## ABSTRACT

Thoroughly documenting prey items and diet composition is crucial for understanding a predator's role in the ecosystem. In gape restricted predators, such as snakes, documenting and analyzing the type and size of the prey is important to interpret their ecological role. We describe the diet patterns of a species of venomous snake, the Terciopelo pit viper (*Bothrops asper*), from its Ecuadorian populations. Examining the gastrointestinal contents of museum specimens collected over an extensive area of the Pacific lowlands of Ecuador, we encountered 69 identifiable prey items from four major taxonomic groups (amphibians, centipedes, mammals, and reptiles). We evaluated the observed composition of prey to check for differences between sexes and size-classes. To complement our observations of the Terciopelo species complex throughout their distribution, we carried out a systematic literature review. Our data show an ontogenetic shift in diet, with a transition from more diverse diet in juveniles towards a mammal-specialized diet in adults, and distinct proportion of prey taxa between the sexes in the juvenile size class.

## INTRODUCTION

Predator-prey interactions play an important part in shaping ecosystems, with both predator and prey constantly adapting their functional roles (Gibert & DeLong, 2017; Schalk & Cove, 2018; Glaudas et al., 2019). Information on the relationship between a predator and the type and size of its prey can contribute to the understanding of the functioning of ecosystems (Reuman & Cohen, 2004; Schalk & Cove, 2018) and of the ecological impact that changes in prey availability can have on a population (Zipkin et al., 2020). This connection is well-known in snakes, given their unique feeding strategies (e.g., use of venom, constriction, luring, ambush, thermal detection, whole prey consumption;

Greene, 1997), due to allometric constraints which had a major role in their feeding biology (Martins, Marques & Sazima, 2002). These strict relationships have the potential to radically change with sex or age (Shine, 1991).

The Terciopelo pit vipers, *Bothrops asper* (Garman, 1883) species complex (Salazar-Valenzuela, 2016; Saldarriaga-Córdoba et al., 2017; Salazar-Valenzuela et al., 2019; Mora-Obando et al., 2020), are highly adaptable venomous snakes distributed from eastern Mexico, throughout Central America, to Colombia and Venezuela (western and Caribbean), western lowlands of Ecuador, and down to the extreme northwestern Peru (Solórzano & Cerdas, 1989; Campbell & Lamar, 2004; Cisneros-Heredia & Touzet, 2004). They occupy a wide range of ecosystems and have successfully adapted to modified habitats (Campbell & Lamar, 2004; Sasa, Wasko & Lamar, 2009). Early dietary records indicate that the Terciopelo is a generalist predator, with a taxonomically diverse diet composed of prey items of various sizes (Mole, 1924; Parker, 1926; March, 1928; Barbour & Loveridge, 1929; Nicéforo-María, 1930; Smith, 1947). The most complete accounts of feeding patterns of *B. asper* come mainly from populations in Central America (Solórzano & Cerdas, 1989; Sasa, Wasko & Lamar, 2009; Wasko & Sasa, 2012). Sasa, Wasko & Lamar (2009) list 42 types of prey, with rodents being the most common (69%), followed by birds (10.3%), lizards (10.3%), and anurans (6.9%), and a significant difference between males and females in terms of the type of selected prey. Additionally, they found that adults consume larger prey masses relative to their body compared to juveniles and subadults. Kuch et al. (2004) and Boada et al. (2005) published the first accounts for populations in Ecuador, registering amphibians, birds, centipedes, insects, and mammals among prey items. Since these reports referred to specimens predominantly from the central-northern part of the country, a broader study that includes specimens from populations from the north and south of the country is needed, reflecting the lineage diversity shown by this species in Ecuador (Salazar-Valenzuela et al., 2019).

In this study, we analyze the diet of *B. asper* along the Pacific coast of Ecuador and provide a comprehensive list of prey items. We also test if niche and prey size are influenced by sexual maturity and/or sex. Additionally, we synthesize all available published data on the diet of the species complex available in the literature, generating a comprehensive list of prey types, countries, and publication type, providing a better understanding of the feeding habits of Terciopelo pit vipers.

## MATERIALS AND METHODS

### Sampling and collections

To describe the diet of the *B. asper* complex in Ecuador (Salazar-Valenzuela et al., 2019), we examined the gastro-intestinal tract (GIT) contents of 193 specimens (105 females and 88 males) from the collections of Museo de Zoología de la Pontificia Universidad Católica del Ecuador (QCAZ) and Museo de Zoología, Universidad Técnica Particular de Loja (MUTPL). Most of the examined specimens were fixed in 10% formalin and stored in 75% ethanol. As some specimens were killed by humans, they showed considerable damage, especially near the head, preventing, in some cases, accurate morphological measurements.

Permits for this research (001-10 IC-FAU-DNB/MA, 005-12 IC-FAU-DNB/MA, 005-14 IC-87 FAU-DNB/MA, MAE-DNB-CM-2015-0016 and MAAE-ARSFC-2020-0727) were issued by Ministerio del Ambiente, Agua y Transición Ecológica del Ecuador.

### Predator-prey relationship

Before examination, each specimen was put in a slightly tilted tray for 30 min to drain as much of the liquid as possible, and, if necessary, dried with blotting paper. For each snake, body mass, snout-vent length (SVL), tail length, and diameter of the narrowest part of the neck were recorded. Measurements were performed with a caliper or a string to the nearest 1.0 mm (three consecutive measurements were performed for consistency and precision). Body mass was recorded with a precision scale to the nearest 0.1 g for specimens of less than 500 g, while larger specimens were measured to the nearest 1 g. Specimens were classified as juveniles (<60 cm), subadult males (60–98 cm), subadult females (60–110 cm), adult males (>98 cm) and adult females (>110 cm; [Solórzano & Cerdas, 1989](#); [Sasa, 2002](#); [Boada et al., 2005](#)). Sex was determined by tail dissection and/or observation of ovaries or testes during GIT inspection. A ventral incision was performed along the body to extract prey items from the snake's digestive tract (stomach and small and large intestines); prey location (distance from the snake's head) and direction of ingestion were recorded.

Subsequently, items found in the GIT were labelled and stored individually in flasks containing 75% ethanol. Depending on the state of digestion, prey items were classified as complete, incomplete, residuals (*e.g.*, hairs, scales, and spines), or unidentifiable. Remains that could not be identified were excluded from further analysis. Each prey item was identified to the lowest taxonomic group possible, using specialized bibliography or with the aid of taxonomic experts. All identifiable items were later grouped into one of four main taxonomic prey categories: Amphibia (Anura), Chilopoda (Scolopendromorpha), Mammalia (Rodentia and Didelphimorphia), and Reptilia (Squamata). Following [Martins, Marques & Sazima \(2002\)](#) and [Martins & Gordo \(1993\)](#), insect remains found in the hindgut were inferred to be secondary ingestion resulting from an ingested amphibian. For each complete prey item, mass was recorded to the nearest 0.1 g, and both length (without tail) and diameter (largest width) were measured to the nearest 1.0 mm.

To study predator-prey relationships, we used the mass ratio (MR; prey mass/snake mass) ([Greene, 1983](#); [Pough & Groves, 1983](#); [Martins, Marques & Sazima, 2002](#); [Campbell & Lamar, 2004](#); [Kuch et al., 2004](#); [Boada et al., 2005](#); [Sasa, Wasko & Lamar, 2009](#)), in those cases where an accurate measurement of the prey was possible (*i.e.*, complete, mostly undigested prey items). Additionally, we calculated the diameter ratio (DR; prey diameter/narrowest snake neck diameter), generally used in studies of sea snakes ([Voris & Voris, 1983](#); [Sanders et al., 2013](#)). We chose this index instead of the ingestion ratio IR—prey width/snake head length ([Martins, Marques & Sazima, 2002](#)) since several specimens had unreliable head length measurements because their heads were damaged. We calculated the relative body mass (*i.e.*, the body condition index or BCI), relative tail length and relative neck diameter as the residuals from the linear regression of log-transformed values

of these measurements on log-transformed SVL, which allowed us to detect differences in shape while controlling for SVL (King, 1989; Sivan et al., 2020).

To assess the relative importance index of the main taxonomic categories, we adapted the formula proposed by Biavati, Wiederhecker & Colli (2004):  $I_x = (n_x\% + f_x\% + m_x\%)/3$ , where:  $n_x\%$  represents the percentage for each taxonomic group of prey from the total number of prey items;  $f_x\%$  represents the percentage of specimens that contained a particular type of prey from the total number of snakes that had prey or remains in their guts, and  $m_x\%$  represents the percentage of mass of the prey type from the total prey mass. We used the mass ( $m_x$ ) recorded for each complete prey item instead of the volume, since we consider it to be a more accurate measurement in our case, as it was shown in previous works (Feldman & Meiri, 2013). We calculated food niche breadth for each of the two sexes and for the three size-classes (juvenile, subadult, and adult) based on Simpson's diversity index:  $B = 1 - \sum p_i^2$ , where  $p_i$  is the proportion of each type of prey (Simpson, 1949).

To evaluate if prey type differed between life stages or between sexes, we performed Chi-square tests. We checked if size-classes differed in the number of prey items with Kruskal-Wallis analysis. To determine the sexual dimorphism, we tested for differences in absolute values of SVL, mass and neck diameter, as well as in the BCI, relative tail length and neck diameter using Welch's  $t$ -tests. To evaluate if the preference for the main taxonomic groups was influenced by snake sex or SVL, we fitted generalized linear models with a binomial distribution and logit link function (MASS package), using all snakes with identifiable GIT-contents ( $n = 46$ ; one male was excluded due to unavailable SVL measurement). We used the full and null models for each predictor separately (Grainger et al., 2020); competing models were compared (package MuMIn) using the corrected Akaike information criterion ( $AIC_c$ ) and Akaike weight ( $w_i$ ), considering the model with the lowest  $AIC_c$  and highest  $w_i$  to be the best fit for the data (Burnham & Anderson, 2004).

To investigate the relationship between characteristics of the snake (SVL and sex) and the relative size of the prey they ingested, we used linear models with either MR or DR as the dependent variable and predator size and sex as predictors, applied over a filtered dataset (i.e., with incomplete prey items removed). All statistical analysis were performed using the R Statistical Software (R Core Team, 2021) with an  $\alpha = 0.05$ .

## Bibliographic research

Various databases were searched for diet reports of *B. asper*: Scopus, Web of Science, Scielo, Google Scholar, and Biodiversity Heritage Library. As keywords, we used the scientific and common names and iterations given to this species throughout the years (e.g., "Fer-de-lance", "Bothrops", "atrox", "asper", "Terciopelo", "barba amarilla", "equis"), as well as the terms diet, feeding, food, single or in combination. We excluded reports of feeding in captivity.

## RESULTS

### Predator-prey relationship

From the 193 analyzed specimens, we found GIT content in 47 individuals: 27 females and 20 males. Further analysis was carried out exclusively on specimens with GIT content. Five

specimens belong to the Chocoan region lineage and 42 to the Pacific lowlands lineage (Salazar-Valenzuela *et al.*, 2019; Mora-Obando *et al.*, 2020), covering 12 Ecuadorian provinces (Table 1). This encompasses most of the species' distribution in Ecuador, except for the populations from Río León and Vilcabamba (Southern Ecuador), since none contained prey items or remains in their gut. In terms of absolute size, the vipers showed a marked sexual dimorphism, females being both larger (SVL,  $t_{40.47} = 2.54$ ,  $p = 0.015$ ) and heavier ( $t_{33.63} = 2.68$ ,  $p < 0.011$ ) than males, as well as having wider necks ( $t_{36.91} = 3.5$ ,  $p < 0.002$ ). Females had a similar body condition to males ( $t_{30.83} = 0.75$ ,  $p = 0.458$ ). In terms of relative values, females had shorter tails ( $t_{40.87} = -3.56$ ,  $p = 0.001$ ) and wider necks ( $t_{37.73} = 3.34$ ,  $p < 0.002$ ) when adjusted for SVL.

We found a total of 69 identifiable prey items and four unidentifiable ones (Table 1). In terms of number of prey items encountered per snake, three specimens (6%) had three items each, 20 snakes (43%) had two items, while 24 snakes had one prey item each, for an average of 1.55 prey items per snake; there was no difference between size-classes (Kruskal–Wallis:  $p = 0.332$ ). Each prey item was classified by the state of preservation in which it was found: complete prey = 22; incomplete prey = nine; residuals = 34. No adult pitviper contained complete prey items. According to our taxonomic grouping, prey included six centipedes (Scolopendromorpha), 11 frogs (Anura), three lizards (Squamata), and 49 mammals (Rodentia and Didelphimorphia) (Table 1). The prey was generally ingested headfirst (96.8%). Centipedes were swallowed folded in two, with a single bite in the first third of the body (QCAZ 5760, 12463).

The analysis of occurrence of prey categories indicated that models based on both snake size and sex were the best fit to determine the presence of frogs, lizards, and mammals in the diet of *B. asper*, whereas the presence of centipedes was best predicted by a model based on SVL alone (Table 2). The sex of the snake was not a significant predictor of the prey taxa it consumed (Table 3), and only the SVL had a significant effect on the probability that a snake consumed amphibians and mammals. Specifically, we observed an ontogenetic shift, showing that the probability that a snake consumes amphibians is reduced and the probability that it eats mammals increases as the snake increases in size (Table 3).

The importance index showed that mammals represented the most important prey type ( $I_{\text{Mammalia}} = 76.9$ ), in regard to all evaluated factors—abundance, frequency of occurrence and mass—while amphibians, centipedes and reptiles represent occasional meals with smaller contribution in particular in terms of mass (Table 4). The proportion of mammals increases from juveniles to subadults and reaches maximum values in adults, although this food type represented a considerable portion of the diet for all size-classes (Fig. 1). Spiny rats (Echimyidae) were common in the diet of *B. asper* ( $n = 4$ ; Table 1); the GIT of one adult female (QCAZ 5858) contained spines with an average length of 10 cm from such a rat (*Proechimys semiespinosus*). The niche breadth values were slightly lower in mature individuals (Simpson's  $B$  juveniles: 0.885; sub-adults: 0.894; adults: 0.778). Juvenile males consumed significantly more ectotherms (mainly amphibians) than juvenile females ( $\chi^2 = 8.5$ , d.f. = 3,  $p = 0.04$ ; Fig. 1), but no differences were found between the other size classes. Diversity indices were identical for the two sexes (Simpson's  $B = 0.89$ ).

**Table 1** General data of specimens of *Bothrops asper* used in this study from Ecuador, and their prey.

Museum #, Museum number. Sex: F, female; M, male. Size-class: J, juvenile; S, subadult; A, adult. TL, Total length; SVL, snout-vent length; ND, Neck diameter (all given in mm); Mass (g). Prey items: L, Prey length (mm); D: Prey diameter (mm); M, Prey mass (g).

The mass ratio in our sample ranged between 0.011–0.727, with an extreme value of 1.577 (Fig. 2A) in the case of a juvenile female (QCAZ 5879) containing a mist rodent (*Nephelomys moerex*). Mass ratio was not influenced by either sex ( $p = 0.07$ ) or SVL ( $p = 0.15$ ) of the snake ( $F_{2,19} = 2.72$ , adjusted  $r^2 = 0.14$ ). Similarly, the model investigating the ratio between the prey's largest width and the snake neck diameter indicated that neither sex ( $p = 0.2$ ) nor SVL ( $p = 0.83$ ) influenced the DR ( $F_{2,19} = 0.92$ , adjusted  $r^2 = 0$ ).

We encountered a total of 54 bibliographic accounts for prey data of *Terciopelos* (Fig. 3, Table S1). We were not able to access the full text of seven of them (older, out of print books, not available through any digital repository), but we include them since their contents regarding the *Terciopelo* diet was cited in previous bibliographic reviews or publications. Most diet records were accessible through the most prominent search databases (Fig. 3A). Diet data were available for 10 of the 12 countries in which this species is present, except for Nicaragua and Peru (Fig. 3B). The prey types were classified into nine classes, with 38 subclasses (mainly Families) and 134 individual records (Fig. 3C, Table S2). *Terciopelo* feeding habits in literature were mainly published as short notes ( $n = 56.4\%$ ), and most were written in English ( $n = 85.5\%$ ). Of the encountered records, 18.2% were not

**Figure 2** Relationship between the size of the snake (Snout-Vent Length) and the mass ratio (MR = prey mass/snake mass) (A) for *Bothrops asper* in Ecuador. The analysis was carried out only for cases where total prey mass could be precisely measured ( $n = 22$ ). (B) For comparison, other reported mass ratios from literature: Martins—MR range between 0.002–0.925 based on data for several *Bothrops* species from Brazil (Martins, Marques & Sazima, 2002); Sasa—MR range between 0.029–0.317, obtained from *B. asper* in Costa Rica (Sasa, Wasko & Lamar, 2009); Boada—MR = 0.07, report of a single complete prey of *B. asper* from Manabí, Ecuador (Boada et al., 2005); Kuch—two MR values (>0.25 partially digested and 0.75) from *B. asper* in Ecuador (Kuch et al., 2004); Greene—MR = 0.65 for *B. asper* and MR = 1.6 for *B. atrox* both from Colombia (Greene, 1992); Cis-Her—MR = 1.1, data for *B. asper* from southern Ecuador (Cisneros-Heredia, 2006). Full-size DOI: 10.7717/peerj.14817/fig-2

available through online search methods, most of these in Spanish. Most of the records come from the last 40 years (76.4%); the establishment of new research stations and scientific collections in the Neotropics, such as La Selva Biological Station, Instituto Clodomiro Picado and the Museum of Zoology QCAZ have contributed to the rise in available information (Costa Rica: 44, Ecuador: 27, representing 53% of the total available data). Mammals represented 47 records, followed by reptiles (34) and amphibians (30). However, 18% of the prey records came from less typical prey items, such as invertebrates, centipedes, crayfish and fish.

## DISCUSSION

### Prey diversity

Following the definition of Martins, Marques & Sazima (2002), a diet specialist should have at least 75% of its diet composed of one particular prey type. Our results concur with previous studies that show *B. asper* to be an overall generalist (Sasa, Wasko & Lamar, 2009) and a highly adaptable predator (Fig. 1), capable of consuming a diverse range of prey types throughout its life (Table 1). However, when looking specifically at various size-classes, our data indicate that subadults and adults should be considered mammal specialists. Nevertheless, although few food items listed in previous literature provide information related to predator sex and size-class ( $n = 20/134$  of individual records) or only size-class ( $n = 83/134$  of individual records), when added to our findings, they confirm an unequal prey use in these vipers (Figs. S1, S2). Terciopelo diet included a

Full-size [DOI: 10.7717/peerj.14817/fig-3](https://doi.org/10.7717/peerj.14817/fig-3)

variety of challenging prey items: aggressive and venomous centipedes (where the snake could become the prey, especially in juveniles), heavily spined mammals, toxic frogs, and venom resistant marsupials (Tables 1 and S2, Figs. S3–S6).

Most of the reports of *B. asper* diet are based on small sample sizes. The only two other studies based on a larger number of specimens—*Boada et al. (2005)* with 21 specimens inspected, 14 with GIT content, and *Sasa, Wasko & Lamar (2009)* with 56 specimens inspected, 32 with GIT content—indicate that it is common for the inspected snakes to not have identifiable prey items. This was certainly the case in our study, where we found that 24.4% of specimens contained some form of prey item (193 inspected, 47 with GIT content), with an average of 1.5 prey item per GIT. The aforementioned large-scale studies also gave us a measure of how frequently different taxonomic groups are taken, reflected by the proportion of snakes that presented them in their GIT: 64.3% insects, 42.9% mammals, 21.4% anurans, 7.1% birds, 7.1% lizards and 7.1% scolopendras in the *Tercioppelos* from Ecuador (*Boada et al., 2005*) and 69% mammals, 10.3% birds, 10.3% lizards, 6.9% anurans and 3.4% orthopterans for the snakes from Costa Rica (*Sasa, Wasko & Lamar, 2009*). In our case, mammals (71%) dominated the diet of *B. asper*, and amphibians (15.9%) and

scolopendras (8.7%) represented an important component in the diet, especially in early stages. The number of reptiles (4.3%) and birds (0%) is lower in our sample compared to these studies (Table 1). Given the large distribution of Terciopelos and the variety of habitats they occupy, the differences in diet might be due to habitat composition and prey availability. The abundance of some amphibians and reptiles in their habitat also changes with seasons, and this in turn affects their proportion in the predator diet (Shine, 1994; Greene, 1997; Martins, Marques & Sazima, 2002). Consequently, these differences should be reflected in the diet of the snakes. For example, large species of frogs (e.g., *Leptodactylus*) or lizards (e.g., *Basiliscus* and *Ctenosaura*) have been reported as prey of Terciopelos in adults (Sasa, Wasko & Lamar, 2009; Wasko & Sasa, 2012; Fortier, 2021), which may relate to their abundance in different areas that may vary temporally. On the other hand, birds seem to be a more difficult prey to catch and a less common prey for most *Bothrops* species. This is due not only to the differences in microhabitat use, and therefore fewer hunting opportunities, but also to the fact that hunting birds may require venom specialization (Hayes, 1992; Martins, Marques & Sazima, 2002). The prevalence of mammals as prey items might be the result of hunting microhabitat preference by sex, and consuming mammals has been shown to enhance the fitness of offspring in *Bothrops* and other vipers (Martins, Marques & Sazima, 2002). Adding to this multidimensional question is the fact that the preferred habitat of Terciopelos seems to be early succession shrubby forest, and consequently they are expected to eat mostly prey species associated with intervened forest (Sasa, Wasko & Lamar, 2009; Hernández-Ordóñez, Urbina-Cardona & Martínez-Ramos, 2015; Ramírez-Arce, Zúñiga-Ortiz & Wasko, 2021). Prey composition may be notably affected by life-stage and sex; however, due to the difficulty of collecting enough samples from different biomes, such relations remain unclear (Urbina-Cardona, Olivares-Pérez & Reynoso, 2006). Ultimately, the lack of diversity displayed in the diet of adults in our data set could be the result of a low sample size, as shown by a better sampled population of adults in Costa Rica (Sasa, Wasko & Lamar, 2009).

We found that SVL was the main predictor for the probability that a Terciopelo consumes amphibians and mammals; as the snakes increase in size, the probability that they consume amphibians decreases, in favor of mammals. This ontogenetic transition from ectotherm to endotherm prey has been previously mentioned (Picado, 1931; Solórzano, 2004; Sasa, Wasko & Lamar, 2009), and this is accompanied by a shift in venom composition (Sasa, Wasko & Lamar, 2009; Mora-Obando et al., 2020). For reptiles or centipedes, SVL had no significant effect, which we attribute to the low sample size, as these prey types are taken in an opportunistic manner.

Terciopelos can thrive in anthropogenic ecosystems (Otero-Patiño, 2009; Sasa, Wasko & Lamar, 2009; Chippaux, 2017), hunting near human settlements and feeding on their pests (Boada et al., 2005), which is supported by our findings of 23% of specimens (45/193) having damaged heads—likely due to negative human encounters. Yet, Wasko & Sasa (2010, 2012) and Ramírez-Arce, Zúñiga-Ortiz & Wasko (2021) show that *B. asper* tends to actively avoid human interaction and settlements, suggesting their relationship with anthropogenic areas as hunting grounds may require further investigation. While some individuals were found in the vicinity of La Selva Biological Station (Costa Rica), the

authors note that the circumstances that motivate these incursions are unknown. Our findings of diet support this observation, since the species of centipedes and amphibians (e.g., *Leptodactylus* sp., *Pristimantis* sp.) that we registered in the GIT contents are associated with modified areas (Ron, Merino-Viteri & Ortiz, 2022). We suspect that such prey is mostly taken by opportunistic juveniles without an established hunting ground. On the other hand, the mammal species which formed part of the diet (e.g., *Melanomys* sp., *Proechimys* sp.) are mostly typical for primary or secondary forest (Sasa, Wasko & Lamar, 2009; Brito, Camacho & Vallejo, 2022). This suggests that adult Terciopelos found near human settlements might have been displaced from their original hunting ground, rather than actively preferring anthropogenic habitats. Although there is no doubt that some Terciopelos find anthropogenic habitats suitable for hunting (Ramírez-Arce, Zúñiga-Ortiz & Wasko, 2021), our results, as well as the literature records, suggest that generally these vipers tend to avoid them.

### Predator-prey size relationship

The size of the snake was not a good predictor for the size of the prey they ingested. The MR values found in our study (Fig. 2A; ranging between 0.011–0.727, with an outlier of 1.577) are consistent with previous observations (Fig. 2B) for this species—Costa Rica (0.029–0.317; Sasa, Wasko & Lamar, 2009), Colombia (0.65; Greene, 1992), Ecuador (0.75–1.1; Boada et al., 2005, 0.07; Kuch et al., 2004; Cisneros-Heredia, 2006). Other *Bothrops* species from Brazil have MR ranging between 0.002–0.925 (Martins, Marques & Sazima, 2002), although there are also reports of more copious meals (Greene, 1992; the present study). An ample review from Glaudas et al. (2019) including 129 snake taxa reports MR ranges of 0.00–1.67 (this being the largest MR reported for snakes). Overall, these works indicate that ambush predators do not specialize in larger prey items, but rather are opportunistic and capable of consuming large prey when given the chance. This is consistent with our findings and prey items reported for *B. asper*.

An increase in MR is often theorized due to the ontogenetic shift from ectothermic prey to endotherms, since taken frogs, lizards, and scolopendras tend to have lower mass than mammals (Table 4, Martins, Marques & Sazima, 2002; Sasa, Wasko & Lamar, 2009). Although this pattern was observed by Sasa, Wasko & Lamar (2009), they attribute this trend to a low sample size. Martins, Marques & Sazima (2002) and Nogueira, Sawaya & Martins (2003) encountered either the inverse pattern or no trend at all in several well sampled species of *Bothrops* from Brazil, while Glaudas et al. (2019) found no such tendency in ambush predators and a decrease of MR in active foragers. Even without records of complete food items in adults, our data do not show this trend. However, the MR is likely to be highly dependent on the characteristics of the available prey; as such, the amphibians and reptiles reported in the diet of *B. asper* from Central America are of considerable mass (Sasa, Wasko & Lamar, 2009; Fortier, 2021). Additionally, Terciopelo individuals can consume several food items in short periods, so the total mass they ingest can be quite large, even if the individual items are small, which is a common tendency in ambush foragers (Glaudas et al., 2019).

### Prey item notes

A female juvenile (QCAZ 12463) had in its stomach a Roof Anole (*Anolis bitectus*) and a centipede, side by side, both showing one bite in the middle of the body. The state of digestion of both specimens was minor, which meant that both kills must have happened recently (Fig. S4). While the separate MR of these items (0.05 and 0.066 respectively) are not remarkable, together they make a considerable meal (MR 0.117). Furthermore, this record supports the idea of the opportunistic nature of *Terciopelos*, which will eat, if given the chance, several small items in short periods of time. Additionally, *Terciopelos* seem to catch long but narrow prey items by a single bite in the middle of the prey's body (Jones, Straka & Kayano, 2014). It is unclear if this strategy is learned, although there seems to be trial and error involved (see Ryan et al., 2010; Díaz-Ricaurte, 2018; Szczygiel & Page, 2020).

The outlier MR record (1.577) found in our sample came from a juvenile female (QCAZ 5879), which ingested an adult mist rodent (*Nephelomys moerex*) measuring 166 mm in length (37% of the snake SVL). This is one of the highest reported values that we encountered in literature for the species. A similar value (MR = 1.6) reported in its sister species, *Bothrops atrox*, by Greene (1992) consisted of a snake that had eaten a whiptail lizard (*Cnemidophorus gramivagus*) in Colombia.

An adult female (QCAZ 5858) had in its stomach the remains of a spiny rat (*Proechimys semiespinosus*). However, the state of digestion in which it was found was very advanced, with no soft tissue left, and only the complete skeleton and spines remaining (Fig. S5). No remains were found in the intestines or rectum. This record is remarkable for two reasons. First, the spines were large, and they had perforated part of the stomach and epithelium of the snake; however, this could have happened after the death of the snake or during the preservation of the specimen. Second, this female was the only one of the snakes we examined with gut contents where we observed developing follicles. She had 19 embryos (the biggest one being 32 mm in diameter), all in an advanced stage of development (stage 37 according to Zehr, 1962). The lack of soft tissue indicates that the prey had been consumed during early stages of embryonic development and the snake stopped all GIT movement (Secor, 2005). Such post-prandial reduction of the activity in the digestive system has been previously reported in ambush-foraging predators, and it is attributed to energy saving (Secor & Diamond, 1998; Glaudas et al., 2019). This is a poorly discussed phenomenon during reproduction stages in snakes, and we recommend future investigation examine it further.

### Sexual dimorphism and diet

Our results show that the sex of the snake influences the type of prey it consumes at least in the juvenile size-class, a pattern similar to the one reported by Sasa, Wasko & Lamar (2009), although they only based their conclusions on adults. In our sample, while sex did not affect the probability that the snake consumed certain taxa, and the detailed diversity index found similar values for males and females, differences appear when considering the proportions for various prey categories, revealing a tendency for juvenile females' diet to consist of more mammals than the diet of juvenile males. A similar pattern is shown by the literature records for which sex and size class are available (Table 1, Figs. S1, S2).

Sexual dimorphism in *B. asper* has been well-documented, females being larger than males (Sasa, 2002; Saldarriaga-Córdoba et al., 2009; Sasa, Wasko & Lamar, 2009; Henao-Duque & Ceballos, 2013; Gómez et al., 2021). This might on its own explain the mammal predominance in the females' diet. However, other factors might cause the observed differences in the diet of the two sexes. For example, in juveniles, although tail coloration is sexually dimorphic (males having bright yellow tails), both sexes exhibit caudal-luring behavior (Neill, 1960; Tryon, 1985; Solórzano & Cerdas, 1989), however the effectiveness of this behavior relating the color variation has not been tested. Venom composition, geographic and ontogenetic venom variation are well documented in the species (Lomonte & Carmona, 1992; Saldarriaga et al., 2003; Alape-Girón et al., 2008; Alape-Girón et al., 2009; Mora-Obando et al., 2020; Gómez et al., 2021), with no differences in venom between the sexes in adults (Gómez et al., 2021). Yet, it is not known if there are venom differences between sexes in juveniles. Spatial ecology and habitat preferences tested in populations from Costa Rica have found no differences overall between sexes; however, there are significant differences between males and females in distance to the nearest body of water and microhabitat usage between daytime and nighttime, although, again, only in adults (Wasko & Sasa, 2010). Since there are no documented male-male combat events in Terciopelos (Sasa, Wasko & Lamar, 2009), and there seem to be differences in sex ratios between populations (Savage, 2002; Wasko & Sasa, 2010; Ramírez-Arce, Zúñiga-Ortiz & Wasko, 2021; 105 females vs. 88 males in our study), the niche partitioning between sexes could be a possible explanation for differences in diet. This would allow enhanced fecundity in females, while males would take advantage of alternative prey species with less competition (Shine, 1994). Hence, differences in head allometry and/or behavior could be crucial in understanding the differences in diets between sexes (Sasa, Wasko & Lamar, 2009). Additionally, sexual dimorphism in *B. asper* should be studied at a population level, due to the high diversity within this species complex (Shine & Goiran, 2021). It is likely that sexual dimorphism is dependent on macrohabitat conditions and heavily influenced by speciation (Hendry, Guiher & Pyron, 2014), which occurs in many Terciopelo populations (Saldarriaga-Córdoba et al., 2009; Salazar-Valenzuela, 2016; Saldarriaga-Córdoba et al., 2017; Salazar-Valenzuela et al., 2019; Mora-Obando et al., 2020).

### Data regarding Terciopelo prey records in literature

The confusion caused by the use of common names is one of the reasons why the binomial nomenclature proposed by Linné is considered crucial in natural sciences (Bennett & Balick, 2014). In our review, we aimed to clarify some inaccuracies present in previous works (Sasa, Wasko & Lamar, 2009; Farr & Lazcano, 2017). Such is the case of a record originally listed as “zorrillos” by Picado (1931) and invalidly cited afterwards by Farr & Lazcano (2017) as “skunks” (“zorrillos” is commonly used as a synonym of marsupials; M. Sasa, 2021, personal communication).

One interesting aspect is that *B. asper* diet contains a rather insignificant number of species which are commonly considered as human-associated (e.g., *Rattus rattus* and *Mus musculus*). This suggests that *B. asper* avoids human vicinities, as supported also by telemetry data (Wasko & Sasa, 2010, 2012; Ramírez-Arce, Zúñiga-Ortiz & Wasko, 2021).

Since the first diet records of the Terciopelos, possums have been listed as prey items ([Mole, 1924](#); [Picado, 1931](#)). Sadly, many of the names used are generic and do not provide a clear taxonomic identification from this diverse group ([Voss & Jansa, 2009](#)). Few and far between, they are extremely important from an evolutionary point of view, since some species of possums are resistant to venoms from pitvipers ([Voss & Jansa, 2012](#)). [Voss \(2013\)](#) revisits some of these records and develops a poorly explored topic in viper ecology and evolution.

It is still unclear if insects are an intentional part of the diet of Terciopelos. [Boada et al. \(2005\)](#) and [Sasa, Wasko & Lamar \(2009\)](#) list insects as prey items, because juveniles might use large grasshoppers and beetles as prey. However, it is generally assumed that insect remains are secondary or unintentional prey, and this appears to be the case in our study, since all the remains came from small insects found in the hindgut.

The importance of methodical and systematic literature searches for previous publications cannot be disregarded. This is especially the case for species with the taxonomic and phylogenetic complexity of *Bothrops*, which has captured the attention of academics for hundreds of years. The hunt for these records must take into account old names in the different locations of distribution and taxonomic history. Researchers working in different parts of the distribution of a taxon must aim to cite local (peer-reviewed) papers that would be difficult for foreign investigators to find. The Internet and many of the research databases are important tools to find such records (for detailed recommendations, see [van den Burg, 2020](#); [Maritz et al., 2021](#)). However, a consequence of the search algorithms, language barriers and skewed impact metrics is that sometimes important regional and localized reports are less likely to be found ([Gasparyan et al., 2017](#)). Research communities are a valuable way to put forward such reports and ensure that primary data from, and throughout, a species range are incorporated into analyses and given weight according to their quality, not age, language, or publication outlet ([Maritz et al., 2021](#)).

Finally, we recommend that the researchers report the highest level of details available. In our case, as discussed before, the identification of the items was done to the lowest taxonomic level possible. Additionally, predator sex, size of prey and predator (diameter, length, and mass), state of digestion, location in the GIT, and pictures (considering the current easy access to technology) should be recorded whenever possible (for a detailed guide see [Maritz et al., 2021](#)). This could provide additional details which can be used in reviews and meta-analyses in the future (e.g., sexual dimorphism influence on the diet). Usually, museums have difficulties maintaining large collections of the same species, especially with large sized specimens, but the preservation of these kind of samples could yield particularly important results for future unforeseen methodologies ([Glaudas et al., 2019](#)).

### **Bias in reporting**

Short dietary scientific notes are crucial to provide additional information about the breadth of the diet of a species ([Fig. S7](#)). However, the tendency to report rare and sensational prey items can lead to biases when evaluating the proportions of different prey

types between sexes and/or age/size class (Maritz *et al.*, 2021). In addition, the use of GIT samples from museum specimens can have its own biases (Glaudas, Kearney & Alexander, 2017), such as lower detection of certain types of prey. For example, amphibians, which are of smaller size and rapidly digested, are likely to be overlooked, so their representation in the diet analysis can be underestimated. This could also affect our sample, since there was a 5% (*i.e.*, four items) of unidentifiable stomach content, consisting of organic material in the small intestine that we were unable to identify. The only way to reduce the bias in reporting would be to systematically collect data from different population, demographics, and seasons, which would allow a better understanding of the niche that this species occupies and the role that it plays in the ecosystem, depending on its sex and life-stage.

## CONCLUSIONS

The diet of the Terciopelo pitviper reflects the diverse habitats it inhabits, supporting the idea of an opportunistic predator. The size of the snake had a strong influence on the type of prey it eats in early stages, but less so on the size of its prey. When looking at the composition of the diet, the lack of prey items associated with humans suggests that *B. asper* tends to avoid anthropogenic areas and the individuals found near settlements are likely ones who have been displaced from their original hunting grounds. Data made available through short scientific notes, packed with as much information as possible, is crucial to provide a better understanding of the dietary diversity of this widespread species and its role in the ecosystem. However, systematic collection of information from different populations, demographics, and seasons is necessary to determine the ontogenetic, sexual and geographic variability in the feeding habits of this species complex. Additional studies are necessary to understand how sexual morphometrics influences the role and selective pressures in this species.

## ACKNOWLEDGEMENTS

We are grateful to S. Ron, F. Ayala-Varela and D. Paucar for taxonomic identifications of prey and advice in the field and laboratory, and to U. Kuch and M. Sasa who provided important suggestions for the methodology used in this research. For advice and comments on the manuscript, we thank A. Benitez and C. I. Espinosa. ALL and DSV would like to acknowledge and thank the people at the “La Cucaracha” ranch for all the various important support given throughout the years working with the “equis” and are still contributing to our new endeavors. We are grateful to the three reviewers and the editor for their valuable feedback on this paper and their insightful comments.

## ADDITIONAL INFORMATION AND DECLARATIONS

### Funding

The authors received no funding for this work.

### Competing Interests

The authors declare that they have no competing interests.

## Author Contributions

- Amaru Loaiza-Lange conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the article, and approved the final draft.
- Diana Székely analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the article, and approved the final draft.
- Omar Torres-Carvajal conceived and designed the experiments, authored or reviewed drafts of the article, and approved the final draft.
- Nicolás Tinoco performed the experiments, authored or reviewed drafts of the article, and approved the final draft.
- David Salazar-Valenzuela conceived and designed the experiments, authored or reviewed drafts of the article, and approved the final draft.
- Paul Székely conceived and designed the experiments, authored or reviewed drafts of the article, and approved the final draft.

## Animal Ethics

The following information was supplied relating to ethical approvals (*i.e.*, approving body and any reference numbers):

The Ministerio del Ambiente, Agua y Transición Ecológica del Ecuador approved the study (MAE-DNB-CM-2015-0016, MAAE-ARSFC-2020-0727, 001-10 IC-FAU-DNB/MA, 005-12 IC-FAU-DNB/MA, 005-14 IC-FAU-DNB/MA).

## Data Availability

The following information was supplied regarding data availability:

The raw data and information regarding museum specimen number, characteristics, and full details of their prey are available in the [Supplemental Files](#).

## Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.14817#supplemental-information>.
