Background. Following spinal cord injury (SCI), a large number of peripheral monocytes infiltrate into the lesion area and differentiate into macrophages (Mø). These monocyte-derived Mø are very difficult to distinguish from the local activated microglia (MG). Therefore, the term Mø/MG are often used to define the infiltrated Mø and/or activated MG. It has been recognized that pro-inflammatory M1-type Mø/MG play "bad " roles in the SCI pathology. Our recent research showed that local M1 cells are mainly $CD45^{-/low}CD68^{+}CD11b^{+}$ in the subacute stage of SCI. Thus, we speculated that the M1 cells in injured spinal cords mainly derived from MG rather than infiltrating Mø. So far, their dynamics following SCI are not yet entirely clear. **Methods.** The female C57BL/6 mice were used to establish SCI model, using an Infinite Horizon impactor with a 1.3 mm diameter rod and a 50 Kdynes force. Sham-operated (sham) mice only underwent laminectomy without contusion. Flow cytometry and immunohistofluorescence were combined to analyze the dynamic changes of polarized Mø and MG in the acute (1 day), subacute (3, 7 and 14 days) and chronic (21 and 28 days) phases of SCI. **Results.** The total Mø/MG gradually increased and peaked at 7 days post-injury (dpi), and maintained at high levels 14, 21 and 28 dpi. Most of the Mø/MG were activated, and the Mø increased significantly at 1 and 3 dpi. However, with the pathological process, activated MG increased nearly to 90% at 7, 14, 21 and 28 dpi. Both M1 and M2 Mø were increased significantly at 1 and 3 dpi. However, they decreased to very low levels from 7 to 28 dpi. On the contrary, the M2-type MG decreased significantly following SCI and maintained at a low level during the pathological process.

Abstract

Background. Following spinal cord injury (SCI), a large number of peripheral monocytes infiltrate into the lesion area and differentiate into macrophages (Mø). These monocyte-derived Mø are very difficult to distinguish from the local activated microglia (MG). Therefore, the term Mø/MG are often used to define the infiltrated Mø and/or activated MG. It has been recognized that pro-inflammatory M1-type Mø/MG play "bad " roles in the SCI pathology. Our recent research showed that local M1 cells are mainly CD45$^{-/low}$CD68$^+$CD11b$^+$ in the subacute stage of SCI. Thus, we speculated that the M1 cells in injured spinal cords mainly derived from MG rather than infiltrating Mø. So far, their dynamics following SCI are not yet entirely clear.
Methods. The female C57BL/6 mice were used to establish SCI model, using an Infinite Horizon impactor with a 1.3 mm diameter rod and a 50 Kdynes force. Sham-operated (sham) mice only underwent laminectomy without contusion. Flow cytometry and immunohistofluorescence were combined to analyze the dynamic changes of polarized Mø and MG in the acute (1 day), subacute (3, 7 and 14 days) and chronic (21 and 28 days) phases of SCI.
Results. The total Mø/MG gradually increased and peaked at 7 days post-injury (dpi), and maintained at high levels 14, 21 and 28 dpi. Most of the Mø/MG were activated, and the Mø increased significantly at 1 and 3 dpi. However, with the pathological process, activated MG increased nearly to 90% at 7, 14, 21 and 28 dpi. Both M1 and M2 Mø were increased significantly at 1 and 3 dpi. However, they decreased to very low levels from 7 to 28 dpi. On the contrary, the M2-type MG decreased significantly following SCI and maintained at a low level during the pathological process.

Introduction

Spinal cord injury (SCI) is a serious neurological disorder, which caused by traffic accidents, trauma and other reasons (Attal 2021; Perrouin-Verbe et al. 2021; Quadri et al. 2020). As the bridge of brain and peripheral nerves, the nerve fibers of spinal cord are distributed to the skin, muscles and various internal organs. 0nce damaged, it will cause serious pathophysiological dysfunctions. For patients, SCI will cause serious physical and mental suffering. The disease also causes serious economic and social burdens. (Chay & Kirshblum 2020). Therefore, to find effective treatment strategies, its pathological mechanism should be deeply explored.
The pathological process of SCI includes primary injury and secondary injury. Primary injury refers to the direct injury of mechanical force to spinal cord. Secondary injury is triggered by primary injury, which includes local vascular disorder, edema, ischemia, free radical reaction, electrolyte change, inflammation, axon necrosis and demyelination, fibroglial scar and cyst formation (Anjum et al. 2020; Zhang et al. 2021).
Inflammation is one of the important mechanisms of secondary pathological damage of SCI (Mallon et al. 2021). After SCI, with the destruction of blood spinal cord barrier, MG are activated, the inflammatory factors and chemokines are increased, and the peripheral immune cells infiltrate into the injured spinal cord to form an immune microenvironment, resulting in neuronal death and demyelination (Brockie et al. 2021; Rezvan et al. 2020; Shields et al. 2020). Following SCI, the different immune cell subsets with different functions affect the local immune microenvironment by producing different cytokines (Mishra et al. 2021). Previous studies have reported that in the injured spinal cord, the cellular components include locally activated MG, infiltrated Mø, lymphocytes, neutrophils, dendritic cells, etc., and these cells are divided into different subsets, some are neuroprotective, while others have neurodamaging

80 effects (Hu et al. 2016; Ma et al. 2015; Milich et al. 2021). Moreover, neurodamaging subsets
81 (e.g., M1, Th1, Th17, etc.) are dominant, which is an important pathological mechanism of SCI
82 (Chen et al. 2021; Chen et al. 2020). However, which of these complex immune cell populations
83 plays a key role? So far, there is still no final conclusion.
84 Following SCI, a large number of peripheral blood-derived monocytes infiltrate into the injured
85 spinal cord and differentiate into Mø, which are indistinguishable from the local MG, therefore
86 the term Mø/MG was often used to define the infiltrated Mø and/or activated MG in the
87 literatures (Fan et al. 2020; Gao et al. 2021; Rismanbaf et al. 2021). However, as research
88 technology advances by leaps and bounds, the peripheral infiltrated Mø and locally activated MG
89 can be identified (Chen et al. 2021; Chen et al. 2020; Milich et al. 2021). Our recent studies have
90 found that proinflammatory M1 cells are absolutely dominant at 7 dpi following SCI, and these
91 cells mainly from MG rather than peripheral infiltrated Mø (Chen et al. 2021; Chen et al. 2020).
92 This suggests that M1 cells derived from MG might be the key inflammatory cells in the immune
93 microenvironment of injured spinal cords. However, the dynamic patterns of MG, infiltrated Mø
94 and their subsets during the whole pathological process of SCI are still unclear. Therefore, the
95 purpose of this study was to explore the dynamic patterns of these cells following SCI using the
96 strategy of combining flow cytometry (FCM) and immunohistofluorescence (IHF).
97
Materials & Methods
99 **Animals**
100 A total of 150 specific-pathogen free adult female C57BL/6 mice (18–20 g) were obtained from
101 Chang Zhou Cavens Laboratory Animal Ltd. (Chang Zhou, China; license No. SCXK (Su) 2016-
102 0010). Animal were housed as previously described (Chen et al. 2021; Chen et al. 2020). All
103 experimental designs and reports were referred to previous to the previous guidelines (Kilkenny
104 et al. 2011). The surgery protocol was approved by the Animal Care Ethics Committee of
105 Bengbu Medical College. The number of Animal Ethical Approval was 2017-037. The mice
106 were randomly divided into sham-operated (sham), 1-, 3-, 7-, 14-, 21- and 28-days post-injury
107 (dpi) groups, using a computer based random order generator (Zhao et al. 2018). The
108 comprehensive description of the total number of mice used is shown in Figure 1.
109 **Contusive SCI**
110 The mice contusive SCI model was established as described previously(Chen et al. 2021; Chen
111 et al. 2020). Specifically, the Infinite Horizon impactor was made by Precision Systems &
112 Instrumentation (Lexington, KY, USA). Anesthetics (80 mg/kg ketamine and 10 mg/kg
113 xylazine) for intraperitoneal injection were obtained from Sigma-Aldrich (St. Louis, MO, USA).
114 The T9 spinal cord was impacted with 50Kdynes force, and the diameter of the impact rod was
115 1.3 mm. After impact, the spinal cord was filled with blood and edema. Sham-operated mice
116 only underwent laminectomy without contusion. After operation, the animal care and welfare
117 were performed as previously described (Chen et al. 2021; Chen et al. 2020), which included
118 bladder emptying three times per day, relieving pain with meloxicam (5mg/kg, CSN pharm, IL,
119 USA), and preventing infection with chloramphenicol (50mg/kg, Sangon Biotech, Shanghai,
120 China) for 7 days after surgery. Inclusion criteria: the animals were undergoing successful
121 contusive SCI, defined by the T9 site was filled with blood and edema, and the spinal cord was
122 intact and not ruptured. Exclusion criteria: the degree of injury is not up to the standard,
123 postoperative infection or sacrifice.
124 **Flow cytometry**

125   At the indicated time points post-injury, the samples were collected and single-cell suspensions
126   were obtained using Percoll gradient centrifugation as previously described (Chen et al. 2021;
127   Chen et al. 2020). Briefly, the chest cavity was opened with surgical scissors to expose the heart.
128   The ventricle was clamped with a vascular clamp to fix the heart. The No.7 needle was inserted
129   into the left ventricle. At the same time, a small opening was cut on the right atrium so that the
130   blood and lavage solution can be drained. Then, 10ml of 0.01M phosphate-buffered saline (PBS)
131   buffer solution (pH = 7.4) was slowly injected at 250 ml/h with a microinjection pump. After
132   perfusion, the 5 mm spinal cord segments which contained the injury center were taken, and the
133   corresponding spinal cord segments were also obtained from sham group. The spinal cords were
134   put into the 45-μm nylon mesh and fully ground with the syringe plunger to obtain single cell
135   suspensions. To obtain enough cells for analysis, 3 spinal cord segments were mixed for one test.
136   The Percoll gradient centrifugation (Amersham Pharmacia Biotech, Piscataway, NJ, USA) was
137   used to separate the single cells. Table 1 showed the fluorescent labeled antibodies used in this
138   study to identify different immune cell subtypes. To eliminate the background staining caused by
139   the non-specific binding of the antibody, the immunoglobulin with the same species, subtype,
140   dose and fluorescein as the primary antibody was used as the isotype control. The cells were
141   collected using a BD Accuri flow cytometer (Becton Dickinson, San Diego, CA, USA), and the
142   data were analyzed using FlowJo7.6.1 software (FlowJo, LLC, Ashland, OR, USA).
143   **Immunofluorescence double-staining**
144   At the indicated time points post-injury, mice were euthanized perfused with PBS as described in
145   "Flow cytometry". Then, the mice were perfused with 10 mL of 4% paraformaldehyde (PFA) at
146   a rate of 180 mL/h. After perfusion, the 5 mm spinal cord segments which contained the injury
147   center were collected and fixed in 10 mL of 4% PFA solution at 4°C overnight. The next day, the
148   spinal cords were removed from 4% PFA solution and placed in 20% sucrose solution (prepared
149   in PBS) at 4°C overnight. The third day, the spinal cords were transferred to 30% sucrose at 4°C,
150   until the samples sinking to the bottom. This process usually needs one day. Next, the embedding
151   agent (Tissue-Tek, Sakura Finetek USA Inc., Torrance, CA, USA) was used to embed the spinal
152   cord segments at -20°C. The 6 μm thick transverse sections were cut using a Leica CM1900
153   cryostat (Leica Microsystems, Bannockburn, IL, USA). The IHF assay was performed as
154   previously described (Chen et al. 2021; Chen et al. 2020). Briefly, the slides were washed three
155   times with 0.01 M PBS to completely clear the embedding agent. When the slides were left to
156   dry, the blocking solution (0.01 M PBS containing 10% normal goat serum) were used for 2
157   hours at room temperature to eliminate the background staining caused by the non-specific
158   binding of antibodies. After cleaning the blocking solution, the primary antibodies with
159   appropriate concentration were incubated overnight at 4°C. The next day, the slides were washed
160   three times with 0.01 M PBS to completely remove the unbound antibodies. Then, the secondary
161   antibodies with appropriate concentration were incubated at 37°C for 1 hour. The primary and
162   FITC and RHO-conjugated secondary antibodies were shown in Table 1. After the second
163   antibody incubation, the 0.01 M PBS was used to wash the slides for three times, and the 1 μg/ml
164   Hoechst 33342 (Sigma-Aldrich; Cat# B2261) containing medium was used to coverslip the
165   slides. Finally, the slides were examined using a ZWISS Axio observation microscope (Carl
166   Zeiss, Oberkochen, Germany). The cell quantification was performed as previously described
167   (Chen et al. 2021; Chen et al. 2020). Specifically, for each spinal cord, the cells of 5 complete
168   cross-sections containing the injury epicenter (0 mm), rostral (1 mm and 0.5 mm) and caudal (-1
169   mm and -0.5 mm) were counted.
170   **Statistical analyses**

171 The SPSS software v.14.0 (SPSS Inc., Chicago, IL, USA) was used to statistical analysis. The
172 non-parametric Kruskal Wallis analysis of variance (ANOVA) following by the individual
173 Mann-Whitney U test was used. The $P < 0.05$ was considered to be statistically significant.
174

Results

Temporal pattern of MG and infiltrated Mø following SCI: the flow cytometry (FCM) analysis

178 To determine the temporal pattern of MG and infiltrated Mø, a panel of cell markers (CD11b,
179 CD45 and CD68) was examined by FCM. Here, CD45^{high} population was peripheral infiltrated
180 leukocytes, CD68$^+$CD11b$^+$ population was activated Mø and MG, CD45^{high}CD11b$^+$ population
181 was peripheral infiltrated Mø, CD45$^{-/low}$CD11b$^+$ population was MG, CD45^{high}CD68$^+$CD11b$^+$
182 population was activated peripheral infiltrated Mø, CD45$^{-/low}$CD68$^+$CD11b$^+$ population was
183 activated MG, and CD45^{high}CD68$^-$CD11b$^-$ population was peripheral infiltrated leukocytes
184 excluding Mø (Figure 2A).
185 Figure 2B showed that CD11b$^+$ cells had no significant difference among sham, 1 and 3 dpi
186 groups ($P > 0.05$, $n = 6$). However, at 7 dpi, the proportion increased significantly and reached to
187 peak, although decreasing at the later time points (14, 21 and 28 dpi), they remained at high
188 levels comparing with sham,1 and 3 dpi groups ($P < 0.01$, $n = 6$).
189 Figure 2C showed that CD68$^+$ cells were the lowest in the sham group comparing with the
190 injured groups ($P < 0.01$, $n = 6$). The proportions increased significantly after injury, reached to
191 peak at 7 dpi, and maintained at high levels at 14, 21 and 28 dpi. There were no significant
192 differences among 7, 14, 21 and 28 dpi ($P > 0.05$, $n = 6$). However, CD68$^+$ cells in these four
193 groups were significant more comparing with sham, 1 and 3 dpi ($P < 0.05$ or 0.01, $n = 6$).
194 Figure 2D showed that CD11b$^+$CD68$^+$ cells were extremely rare in sham group, however, they
195 increased significantly in the injured groups ($P < 0.01$, $n = 6$). The proportions had no significant
196 differences between 1 and 3 dpi ($P > 0.05$, $n = 6$). However, it reached to peak at 7 dpi, and then
197 decreased, but remained at high levels at 14, 21 and 28 dpi.
198 Figure 2E showed that CD45^{high} cells were extremely rare in sham group, and they gradually
199 increased after injury, peaked at 7 and 14 dpi, and then decreased, but still maintained at high
200 levels at 21 and 28 dpi.
201 Figure 2F showed that CD11b$^+$CD45^{high} cells were also extremely rare in sham group, and they
202 significantly increased after injury, peaked at 7 dpi, and then decreased, but still maintained at
203 high levels at 14, 21 and 28 dpi. The proportion of CD11b$^+$CD45^{high} cells in each group is
204 significantly lower than that of their corresponding CD11b$^+$ cells (Figure 2B).
205 Figure 2G showed that CD11b$^+$CD45$^{-/low}$ cells had no significant difference among sham, 1 and 3
206 dpi groups ($P > 0.05$, $n = 6$). However, at 7 dpi, the proportion increased significantly and
207 reached a peak, although decreased at the later time points (14, 21 and 28 dpi), they still
208 maintained at high levels comparing with sham,1 and 3 dpi groups ($P < 0.01$, $n = 6$). Except for
209 the 1 and 3 dpi groups, CD11b$^+$CD45$^{-/low}$ cells constitute the majority of CD11b$^+$ cells (Figure
210 2B).
211 Figure 2H showed that CD68$^+$CD45^{high} cells were also extremely rare in sham group, and they
212 rapidly increased after injury. Up to 28 dpi, they still maintained at high levels. The proportion of
213 CD68$^+$CD45^{high} cells in each SCI group is significantly lower than that of their corresponding
214 CD68$^+$ cells (Figure 2C).
215 Figure 2I showed that the percentages ofCD68$^+$CD45$^{-/low}$ cells in sham group was the lowest
216 comparing with the injured groups ($P < 0.05$ or 0.01, $n = 6$). The proportions had no significant

217 differences at 1 and 3 dpi ($P > 0.05$, $n = 6$). However, they reached to peak at 7 and 14 dpi, and
218 remained at high levels at 21 and 28 dpi. The proportion of CD68$^+$CD45$^{-/low}$ cells in each SCI
219 group is significantly lower than that of their corresponding CD68$^+$ cells (Figure 2C).
220 Figure 2K showed that CD68$^+$CD11b$^+$CD45^{high} cells were extremely rare in sham group, and
221 they rapidly increased after injury, peaked at 1, 3 and 7 dpi. Comparing with sham group, these
222 cells in the 1, 3 and 7 dpi groups were significantly more ($P < 0.01$, $n = 6$). Although, comparing
223 with 1, 3 and 7 dpi groups, the proportions decreased to the lower levels at the later time points
224 (14, 21 and 28 dpi) ($P < 0.05$, $n = 6$), they still maintained at higher levels comparing to the sham
225 group ($P < 0.05$, $n = 6$). Comparing with Figure 2H, the proportion of cells in Figure 2K is
226 lower. This indicated that the activated peripheral infiltrated Mø in the injured spinal cord are
227 significantly inferior to activated MG.
228 Figure 2L showed that CD68$^+$CD11b$^+$CD$^{45-/low}$ cells were also extremely rare in sham group, and
229 they gradually increased after injury, peaked at 7 dpi, and then decreased, but still maintained at
230 high levels at 14, 21 and 28 dpi. Comparing to sham group, the percentages of
231 CD68$^+$CD11b$^+$CD$^{45-/low}$ cells in all SCI groups had significant differences ($P < 0.01$, $n = 6$).
232 **Temporal pattern of MG and infiltrated Mø following SCI: the immunohistofluorescence**
233 **(IHF) analysis**
234 To verify the temporal pattern of MG and infiltrated Mø detected by FCM, the spinal cords from
235 several representative time points after SCI (sham, 1, 7 and 28 dpi) were selected for IHF
236 analysis. CD11b, CD68 and TMEM119 antibodies were used for immunofluorescence labeling
237 (Figure 3). Here, TMEM119$^+$CD11b$^+$ cells are total MG, TMEM119$^-$CD11b$^+$ cells are monocyte-
238 derived Mø, TMEM119$^+$CD68$^+$ cells are activated MG, TMEM119$^-$CD68$^+$ cells are activated
239 monocyte-derived Mø, respectively (Figure 3A-H).
240 The representative images showed that TMEM119$^+$CD11b$^+$ cells could be detected in all groups
241 (Figure 3A-D). The statistical results (Figure 3E) showed that the number (cells/mm^2) of
242 TMEM119$^+$CD11b$^+$ cells had no significant difference between sham (117.50 ± 19.30) and 1 dpi
243 (200.33 ± 16.59) groups ($P > 0.05$, $n = 6$). Comparing with the other three groups, there were
244 most TMEM119$^+$CD11b$^+$ cells in 7 dpi (537.33 ± 99.80) ($P < 0.01$, $n = 6$). Although, the cells
245 were decreased at 28 dpi (308.33 ± 50.27), the number still significantly more comparing with
246 sham and 1 dpi groups ($P < 0.01$, $n = 6$). In sham group, TMEM119$^-$CD11b$^+$ cells were
247 extremely rare (Figure 3A), and they significantly increased in the three SCI groups (Figure 3B-
248 D). The statistical results (Figure 3F) showed that the numbers of TMEM119$^-$CD11b$^+$ cells in all
249 three SCI groups were significant more than that of sham (70.17 ± 7.65) group ($P < 0.01$, $n = 6$).
250 Comparing with the other three groups, there were also most TMEM119$^-$CD11b$^+$ cells in 7 dpi
251 (201.80 ± 42.53) group ($P < 0.05$, $n = 6$).
252 In Figure 4A, both TMEM119$^+$CD68$^+$ and TMEM119$^-$CD68$^+$ cells were extremely rare in sham
253 group. However, both of them could be detected in all SCI groups (Figure 4B-D). The statistical
254 results (Figure 4E and F) showed that the numbers of these two types of cells had significant
255 differences among sham and SCI groups ($P < 0.01$, $n = 6$). Comparing with the three other
256 groups, there were most TMEM119$^+$CD68$^+$ cells in 7 dpi (473.50 ± 64.48) group ($P < 0.01$, $n =$
257 6). Although, the number of these cells decreased at 28 dpi (269.67 ± 42.49), it still significantly
258 more comparing with sham (6.67 ± 6.31) and 1 dpi (156 ± 43.75) groups ($P < 0.01$, $n = 6$).
259 Comparing with the other two groups, TMEM119$^-$CD68$^+$ cells were most in 1 (155.00 ± 18.51)
260 and 7 dpi (124.75 ± 34.88) groups ($P < 0.01$, $n = 6$).
261 **Temporal pattern of SCI-induced M1 and M2 differentiation of Mø and MG: the FCM**
262 **analysis**

263   To further explore the temporal pattern of SCI-induced M1 and M2 differentiation of Mø and
264   MG, FCM was used by combining CD68, CD45, CD11b and CCR7 antibodies.
265   As shown in Figure 5A, the same size "region" of total $CD11b^+$ cells (R1) were set for each
266   sample in the pseudocolor plots of CD45/CD11b, and then the percentage of each cell population
267   was analyzed in the pseudocolor plots of CD68/CCR7 by setting the boundary between negative
268   and positive with isotype-matched antibodies. The statistical results (Figure 5B) showed that the
269   percentage of $CD11b^+CD68^+CCR7^+$ M1 cells in the sham group was the lowest. The proportions
270   significantly increased after injury, reached to peak from 7 dpi, and maintained at high levels at
271   14, 21 and 28 dpi. There were no significant differences among 7, 14, 21 and 28 dpi ($P > 0.05$, n
272   = 6). However, the percentages in these four groups were significant higher comparing with
273   sham and 1 dpi groups ($P < 0.01$, $n = 6$).
274   Figure 5C showed that $CD11b^+CD68^+CCR7^-$ M2 cells had no significant differences among all
275   groups ($P > 0.05$, $n = 6$). However, when converted to ratio (Figure 5D), the total M1/M2 ratios
276   in all SCI groups were significant increased comparing with the sham group ($P < 0.01$, $n = 6$).
277   As shown in Figure 5E, in the pseudocolor plots of CD11b/CD45, the same size "region" of
278    $CD11b^+CD45^{-/low}$ cells (R2) were set for each sample, and then the percentages of cell
279   populations were analyzed same as Figure 5A. The statistical results (Figure 5F) showed that the
280   percentage of $CD11b^+CD45^{-/low}CD68^+CCR7^+$ MG-derived M1 cells in sham group was the
281   lowest comparing with the injured groups, and the differences were statistically significant ($P <$
282   0.01, $n = 6$). The proportions significantly increased after injury, and reached to peak at 14 and
283   21 dpi, and continued at high level at 28 dpi. The percentages in the groups of 3, 7, 14, 21 and 28
284   dpi were significantly higher than that of 1 dpi ($P < 0.05$ or 0.01, $n = 6$).
285   Figure 5G showed that $CD11b^+CD45^{-/low}CD68^+CCR7^-$ MG-derived M2 cells had no significant
286   differences among all groups ($P > 0.05$, $n = 6$). However, when converted to ratio (Figure 5H),
287   the M1/M2 ratio of MG was very low in sham group, and they increased after SCI, peaked at 7
288   dpi, and then decreased at 21 and 28 dpi. In the group of 7 dpi, the ratio was significantly higher
289   than those of the other groups ($P < 0.05$, $n = 6$).
290   In Figure 5I, in the pseudocolor plots of CD11b/CD45, the same size "region" of
291    $CD45^{high}CD11b^+$ cells (R3) were set for each sample, and then the percentages of cell
292   populations were analyzed same as Figure 5A. Figure 5J showed that the percentages of
293    $CD11b^+CD45^{high}CD68^+CCR7^+$ peripheral infiltrated M1 cells showed an increasing trend after
294   SCI, and reached the highest levels at 28 dpi. The 7, 14, 21 and 28 dpi groups had statistically
295   significant comparing with sham and 1dpi ($P < 0.05$ or 0.01, $n = 6$). Figure 5K showed that the
296   percentages of $CD11b^+CD45^{high}CD68^+CCR7^-$ peripheral infiltrated M2 cells were highest at 3
297   and 7 dpi, which were statistically significant comparing with the other groups ($P < 0.01$, $n = 6$).
298   When converted to ratio (Figure 5l), the infiltrated M1/M2 ratio was very low in sham group,
299   and there was a transient rise at 1 dpi. Then, the ratios decreased to sham level at 3 and 7 dpi, and
300   then showed an increasing trend from 14 to 28 dpi, it reached the highest levels at 28 dpi. Among
301   sham, 3 and 7 dpi groups, the ratios had no significant differences ($P > 0.05$, $n = 6$). However,
302   comparing with the other groups, the ratios were significant lower ($P < 0.05$ or 0.01, $n = 6$).
303   **Temporal pattern of SCI-induced M1 and M2 differentiation of Mø and MG: the IHF**
304   **analysis**
305   In IHF analysis, $CD68^+CCR7^+$ and $CD68^+Arg1^+$ were used to label total M1 and M2 cells,
306   respectively (Figure 6); $TMEM119^+ CCR7^+$ and $TMEM119^+Arg1^+$ cells were M1 and M2 MG,
307   respectively (Figure 7A-J). Therefore, ($CD68^+CCR7^+$ minus $TMEM119^+CCR7^+$) and

308 (CD68$^+$Arg1$^+$ minus TMEM119$^+$Arg1$^+$) were M1 and M2 monocyte-derived Mø, respectively
309 (Figure 7K and L).
310 The representative images showed that CD68$^+$CCR7$^+$, CD68$^+$Arg1$^+$, TMEM119$^+$CCR7$^+$ and
311 TMEM119$^+$Arg1$^+$ cells were both extremely rare in sham-operated spinal cords (Figures 6A and
312 E, 7A and E). However, these cells could be detected in all SCI groups (Figure 6B-D, F-H, and
313 7B-D, F-H).
314 The statistical results (Figure 6I) showed that in the groups of sham, 1, 7 and 28 dpi, the numbers
315 of CD68$^+$CCR7$^+$ cells were 2.67 ± 2.50, 235.33 ± 5.13, 577.17 ± 40.18 and 543.17 ± 31.35,
316 respectively. All SCI groups were significant more than that of sham ($P < 0.01$, $n = 6$). Up to 7
317 dpi, the cell number reached to peak, and continued at high levels at 28 dpi.
318 In Figure 6J, the numbers of CD68$^+$Arg1$^+$ cells in the groups of sham, 1, 7 and 28 dpi were 3.83
319 ± 3.43, 105.33 ± 9.56, 72.83 ± 10.55 and 150.17 ± 22.21, respectively. Although, CD68$^+$Arg1$^+$
320 cells in all SCI groups were significant more than that of sham group ($P < 0.01$, $n = 6$), the 7 dpi
321 had the least number of cells among the three SCI groups, and there were most cells in 28 dpi
322 group.
323 In Figure 7I, TMEM119$^+$CCR7$^+$ cells in the groups of sham, 1, 7 and 28 dpi were 3.17 ± 1.83,
324 205.17 ± 9.97, 412.33 ± 18.04 and 410.17 ± 50.92, respectively. The overall change trend was
325 similar to that of CD68$^+$CCR7$^+$ cells. Figure 7J showed that TMEM119$^+$Arg1$^+$ cells in the groups
326 of sham, 1, 7 and 28 dpi were 4.33 ± 2.42, 85.83 ± 10.68, 50.00 ± 4.29 and 125.00 ± 13.33,
327 respectively. The overall trend was also similar to that of CD68$^+$Arg1$^+$ cells.
328 In Figure 7K, the infiltrated CD68$^+$CCR7$^+$ cells in the groups of sham, 1, 7 and 28 dpi were 0.00
329 ± 0.00, 30.17 ± 11.72, 164.83 ± 45.64 and 133.00 ± 56.67, respectively. All SCI groups were
330 significant more than that of sham group ($P < 0.01$, $n = 6$). Up to 7 dpi, the cell number reached
331 to peak. Although the number of cells had a decreasing trend, it remained at a higher level at 28
332 dpi. Figure 7L showed that although the infiltrated CD68$^+$Arg1$^+$ cells could be detected in SCI
333 groups, they were very rare. The numbers in the groups of sham, 1, 7 and 28 dpi were 0.00 ±
334 0.00, 19.50 ± 12.65, 22.83 ± 12.04 and 25.17 ± 15.74, respectively. All three SCI groups were
335 significant more than that of sham group ($P < 0.01$, $n = 6$).
336 **Summary of dynamic changes of MG, infiltrated Mø and their subsets**
337 As shown in the first row of Figure 8, the proportions of total Mø/MG in the groups of SCI were
338 gradually increased and peaked at 7 dpi. Although, decreasing at 14, 21 and 28 dpi, they were
339 still maintained at high levels compared with sham, 1 and 3 dpi groups.
340 The second row of Figure 8 showed that most of the Mø/MG were activated following SCI.
341 The third row of Figure 8 showed that MG were absolutely dominant and Mø were few in the
342 sham-operated spinal cords. In the acute phase of SCI (1 and 3 dpi), the proportions of activated
343 Mø increased significantly. However, with the progression of the SCI, the proportions of
344 activated MG increased nearly to 90% in subacute phase (7 and 14 dpi) and chronic phase (21
345 and 28 dpi).
346 Finally, we further analyzed the proportion of M1 and M2 subsets in the activated MG and
347 infiltrated Mø. The fourth row 4 of Figure 8 showed that in sham, 1, 3, 7, 14, 21 and 28 dpi
348 groups, the proportions of M1 Mø were 7%, 43%, 51%, 7%, 9%, 17% and 12%, respectively,
349 while M2 Mø were 6%, 6%, 23%, 3%, 1%, 1% and 0%, respectively. The proportions of M1
350 MG were 31%, 43%, 20%, 69%, 79%, 66% and 68%, respectively, and M2 MG were 56%, 8%,
351 6%, 21%, 11%, 16% and 20%, respectively. These results showed that there are very few
352 peripheral Mø in the sham-operated spinal cords, while the proportion of MG is absolutely
353 dominant, and the MG are mainly M2 subtype. In the acute phase of SCI, the proportion of

354 peripheral infiltrated Mø increased transiently, and M1 Mø are absolutely dominant, but in the
355 subacute phase, M1 MG were absolutely dominant and continued to the chronic phase (28 dpi,
356 the longest time point observed in this study).
357
Discussion
359 Following SCI, the local microenvironment of spinal cord is destroyed (Anjum et al. 2020; Fan
360 et al. 2022; Fan et al. 2018). SCI not only leads to neuronal and oligodendrocyte necrosis and
361 astrocyte activation, it also triggers the immune response, which includes the local MG
362 activation and the peripheral immune cell infiltration (Donnelly & Popovich 2008; Lee et al.
363 2009). Among these immune cells, some are neuroprotective, while others are destructive. The
364 final outcomes of SCI depend on the dynamic balance of these cells (DiSabato et al. 2016; Wolf
365 et al. 2002).
366 Previous studies found that local pro-inflammatory M1-type MG (MG) and/or infiltrated M1-
367 type Mø are absolutely dominant following SCI (Fan et al. 2019; Sato et al. 2012). These suggest
368 that M1 cells may be the key factor for the imbalance of local immune microenvironment of SCI.
369 However, it remains controversial that these M1 cells are mainly from MG or the infiltrated Mø.
370 Our recent research showed that the local M1 cells are mainly $CD45^{-/low}CD68^{+}CD11b^{+}$, rather
371 than $CD45^{high}CD68^{+}CD11b^{+}$ cells in the subacute stage of SCI (Chen et al. 2021; Chen et al.
372 2020). In fact, CD45 is not only a common marker of peripheral leukocytes, it can also be
373 expressed at a low level in MG (Sedgwick et al. 1998), CD11b is mainly expressed in MG and
374 monocyte-derived Mø (Martin et al. 2017), and CD68 is the common marker of activated MG
375 and Mø (Chen et al. 2015; Greaves & Gordon 2002). Therefore, $CD45^{high}CD68^{+}CD11b^{+}$
376 population was activated peripheral infiltrated Mø, $CD45^{-/low}CD68^{+}CD11b^{+}$ population was
377 activated MG, and $CD45^{high}CD68^{-}CD11b^{-}$ population was peripheral infiltrated leukocytes
378 excluding Mø. Thus, we speculated that the M1 cells in the injured spinal cords mainly derived
379 from MG rather than infiltrating Mø. To test this hypothesis, in this study, the mouse SCI model
380 was established, the activation and proportion of MG and infiltrated Mø at different time points
381 following SCI were dynamically observed by a panel of specific cell markers using FCM and
382 IHF.
383 Generally, in the rodent model, the pathological process of traumatic SCI is divided into the
384 acute (< 48 h), subacute (2 to 14 dpi) and chronic (> 14 dpi) phases (Rodrigues et al. 2018; Shi et
385 al. 2017). Therefore, in this study, we selected the sham-operated spinal cord as the normal
386 control, 1 dpi as acute, 3, 7 and 14 dpi as subacute, 21 and 28 dpi as chronic phases, respectively.
387 The results showed the proportions of total Mø/MG peaked at 7 dpi. Although, the proportions
388 decreased at 14, 21 and 28 dpi, they were still maintained at high levels comparing with sham, 1
389 and 3 dpi. This change trend is consistent with the previous reports (Chen et al. 2015; Kigerl et
390 al. 2009; Wang et al. 2015). We also found that the activated Mø increased significantly at 1 and
391 3 dpi following SCI. However, with the progression of pathological process, the activated MG
392 dominated absolutely and increased nearly to 90% at 7, 14, 21 and 28 dpi. These demonstrate
393 that in the early stage of SCI, the peripheral Mø infiltrate into the injured area rapidly, and the
394 activated MG and Mø are in a roughly balanced state. This is consistent with previous report
395 (Hellenbrand et al. 2021).
396 Here, we can find that the percentages of $CD68^{+}$ cells in 7, 14, 21 and 28 dpi groups were
397 significant higher comparing with sham, 1 and 3 dpi groups, and there were no significant
398 differences among 7, 14, 21 and 28 dpi groups. These may because in the later stage of subacute
399 phase and chronic phase, most of the $CD68^{+}$ cells are activated MG and Mø, and their number

400 has reached the maximum. The possible reason is that lesion-associated factors (e.g.,
401 proinflammatory cytokines, oxygen tension, chemokines, etc.) persist indefinitely in the local
402 microenvironment, and the recruitment of MG/Mø might promote new blood vessel growth and
403 extracellular matrix deposition in these stages of SCI (Kigerl et al. 2009).
404 In this report, the activated MG are dominant at 7 dpi. Although, this is not consistent with
405 previous report (Hellenbrand et al. 2021), it is consistent with the recent reports which using
406 single-cell RNA sequencing to analyze the temporal changes at molecular and cellular leve
407 ls in the injured mouse spinal cords (Li et al. 2022; Milich et al. 2021). The possible reason is
408 that MG response following acute SCI limits infiltrated Mø dispersion (Plemel et al. 2020).
409 Accordingly, we further found that both the proportions of M1 and M2 Mø were increased
410 significantly at 1 and 3 dpi. However, they decreased to very low levels from 7 to 28 dpi. This
411 phenomenon also shows that the activated MG might inhibit both infiltrated M1 and M2 Mø.
412 Following SCI, the M1 MG increased and maintained at high levels from 7 to 28 dpi. On the
413 contrary, the proportion of M2 MG decreased significantly after SCI and remained at a low level
414 during the whole pathological process. Based on these results, we can infer that the activated MG
415 are mainly M1 subtype following SCI. They inhibit not only the infiltration of peripheral
416 monocytes, but also the polarization of these cells into M2 Mø. In the same way they can also
417 inhibit the polarization of themselves into M2 MG. Therefore, M1 cells derived from MG are the
418 key cells involved in proinflammatory response of SCI.
419 Following SCI, the main effector cells are the peripheral infiltrated Mø and resident MG (David
420 & Kroner 2011). In fact, whether the immune response of these cells is good or bad depends on
421 their subtypes and functional characteristics. Based on their functions, Mø/MG can be divided
422 into M1 and M2 subtypes. M1 cells can damage nerve cells by secreting inflammatory cytokines,
423 while M2 cells can regulate immune inflammatory response, remove necrotic tissue fragments,
424 promote vascular regeneration, tissue reconstruction and repair (Kigerl et al. 2009; Kroner et al.
425 2014; Wang et al. 2015). In this study, we demonstrated that most Mø and MG in the injured
426 spinal cords are M1 cells, only a small number showing M2 phenotype and they are transient.
427 This shows that the predominance of M1 macroglia and lower number of M2 macroglia and/or
428 Mø may contribute to the early inflammatory response and secondary damage following SCI.
429 Therefore, for clinical transformation and application of Mø/MG, it is very necessary to
430 determine the appropriate "time window" of these cells for immune intervention. Our temporal
431 dynamic analysis suggests that the acute and early stage of subacute phase may be the "window
432 period" for immune intervention targeting MG. During this "time window", using effective
433 intervention measures to timely inhibit the differentiation of MG into M1 subtype, rather than
434 focusing on the infiltration and activation of peripheral monocytes, is of positive significance for
435 increasing the proportion of M2 cells, improving the immune microenvironment and providing
436 neuroprotection.
437 One limitation of this study is that the temporal dynamic analysis and the "window period" for
438 immune intervention targeting MG only from mouse SCI model. Whether these laws are
439 consistent with human related diseases still need to be further explored.
440

Conclusions
442 In summary, this study not only demonstrate that the pro-inflammatory M1 cells mainly come
443 from MG rather than infiltrated Mø after SCI, but also determine their dynamic patterns.
444 Therefore, these findings not only answer the academic debate about which of the infiltrating Mø

445 and MG plays a key role, but also determines the appropriate "time window" of immune
446 intervention targeting M1-type MG for the treatment of SCI.
