**Background:** In the past several decades, obesity has become a major public health issue worldwide, associated with increased rates of chronic disease and death. Like many developing nations, South Africa is experiencing rapid increases in BMI, and as a result, evidence-based preventive strategies are needed to reduce the increasing burden of overweight and obesity. This study aimed to determine the prevalence and predictors of overweight and obesity among a multi-ethnic cohort from the rural Northern Cape of South Africa. **Methods:** These data were collected as part of a tuberculosis (TB) case-control study, with 395 healthy control participants included in the final analysis. Overweight and obesity were defined according to WHO classification. Multivariate linear models of BMI were generated using sex, age, education level, smoking, alcohol consumption, and diabetes as predictor variables. We also used multivariable logistic regression analysis to assess the relationship of these factors with overweight and obesity. **Results:** The average BMI in our study cohort was 25. 2 . The prevalence overweight was 18. 0 % and the prevalence of obesity was 2 5 .0 %. We find that female sex, being older, having more years of formal education , having diabetes, and being in a rural area are all positively associated with BMI in our dataset. Women (OR = 5.6, 95% CI = 3.3-9.8), rural individuals (OR = 3.3, 95% CI = 1.9-6.0), older individuals (OR = 1.02, 95% CI = 1-1.04), and those with more years of education (OR = 1.2, 95% CI = 1.09-1.32) were all more likely to be overweight or obese. Alternatively, being a smoker is negatively associated with BMI and decreases one's odds of being overweight or obese (OR = 0.28, 95% CI = 0.16-0.46). **Conclusions:** We observed a high prevalence of overweight and obesity in this study. The odds of being overweight and obes e were higher in women, those living in rural areas,

and those with more education, and increases with age. Community-based interventions to control obesity in these communities should pay special attention to these groups.

25 **Abstract**
26 **Background.**

27 In the past several decades, obesity has become a major public health issue worldwide,

28 associated with increased rates of chronic disease and death. Like many developing nations,

29    South Africa is experiencing rapid increases in BMI, and as a result, evidence-based preventive

30    strategies are needed to reduce the increasing burden of overweight and obesity. This study

31    aimed to determine the prevalence and predictors of overweight and obesity among a multi-

32    ethnic cohort from the rural Northern Cape of South Africa.

33    **Methods.**

34    These data were collected as part of a tuberculosis (TB) case-control study, with 395 healthy

35    control participants included in the final analysis. Overweight and obesity were defined

36    according to WHO classification. Multivariate linear models of BMI were generated using sex,

37    age, education level, smoking, alcohol consumption, and diabetes as predictor variables. We also

38    used multivariable logistic regression analysis to assess the relationship of these factors with

39    overweight and obesity.

40    **Results.**

41    The average BMI in our study cohort was 25.2. The prevalence overweight was 18.0% and the

42    prevalence of obesity was 25.0%. We find that female sex, being older, having more years of

43    formal education, having diabetes, and being in a rural area are all positively associated with

44    BMI in our dataset. Women (OR = 5.6, 95% CI = 3.3-9.8), rural individuals (OR = 3.3, 95% CI

45    = 1.9-6.0), older individuals (OR = 1.02, 95% CI = 1-1.04), and those with more years of

46    education (OR = 1.2, 95% CI = 1.09-1.32) were all more likely to be overweight or obese.

47    Alternatively, being a smoker is negatively associated with BMI and decreases one's odds of

48    being overweight or obese (OR = 0.28, 95% CI = 0.16-0.46).

49    **Conclusions.**

50    We observed a high prevalence of overweight and obesity in this study. The odds of being

51    overweight and obese were higher in women, those living in rural areas, and those with more

52   education, and increases with age. Community-based interventions to control obesity in these

53   communities should pay special attention to these groups.

54

55   **Introduction**

56          Obesity, a medical condition characterized by excessive fat accumulation, can have

57   severe consequences for health, including increased risk of cardiovascular disease, certain

58   cancers, and stroke [1].  Obesity is most commonly determined through the measurement of

59   Body Mass Index (BMI), a metric calculated by dividing an individual's weight in kilograms by

60   their height in meters squared. From 1990 to 2015, global mortality associated with elevated

61   BMI increased by 28.3%, with the majority of these deaths being caused by cardiovascular

62   disease [4]. In addition to its effects on individual health, high obesity incidence can have

63   substantial economic implications, with a global impact of approximately $2.0 trillion annually

64   [5]. The costs linked to obesity range from medical expenses and pharmaceuticals to absenteeism

65   and premature mortality [6].

66          Global obesity prevalence increased almost three-fold between 1975 and 2016 [7]. A

67   2015 study showed that 603.7 million adults globally were classified as obese, representing

68   12.0% of the adult population [4]. Based on current trends, it has been estimated that 1.12 billion

69   adults worldwide will be classified as obese by 2030, and an additional 2.16 billion as

70   overweight [8], roughly 40% of the world population. Sub-Saharan Africa in particular has

71   shown staggering increases in obesity prevalence in the past several decades. Among seven

72   countries surveyed in this region in 2009, an average of 31.4% of women were classified as

73   overweight or obese [9]. But this varies by sex, with men frequently having much lower rates of

74   obesity compared with women [10].

75    The etiology of overweight and obesity is multi-factorial with many genetic and

76    environmental inputs that have been previously identified. Behavior plays an important role, with

77    nutrition, physical activity levels, and sleeping patterns all being previously associated with an

78    individual's BMI [45].  Smoking is correlated with lower BMI, and BMI tends to increase after

79    individuals stop smoking [11-12]. Alcohol consumption has also been linked to BMI outcomes,

80    however whether this correlation is positive or negative has been widely debated in the literature

81    [13]. Understanding the factors involved in overweight and obesity is of high importance to

82    public health researchers, as obesity is a risk factor for type 2 diabetes, among other diseases that

83    are increasing in many LMICs [2, 3].

84    In accordance with both global trends and those observed in sub-Saharan Africa, the

85    population of South Africa has also seen a rapid increase in average BMI over the past several

86    years [14–16]. As of 2016, 33% of men and 68% of women in South Africa were categorized as

87    overweight or obese [17]. These values are higher than what has been reported in other African

88    nations [18]. Various behavioral factors have also been studied in South African populations,

89    with several studies indicating an inverse correlation between smoking and BMI [12, 19]. The

90    higher obesity incidence among women as compared to men in South Africa is a trend often

91    observed in developing nations [8, 18, 20].

92    It is important to note, however, that the majority of research on BMI and obesity in

93    South Africa has been conducted on urban cohorts, particularly in the Eastern and Western Cape

94    Provinces [21, 22]. Although national statistics on measures of obesity are available that are

95    representative of both urban and rural communities in South Africa [17], these are reported at the

96    provincial level as part of the South Africa Demographic and Health Survey (DHS). As part of

97    the most recent DHS, only 177 residents of the Northern Cape province were sampled for

98     measures of body mass index (68 men and 109 women) [17]. As a result, the variation in

99     overweight and obesity across rural and peri-urban South African districts and municipalities,

100    such as those in the Northern Cape Province, remains limited, restricting our understanding of

101    how overweight and obesity manifest in these communities. This gap in the literature is

102    important given the observed differences in obesity trends between urban and rural communities

103    in lower- and middle-income nations [23]. In South Africa specifically, women in urban areas

104    were 1.6 times more likely, and urban men 2.3 times more likely, to have excessive BMI than

105    those in rural areas [20]. However, the average BMI of both men and women is increasing much

106    more rapidly among rural communities than urban communities globally [24]. Further

107    investigation in these smaller communities is crucial in identifying risk factors and working

108    towards improved public health initiatives and education.

109            In this study, we analyze some of the demographic and behavioral factors related to BMI

110    in the Northern Cape of South Africa. Our sample consists of 395 individuals from rural areas,

111    small towns, and one large municipality in the province. Investigating these factors will give us a

112    more fine-grained understanding of obesity across the region and lay the groundwork for the

113    development of specialized public health and education initiatives to reduce the prevalence of

114    obesity and overweight among this region.

115
116    **Materials & Methods**
117    Study Design and Sampling Procedure

118            The data used in this study were collected as part of the Northern Cape Tuberculosis

119    (NCTB) Project, a case-control study on host susceptibility to TB. Between 2017 and the

120    beginning of the SARS-CoV-2 pandemic in 2020, data was collected on 1,095 individuals ($N_{men}$

121    = 544; $N_{women}$ = 551) recruited from 12 community (public) health clinics in the Northern Cape

122    Province, South Africa that serve populations with high TB rates, mostly in rural towns with

123    populations under 10,000. The Northern Cape Province has the largest area, lowest population

124    size and lowest population density among provinces in South Africa [50]. Data was collected via

125    participant interviews, medical histories, saliva samples, and anthropometric measurements.

126    Patients ≥18 years and older evaluated for TB were invited to participate.  Participants were

127    partitioned into the case or control group based on a decision tree considering previous TB

128    diagnosis, treatment for TB, and TB test results obtained during the course of the study

129    (Oyageshio, in prep.).  In the present study, only participants with a negative TB result were

130    included due to a symptomatic effect of TB on BMI [25].  Because TB was much more common

131    among men than women in our study (Oyageshio, in prep.), our final sample of 395 healthy

132    controls included substantially more women than men ($n_{male} = 145$; $n_{female} = 250$). Community

133    healthcare clinics are the front-line for medical care and triage, and often the sole healthcare

134    facility.  The sampling strategy was purposively designed for TB cases and controls not for BMI

135    (i.e., convenience sample), however, this sample retains some heterogeneity in controls as most

136    members of the population seek medical care from the community healthcare clinics and because

137    TB exposure is community-wide [52-56] anyone meeting the minimum criteria for TB

138    evaluation is tested.

139

140    Ethics and Informed Consent

141         Data collected from study participants was approved by the Health Research Ethics

142    Committee of Stellenbosch University (Project number: N11/07/210A) and the Institutional

143    Review Board of the University of California, Davis (IRB number: 1749073-1). Participation in

144    this study was voluntary, with the ability to withdraw at any time. Written informed consent was

145    obtained and subsequent medical and demographic questionnaires were conducted in the local

146    language of Afrikaans by trained research assistants from the community. All data was kept

147    confidential with no connections to participant names. Deidentified variables were stored in a

148    secure RedCap database following data collection.

149

150    Demographic and Socio-economic Factors

151         Demographic information was collected through interviews and recorded on a data

152    collection sheet. Participants were asked to provide their town of residence, highest level of

153    education achieved, and the ethnic group with which they self-identify.

154

155    Medical History

156         During interviews, participants self-reported diabetes, HIV, asthma, and TB status. If

157    participants reported having diabetes, they were asked to identify if they were a type 1 or type 2

158    diabetic. HIV status was self-reported as positive, negative, or unknown. Asthma was recorded as

159    no, yes, or unknown. In addition to asking participants whether they had TB at the time of the

160    study, they were also asked if they were currently taking TB medication, whether they had TB in

161    the past, and if so, how many TB episodes they had experienced. Following the self-reporting of

162    TB information, TB tests were administered to all participants using GeneXpert, Auramine O

163    Stain, GeneXpert Ultra, SMEAR, or Culture tests.

164

165    Behavioral Factors

166         Alcohol use was evaluated by asking participants if they drink alcohol. If yes, further

167    information was collected regarding the specifics of their alcohol consumption. Participants were

168 asked whether they drink beer, wine, liquor, or ginger beer, and how much of each they consume

169 during the week and weekend. Smoking behavior was categorized as yes or no. If participants

170 answered yes to smoking, they were asked to provide the age at which they began smoking, as

171 well as the average amount they smoke per day.

172

173 Anthropometry

174  Height was measured using a Charder HM200P stadiometer. Participants were asked to

175 look straight ahead and stand with their heels against the wall while measurements were being

176 taken. One height measurement was recorded for participants in pilot data collection and two

177 measurements were taken upon initiation of the primary study. For individuals with two recorded

178 measurements for height, the average of these values was used. Weight was measured with a

179 Seca 876 digital scale and recorded once. Height and weight measurements were used to

180 calculate BMI for each participant using the equation: $BMI = kg/m^2$. Waist and hip

181 circumference measurements were taken with the guidance of a research assistant using a

182 measuring tape, following WHO measurement guidelines [49]. Waist-to-hip ratio was calculated

183 by dividing average waist circumference (cm) by average hip circumference (cm).

184 Anthropometric variables were collected by community research assistants trained by the

185 researchers. The collection procedures of all research assistants are evaluated every 3-6 months

186 to ensure continued accuracy of the measurements and consistency across research assistants.

187 Following calculation of BMI, participants were assigned to weight categories based on the

188 guidelines set forth by the Centers for Disease Control and Prevention: those with a BMI < 18.5

189 were classified as "Underweight", 18.5 to <25 as "Healthy," 25 to <30 as "Overweight," and 30

190 or higher as "Obese" [26].

191

192    Quality Control

193         Participants who were TB positive, HIV positive, or both (N = 642), were removed from

194    this study due to an expected effect of disease on BMI. All hip and waist measurements

195    supervised by community health care worker #5 were also removed due to errors in measurement

196    technique, where waist and hip circumferences were not being measured at the widest point.

197    BMI could not be calculated for an additional 18 participants due to an absence of height

198    measurements, weight measurements, or both, and these individuals were removed. A

199    total of 395 individuals were included in BMI analyses, 206 of which were recruited during pilot

200    data collection. The addition of WHR measurements and additional questions about smoking and

201    drinking behavior (types and amounts of alcohol/tobacco consumed daily) were added to the

202    collection protocol after the pilot phase. As a result, these additional behavioral variables were

203    not included in the BMI model, and our sample sizes for the WHR measurements are much

204    lower than that of the overall BMI analysis (**Table 1**).

205

206    Statistical Analyses

207         Quality control and data analysis were performed in R 4.0.2 and ggplot2 [29] was used

208    for data visualization. Seven covariates (alcohol intake (yes or no), smoking (yes or no), diabetes

209    (yes or no), sex, age, clinic type (large town, small town, rural) and years of education) were

210    entered into a generalized linear model to further characterize their association with BMI. As

211    observed in other studies, BMI was not normally distributed among our sample, therefore we

212    used log-transformed BMI as the outcome variable. Large town, the most common outcome for

213    clinic type, was used as the reference for this variable. Bivariate effect plots were generated

214    between BMI and each individual covariate included in the model using the *effects* R package

215    [27, 28].

216          We also performed statistical analyses using waist-to-hip ratio (WHR) in place of BMI. A

217    generalized linear model was created using WHR as the outcome variable and included alcohol

218    intake, smoking, diabetes, sex, clinic type, years of education, and age. This model included 161

219    participants. Our generalized linear models were supplemented by binomial models and the

220    generation of odds ratios using the *questionr* package [30] to investigate the relationship between

221    individual variables and WHO-established BMI categories (overweight/obese versus not).

222

223    **Results**

224    Participant Demographics

225          Our final sample (**Table 1**) included 395 participants ($n_{male}$ = 145; $n_{female}$ = 250). The

226    mean age was 44 years ± 15, with all participants falling between 18 and 86 years of age. Our

227    dataset was collected across twelve study sites, representing rural areas (n=158), small towns

228    (n=106), and one small city (n=131) from the Northern Cape Province, South Africa. The most

229    common self-identified ethnicity among participants was Coloured (87%, people of indigenous

230    Khoe-San, Bantu-speaking African, European, Southeast Asian and East Asian ancestry) [51],

231    followed by Nama (4%) and Tswana (3%) (**Table S1**). Approximately 7% of participants

232    reported having no education, 27% reported attending or completing primary school only, and

233    66% reported attending or completing secondary school.

234

235    Behavioral Factors

236          The majority (62%) of participants were smokers. Among women, 54% reported that

237    they smoked, compared to 75% of men. Only 39% of participants reported consuming some

238 quantity of alcohol. This also differed by sex, with 50% of men and 34% of women in our

239 sample reporting alcohol consumption.

240

241 Anthropometry and BMI

242 Mean height and weight were 159.2cm ± 10.0 (range: 109.4-184.9cm) and 63.5kg ± 19.3

243 (range: 27.0-134.0kg) respectively. The mean BMI was 25.2 ± 8.0. Nearly a quarter (22.3%) of

244 participants were classified as underweight, 35.2% as healthy, 18.0% as overweight, and 24.6%

245 as obese. The distribution of individuals between these classifications differed substantially

246 between male and female participants, with 36.0% of female participants being placed in the

247 obese category compared to only 4.8% of male participants (**Table 1**).

248

249 Factors associated with BMI, WHR, and obesity

250 We fit a generalized linear model to investigate the relationship between BMI and the

251 factors of sex, age, education, smoking, drinking, diabetes status, and clinic type. This model

252 showed significant relationships between BMI and smoking, sex, education level, age,

253 diabetes, and rural clinics (**Table 2**). Together, these factors explained 27% of the variance in

254 BMI among our cohort, with an F-value of 26.54 ($p<0.001$). Being female showed a strong

255 positive correlation with BMI, as did age, years of education, and rural clinic type. The

256 relationships between each of these variables and BMI were observed in our bivariate effect plots

257 (**Figure S1**), which indicated a 5-point BMI increase for women, a 4-point decrease for smoking,

258 a 6-point increase for having 14 years of education as compared to zero, and a 4-point increase

259 for rural clinic locations as compared to large towns

260    We find evidence that women in our sample had over 5 times greater odds of being

261    overweight or obese compared to men (OR = 5.56, 95% CI = 3.3-9.8, p < 0.001; **Table 3**). In our

262    dataset, increasing age as well as additional years of school increased the odds of being

263    overweight or obese (p = 0.01). Smoking, on the other hand, showed a significant negative

264    correlation with BMI (p <0.001). In fact, smoking decreased the odds of being overweight or

265    obese by nearly 75% in our study population (OR = 0.28, 95% CI = 0.16-0.46). Rural clinic type

266    was associated with 3 times greater odds of being overweight or obese (OR = 3.29, 95% CI =

267    1.85-5.97, p < 0.001). Additionally, the odds of being overweight or obese were more than 4

268    times greater in participants with type 2 diabetes (p = 0.01).

269    We also explored the factors associated with waist-to-hip measurement ratios in our

270    dataset. This model was fit on a subset of the dataset (**Table S1**; n=160), as waist and hip

271    measurements were not available for all participants. We find a slight positive correlation

272    between WHR and years of education (p = 0.03), but together these variables only explain ~1

273    % of the variance in WHR in our dataset with an F-value of 1.15 (p = 0.33). No other covariates

274    showed a significant association with WHR.

275

276    **Discussion**

277    In this study we analyzed the demographic and socio-behavioral factors related to BMI in

278    an adult cohort from the Northern Cape Province, South Africa. Our results suggest a significant

279    difference in obesity trends between men and women in the study population, with 57% of

280    female participants being overweight or obese compared to only 19% of male participants. This

281    may be partly explained by differences in behavior. In our dataset and elsewhere in the published

282    literature [12, 31, 35], smoking has a strong negative correlation with BMI in both men and

283 women, with our results indicating that smoking decreases odds of being overweight or obese by

284 75%. Nicotine use suppresses appetite and causes an increased resting metabolic rate, resulting

285 in weight loss [48]. With 25% more men in our dataset reporting smoking compared to women,

286 this may in part explain the sex difference in obesity rates observed in our dataset.

287       Social factors are also likely important in explaining these sex differences in overweight

288 and obesity, as they influence behavioral traits associated with overweight and obesity. Past

289 research has shown that higher BMI is desirable in many African countries, as it is representative

290 of wealth, health (particularly absence of HIV), and fertility in low-income communities where

291 many lack adequate access to food [36-41]. This preference, along with women having control

292 over household food spending [36], may be contributing to nutritional behavior of individuals in

293 our study population as well, leading to increased rates of overweight and obesity in women

294 relative to men [19]. Socioeconomic status, including educational level, is also positively

295 correlated with BMI and negatively correlated with physical activity for both men and women in

296 South Africa [35, 42, 43], as well as other low- and middle-income nations [35, 44, 46, 47]. This

297 aligns with our result demonstrating the more education one has, the higher their BMI and may

298 be reflective of better access to resources for those individuals.

299       To better understand our findings within the wider national context, we compared our

300 results to the 2016 South Africa Demographic and Health Survey [17], which collects

301 representative provincial-level data on several public health metrics. Compared with the DHS

302 data on the Northern Cape province as a whole, we find similar levels of overweight and obesity

303 for women in our study area (57% and 62%, respectively). However, we find substantially fewer

304 overweight and obese men (18% versus 32%) and substantially more underweight men in our

305 sample compared to the province as a whole (39% versus 19%). Interestingly, our findings

306    demonstrate greater odds of being overweight or obese in rural regions than in large towns.

307    While previous data in South Africa has found that men and women in urban areas were more

308    likely to have excessive BMI than those in rural areas, on a global scale, the average BMI of both

309    men and women is increasing much more rapidly among rural communities than urban

310    communities [24]. In contrast to our findings, province-wide measurements from the DHS show

311    no substantial differences in BMI between urban and rural samples, demonstrating the regional

312    variability in obesity and reinforcing the need to collect more data at the district and municipality

313    level to better understand the demographic and social factors that may be influencing obesity on

314    a local scale.

315        The present study is not without limitations. BMI is a simple and widely used metric for

316    obesity, however, it does not distinguish between excess fat, muscle, or bone mass, or provide

317    any indication of the distribution of fat among individuals [31, 32], whereas WHR is better at

318    predicting visceral adiposity and cardiometabolic disease risk [33, 34]. Future work

319    incorporating these and other more sensitive measures of adiposity will provide greater detail

320    into the risk-factors and consequences of obesity in this population.

321        In addition, the sampling strategy for this study was purposively designed to maximize

322    TB cases and controls, not necessarily for maximizing heterogeneity of BMI in the population.

323    Despite this limitation, our controls are fairly evenly distributed across important variables such

324    as age, education, height, and weight. Additionally, because TB exposure is community-wide,

325    reaching ~90% by age 30 [52-56], TB nurses and healthcare staff test anyone meeting the

326    minimum criteria for TB evaluation; and because these community healthcare clinics are

327    typically the only accessible facility, it is seen by all members of the community. While this

328    sample includes more heterogeneity than a typical convenience sample, it does not fully assuage

329    biases, such as higher SES patients who opt for out-of-area private medical clinics or selection

330    biases in who decided to seek medical attention, among others.

331

332    **Conclusions**

333         Overall, our results suggest that smoking, sex, education level, age, location, and diabetes

334    all influence BMI outcomes among the rural population of the Northern Cape of South Africa,

335    consistent with previous research in other South African cohorts and developing nations. These

336    results deepen our understanding of the factors contributing to obesity risk in this region. They

337    also highlight the regional diversity in BMI across South Africa and the need for more

338    monitoring at the local level. The present study was limited somewhat by the behavioral data

339    collected as part of the larger TB study. A necessary future direction of this work will be to

340    include additional measures of adiposity, physical activity and dietary behaviors, and socio-

341    economic status to obtain a more complete understanding of the risk-factors for obesity in the

342    Northern Cape. This will allow for better identification of high-risk groups for behavioral

343    interventions, ultimately mitigating the public health and economic burdens created by the global

344    obesity epidemic at the local level.

345

346    **Acknowledgements**

347    First and foremost, we would like to thank our participant communities in the Northern Cape for

348    their continued trust and support in helping us undertake this project. We would also like to

349    thank our community research assistants and translators who assisted in data collection for the

350    project. Finally, we want to thank the Department of Health in the Northern Cape Province,

351    South Africa for their continued support of the project.
