertility from
631 copulations with different male kākāpō. With no male parental care in kākāpō due to their lek breeding
632 system, there are no clear benefits from increased access to resources from having multiple mates, which
633 is one proposed explanation for polyandry (Reding, 2014; Kempenaers, 2020). Instead, improved fertility
634 is likely to be a driver for polyandry in kākāpō (Parker and Birkhead, 2012). There is support for this
635 from observations of the passerine blue tit (*Cyanistes caeruleus*), in which extra-pair copulations appear
636 to be used to ensure a higher likelihood of fertility when a partner is infertile (Schmoll and Kleven, 2016;
637 Santema et al., 2020). This effect is also likely to apply to lekking species, as copulating with a single
638 male, which might be infertile, has a higher risk of clutch infertility.

639 **Sperm competition**

640 Competition between sperm from different males in the female reproductive tract might also be important
641 for increasing egg fertility in kākāpō through post-copulatory sperm selection (Birkhead et al., 1987;
642 Pizzari and Birkhead, 2000; Calhim et al., 2008; Santema et al., 2020). Evidence supporting this 'sperm
643 competition hypothesis' in kākāpō is provided by sperm morphology. Carballo et al. (2019) demonstrated
644 that parrot species which are gregarious, sexually dichromatic and/or have a high level of extra-pair
645 paternity all have longer sperm than monogamic psittacine species, indicating a higher level of sperm
646 competition. Their results therefore support the hypothesis that variation in sperm morphology is driven
647 by sperm competition in psittacines, as it is in passerines. Interestingly, Carballo et al. (2019) also
648 demonstrated that kākāpō sperm is longer than many other parrots and is in the range of species with
649 a high level of sperm competition. This suggests that the kākāpō has a naturally high level of sperm
650 competition, which is in accordance with their polyandrous lek breeding system.

651 Further support for the sperm competition hypothesis driving female kākāpō to copulate with multiple
652 males is provided by the incidence of mixed paternity broods. Under the hypothesis, copulating with
653 multiple males should be common, but mixed paternity within broods should be rare. This is because

654 copulation with multiple males is assumed to be driven by post-copulatory sperm assessment — for
655 example, if the initial mate is unlikely to fertilise the eggs due to infertility or insufficient sperm (Birkhead
656 et al., 1987; Jennions and Petrie, 2000; Rivers and DuVal, 2019). The frequency of mixed paternity is
657 low in kākāpō: only 2% (one out of 63) of clutches produced by natural copulations with multiple males
658 resulted in mixed paternity.

659 ***Mate guarding***

660 Mate guarding can also explain the instances in which females copulated repeatedly with the same
661 male. With competition for preferred males, female kākāpō may monopolise their preferred mate with
662 repeated courtship and copulations, as hypothesised for other species (Petrie, 1992; Hunter et al., 1993),
663 including lekking birds (Petrie et al., 1992). Females of polyandrous species may do this when there is
664 intense competition for males and a low male:female sex ratio, in order to distract the male from another
665 copulation or to reduce the capability of a male to fertilise another female (Petrie, 1992; Hunter et al.,
666 1993). Additionally, in populations with high genetic variability among males, females may use repeated
667 copulations to mate guard after copulating with a high-value male, to preserve the genetic advantage of
668 their offspring (Hunter et al., 1993). These mate guarding tactics may therefore offer advantages over
669 using aggression to deter other females (Petrie et al., 1992). Petrie et al. (1992) reported that of feral
670 female peahens which engaged in multiple copulations, approximately half copulated repeatedly with the
671 same male, which is a similar proportion to that found in kākāpō in our study (44%).

672 Copulations with multiple males can also be explained by mate guarding by female kākāpō, which is
673 common in polygamous species (Birkhead and Montgomerie, 2020). In a mating system driven by female
674 choice, it could be expected that since females can assess male quality before copulating, there would
675 be little cause for copulating with multiple males (Balmford, 1991; Rivers and DuVal, 2019). However,
676 if mate guarding by females takes place, then copulations with multiple males can result from females
677 having to ‘wait’ to copulate with their preferred male, and copulating with a non-preferred male first.
678 There is evidence for this in other lekking species, in which females which copulate with non-preferred,
679 subordinate or inexperienced males are more likely to copulate with multiple males (Petrie et al., 1992;
680 Rivers and DuVal, 2019). This suggests that in such systems the cost of copulation is low compared to the
681 cost of not copulating at all (Rivers and DuVal, 2019). In addition to evidence from multiple copulations,
682 there is also observational support for kākāpō females practising mate guarding: at least 13 females have
683 been detected at the display sites of males either the night before and/or after copulation (Joyce 2009;
684 KRT, 2021, personal observations). Leks are usually outside of females’ home ranges (Joyce, 2009),
685 so their presence at a male’s display site before and particularly after copulation is difficult to explain
686 without invoking repeated copulations and/or mate guarding (Petrie et al., 1992).

687 The correlation of the likelihood of multiple copulations increasing with female:male sex ratio is
688 consistent with the hypothesis that there is mate guarding by female kākāpō. As the threat of competition
689 for mates grows with a changing sex ratio, there may be more mate guarding by females through
690 monopolisation of preferred males with repeated copulations and subsequently more instances of females
691 copulating with different males when their preferred choice is not available (Petrie et al., 1992; Rivers and
692 DuVal, 2019). Similar variations in mate guarding behaviour with changing levels of competition from
693 varying sex ratio are evident in other species (Grant and Grant, 2019; Birkhead and Montgomerie, 2020).

694 ***Conservation implications of multiple copulation effects***

695 From their sperm morphology, mating system and our finding of lower fertility from single copulations,
696 we speculate that it is usual for female kākāpō to copulate multiple times and with multiple males. The
697 current situation in which females often copulate once with one male (48% of 217 clutches) may therefore
698 represent an abnormal state.

699 This situation may be the result of management practices, in which the density of kākāpō on breeding
700 islands (15–20 ha/bird; Whitehead et al. 2011) has been limited to reduce the likelihood of male deaths
701 from fighting, to ensure sufficient habitat for females, and to reduce nest interference. If the subsequent
702 density of kākāpō was lower than their natural state, particularly for females, this may have resulted in
703 fewer multiple copulations. Coupled with possible behavioural deficiencies in hand-reared males, this
704 could have led to reduced sperm competition and lower fertility in the contemporary population.

705 Having sufficient males available at leks was previously assumed to be important to encourage
706 females to visit and mate, but now takes greater significance in ensuring sufficient sperm competition by
707 encouraging repeated copulations and multiple mates. Kākāpō sites should therefore be stocked with high

708 densities of breeding males, while recognising that too many males on leks can lead to higher mortality
709 among males due to fighting. However, the potential impact of female density on fertility, not previously
710 considered in management strategy, appears to be more important than that of males density. Female
711 densities should be kept as high as the habitat can support, with a high female:male adult sex ratio. There
712 is no evidence of reduction in the number of multiple copulations at high sex ratios, so it appears that adult
713 female:male ratios could be at least as high as 1.6:1. However, this must be balanced against ensuring that
714 nesting females have sufficient quality habitat to enable them to rear chicks in nests.

715 The optimal sex ratio for kākākāpō is unknown, but the only remnant population with both sexes had a
716 male bias of 2:1 (Powlesland et al., 1995), which was relieved once the threat of predation was removed
717 and optimised supplementary feeding was introduced (Clout et al. 2002; Supplementary Data S3). Wild
718 bird populations tend to have male-biased adult sex ratios, but there is evidence that a female bias is
719 normal in lek species such as capercaillie (*Tetrao urogallus*), great bustard (*Otis tarda*) and hummingbirds
720 (Donald, 2007). Some populations of these species are heavily male-biased (female:male sex ratio
721 from 1:1.4 to 1:15), but this may be a result of sampling biases or sex-dependent survival in threatened
722 populations (Mollet et al., 2015; Santorek et al., 2021; Jiménez et al., 2022). Indeed, male sex bias may
723 reflect population vulnerability: it is common in small and fragmented populations (Dale, 2001); increases
724 with species' IUCN threat status (Donald, 2007); and population models and viability analyses for lekking
725 species shows that extinction risk is lowest with a female sex bias (Bessa-Gomes et al., 2004; Morales
726 et al., 2005). So examples of sex ratio from other birds, including lek species, further supports the need to
727 maintain a female sex bias in kākākāpō.

728 Artificial insemination should also be continued in kākākāpō, as a way to introduce sperm competition
729 when females copulate with only one male. Increasing sperm competition may be as important as
730 the primary reason artificial insemination was initiated in kākākāpō, which was to override any natural
731 copulations with a genetically unsuitable (i.e. closely related) mate.

732 Age effects

733 There was no strong impact of the age of either the clutch mother or clutch father on clutch fertility, with
734 both variables contributing negligibly to the model variance. Our analyses were limited in their ability to
735 investigate age effects, given the relatively young age of the contemporary population (mean age = 20.9
736 and 22.7 respectively for females and males in the model dataset). Our conservative estimate that kākākāpō
737 of unknown age were 10 years old on discovery may have exacerbated this by underestimating their true
738 age, but we consider this preferable to removing these individuals from the model, which would impact
739 the ability to investigate other variables. It was also not possible to assess differences in fertility between
740 hand-reared and wild-reared kākākāpō with increasing age, since all hand-reared kākākāpō were under 25
741 years old. This should be a focus of future analysis when the data set is sufficiently large, since the
742 developmental environment, including rearing method, has been shown to affect reproductive senescence
743 in other bird species (Balbontín and Møller, 2015; Murgatroyd et al., 2018; Cooper and Kruuk, 2018).

744 Despite the limitations, our finding of no impact of age on clutch fertility is unsurprising considering
745 that factors such as individual condition, food availability and population density can outweigh age effects
746 (Hammers et al., 2012; Oro et al., 2014). Similarly, that there were no strong differences in the contribution
747 of mother and father age to clutch fertility can also be explained by kākākāpō ecology. Sex differences in
748 senescence are often more pronounced in polygamous vertebrate species, with males tending to have
749 declining reproductive success at an earlier age than females (Clutton-Brock and Isvaran, 2007). This is
750 thought to be a result of males being less likely to win fights as they age, and therefore having reduced
751 access to females (Clutton-Brock and Isvaran, 2007). This might be expected in kākākāpō, with older, less
752 fit males less able to defend their position in the lek and attract females. However, with the 'exploded' lek
753 system in kākākāpō (Merton et al., 1984), direct competition among males may be less important.

754 Mating experience

755 Mating experience (in terms of the number of previous copulations observed since recording began) had
756 no impact on clutch fertility in kākākāpō for either sex, unlike in other species (DuVal, 2012; Kokko, 1997).
757 Our data were limited since some individuals will have had copulations before records began, and some
758 later copulation events were likely to have been missed. However, with the advent of automatic mating
759 detection systems these missed copulations will have been few, and the mating history information of
760 kākākāpō is very detailed compared to most other wild bird species.

761 Our results are in accordance with female kākāpō not preferentially copulating with the most experi-
762 enced males (Supplemental Data S1). Some males have displayed for decades, but have never or rarely
763 mated and produced offspring, despite being visited at the lek by females (Eason et al., 2006). Conversely,
764 some young males have produced offspring from first-time matings.

765 **Inbreeding**

766 Our model showed no discernible effect of parental kinship on apparent fertility, with a very small
767 contribution to the model variance (0.3% of the total ELPD difference). The use of apparent fertility,
768 which combines both ‘true’ infertility and very early embryo deaths, impeded the ability of our model to
769 determine parental kinship effects. Savage et al. (2021) suggest that our sample was likely to be dominated
770 by very early embryo death, which has been attributed to maternal and environmental effects as well as
771 genetic incompatibility (Savage et al., 2021; Assersohn et al., 2021b) – one measure of which is parental
772 kinship.

773 For the majority of bird species, small sample sizes combined with low rates of infertility have led to
774 reduced statistical power to detect genetic effects on fertility (Garamszegi, 2016; Assersohn et al., 2021b).
775 Our analyses were less impacted by these issues, but were unavoidably restricted by low kinship values
776 and range (0.0–0.265; median = 0.0074; Figure S2). This was perhaps at least partially a result of genetic
777 management methods such as translocations reducing the likelihood of closely related matings.

778 However, a study of whooping cranes showed lower parental kinship values and a lower spread (range
779 = 0–0.125; median = 0.0), yet still detected a strong association between parental kinship and apparent
780 fertility (Brown et al., 2019). It is unclear why this was not the case with kākāpō, although their different
781 breeding ecology could have led to a different relative contribution of genetic and behavioural effects.

782 Jamieson and Ryan (2000) also reported that higher apparent infertility of takahē on islands compared
783 to their mainland counterparts was at least partially attributable to genetic factors. However, environmental
784 factors were considered to dominate in takahē fertility, and both the whooping crane and takahē studies
785 did not distinguish true infertility from early embryo death (Assersohn et al., 2021b).

786 The results of most other studies assessing effects of parental kinship on fertility cannot be compared
787 to ours, since they use different measures of reproductive success, such as fledging rates (Morrison, 2020).
788 However, our results still suggest that parental kinship is not a strong driver of early reproductive failure
789 in kākāpō, relative to the behavioural effects.

790 Future studies should more closely examine the relationships between other measures of genetic
791 incompatibilities and low rates of fertility in kākāpō. For example, very early embryo death can also
792 be attributed to gross chromosomal abnormalities (Assersohn et al., 2021a) which would not have been
793 detected in our study.

794 **Sperm quality**

795 Many male kākāpō in the contemporary population have poor sperm quality, with low concentration and a
796 high frequency of morphological abnormalities (White et al., 2014). This is quite unusual for polyandrous
797 parrots. Bublat et al. (2017) demonstrated that *Electus* parrots, which also have a polyandrous breeding
798 strategy, had a high sperm density, very high total sperm count and few morphological issues compared to
799 monogamous macaws, which had a low sperm density, low total sperm count, lower motility and many
800 altered sperm cells. The authors speculated that sperm competition in polyandrous birds is an evolutionary
801 force for high semen quality. Calhim et al. (2007) also suggested that sperm competition can lead to
802 convergence to an optimum sperm morphology within a species. Therefore the low semen quality and
803 quantity found in the contemporary kākāpō population is not expected from their breeding biology, and
804 may instead be due to other reasons such as inbreeding (White et al., 2014) or diet.

805 Recent evidence suggests that male sperm quality may not be such a limiting factor in kākāpō fertility.
806 The microscopic egg analysis of Savage et al. (2021) showed that the true egg infertility rate in 2019
807 was 14%, rather than the 52% assumed. Infertility was still higher in males than females (17% and 2%
808 respectively), but this suggests that embryo deaths, rather than insufficient sperm reaching the egg, are the
809 biggest factor in kākāpō infertility. It is however still possible that sperm abnormalities could be a result
810 of genetic defects which in turn cause embryo deaths.

811 **Environmental effects**

812 The year random effect in the fertility model accounted for only a relatively small amount of the total
813 variance compared to the random effects of clutch father and mother identity (8% of total ELPD variation

814 for year; 50% and 12% for father and mother respectively). This suggests that variation among years was
815 less important than among individuals (particularly the clutch father), and that unmodelled individual
816 effects dominated unmodelled inter-annual ones. Factors which varied among years would have included
817 environmental factors such as climatic conditions, which may affect fertility, although this is poorly
818 studied in wild species (Walsh et al., 2019). Inter-annual variation would also have occurred in food supply,
819 particularly rimu abundance and whether ripe rimu fruit was available. Rimu abundance is correlated
820 with clutch size in kākāpō (Harper et al., 2006), but our results indicate that it is not strongly associated
821 with clutch fertility, nor are other environmental, dietary or climatic variations.

822 **Other species**

823 The implications from this study, particularly the impacts of hand-rearing, can also be considered for
824 conservation programmes of other species. In a review of global psittacine re-establishment projects,
825 Joustra (2018) reported that nearly a quarter (24%) used hand-reared individuals, with two-thirds of
826 those relying on them entirely. Although there are widely-reported negative impacts on behaviours such
827 as reduced predator avoidance, increased human interactions and aggression toward or avoidance of
828 conspecifics (Carrete and Tella, 2015; Utt et al., 2008; Joustra, 2018), further attention should be paid to
829 the more subtle but potentially more damaging impacts on fertility.

830 **CONCLUSIONS**

831 Our study suggests that some aspects of conservation management have inadvertently affected kākāpō
832 productivity by reducing clutch fertility. The management intervention of hand-rearing, while undoubtedly
833 increasing chick survival, has decreased clutch fertility. The sex difference in this effect indicates that
834 hand-rearing affects copulation behaviour in males more than females, in accordance with imprinting
835 behaviours found in hand-reared male but not female kākāpō. The evidence that female copulation
836 behaviour affects clutch fertility and is in turn affected by adult sex ratios, together with sperm morphology
837 and a mating system which indicates high levels of sperm competition, suggests that current kākāpō
838 population frequencies are lower than those previously selected for. This effect is perhaps a result of low
839 population size and may have been compounded by management of population densities.

840 That female copulation behaviour affects fertility in the lek-breeding kākāpō also has implications
841 for hypotheses for polyandry and repeated copulations. Our results, combined with those on kākāpō
842 sperm morphology, indicate that this behaviour is driven by high levels of sperm competition in kākāpō to
843 improve the likelihood of fertilisation. The increase in multiple copulations with increasing female:male
844 adult sex ratio also provides evidence that female mate guarding occurs in this species.

845 These combined findings have immediate applications in kākāpō conservation management. Hand-
846 rearing should be limited as much as possible for males; a reversal from previous strategies in which
847 retaining female chicks in nests was prioritised. Population densities should be maximised so that there
848 are sufficient males at leks to ensure adequate mate choice for females, but such that the female:male sex
849 ratio is kept as high as the habitat can support. Artificial insemination should also be continued, to ensure
850 sufficient sperm competition and increase founder representation.

851 As a growing kākāpō population provides a larger breeding data set, these analyses should be extended
852 to further investigate impacts on fertility. It is particularly important to assess whether the timing of
853 hand-rearing influences fertility. The effects of age, and its interaction with hand-rearing, should also be
854 re-assessed when there is a wider age range. With a rich genomics data set available for kākāpō (Guhlin
855 et al., 2022), the relationship between fertility and measures of genetic incompatibility beyond parental
856 kinship should also be explored. Finally, the findings of this study indicate the critical importance of
857 collecting detailed longitudinal data, and investigating similar impacts of hand-rearing and sex ratios in
858 other threatened bird species.

859 **ACKNOWLEDGMENTS**

860 Conservation management of kākāpō is led by the Kākāpō Recovery Programme of the New Zealand
861 Department of Conservation (NZDOC), in close partnership with Ngāi Tahu, the largest Māori iwi (tribe)
862 of the South Island of Aotearoa/New Zealand. The intent is to restore the *mauri* (life force) of the species
863 by returning them to their original range on mainland Aotearoa.

864 This study relied upon the observational data collected and managed over more than 30 years by the
 865 Kākāpō Recovery Team. Members of this team who collected field data from 1990 – 2019 are listed
 866 in Supplementary Data S4. Thanks are also due to the many volunteers, veterinarians and others who
 867 contributed to kākāpō conservation over this period. Huge respect and admiration are especially deserved
 868 by the personnel who worked under difficult field conditions without the benefit of remote monitoring
 869 methods during periods of low kākāpō productivity from the 1970s to early 2000s. Particular thanks also
 870 go to Daryl Eason, Graeme Elliott and Ron Moorhouse for the generation, maintenance and accessibility
 871 of this data set. Lydia Uddstrom provided helpful comments on the manuscript.

872 The genetic data relied upon the Kākāpō 125+ Project, which generated genomic sequences for all
 873 living and recently-deceased kākāpō. The generation and availability of these data owed much to the
 874 Genetic Rescue Foundation, Science Exchange and Experiment.com who coordinated and provided
 875 funding; Ngāi Tahu who provided advice on Mātauranga Māori (indigenous knowledge) and cultural
 876 safety and provided governance; Bruce and Fiona Robertson (University of Otago, Dunedin, New Zealand)
 877 who performed DNA extractions; Erich Jarvis (Rockefeller Institute, NY, USA) and Jason Howard (Duke
 878 University, USA) who provided genetic advice; many staff members at NZDOC who collected samples;
 879 and Genomics Aotearoa who provided advice on conservation genetics and governance.

880 The authors wish to thank two anonymous referees and editor Donald Kramer for the suggestions
 881 which greatly improved this manuscript.

882 **ADDITIONAL INFORMATION AND DECLARATIONS**

883 **Author Contributions**

884 Conceptualisation: AD, DE, DV and ML.

885 Data curation (clutch fertility and demography): DE, AD, DV, KRP (many staff and volunteers since
 886 1981).

887 Data curation (parental kinship data): SG, DE, JG, ML, LU, TJ, CL, TS, PD.

888 Formal analysis (clutch fertility and demography): AC, AD, DE.

889 Formal analysis (parental kinship): SG, JG, ML, LU, TJ, CL, TS, PD.

890 Writing - original draft: AD.

891 Writing - review and editing: AD, DE, ML, AC, DV, LU, TS, JG, PD, TJ, TD, KRP, CL.

892 Supervision: DV, TD, TS, PD.

893 Funding: DV.

894 **Data Availability**

895 The clutch data, demographic data and R code used in the fertility models and analysis of multiple
 896 copulations are available as Supplementary Files.

- 897 • Supplemental Figure S1: distribution of the number of days for which kākāpō were hand-reared,
 898 from the 59 kākāpō (38 females and 21 males) hatched after intensive management and hand-rearing
 899 began which contributed to the data set of 225 clutches
- 900 • Supplemental Figure S2: distributions for the numeric fixed parameters in the Bayesian model of
 901 clutch fertility.
- 902 • Supplemental Table S1: likelihood of paternity based on male copulation order, used to sample
 903 from candidate males to select a clutch father for clutches without genetic confirmation of paternity.
- 904 • Supplemental Data S1: Comma-separated file containing clutch data used in the Bayesian model.
- 905 • Supplemental Data S2: Comma-separated data file containing numbers of kākāpō per island per
 906 year used in the multiple copulation – density analysis.
- 907 • Supplemental Data S3: `html` file produced by `RMarkdown`, containing code and results for the
 908 fertility models and multiple copulation – density analysis.
- 909 • Supplemental Data S4: text file listing employees of the Kākāpō Recovery Team who collected
 910 field data from Jan 1990 – May 2019.

Figure S1. Distribution of length of hand-rearing. Distribution of the number of days for which kākāpō were hand-reared, from the 59 kākāpō (38 females and 21 males) hatched after intensive management and hand-rearing began which contributed to the data set of 225 clutches. Values at the right edges are included in each bin.

Figure S2. Model predictor distributions. Distributions for the numeric fixed parameters in the Bayesian model of clutch fertility. The values at the right edges are included in each bin.

911 Supplementary Information

912 Animal Ethics

913 The following information was supplied relating to ethical approvals:

914 The data used in this study were collected as part of routine kākāpō conservation management
 915 conducted by NZDOC as required by the New Zealand Conservation Act (1987), and so this study was
 916 exempt from the requirement of animal ethics approval under NZDOC's obligations to the New Zealand
 917 Animal Welfare Act (1999).
