Background. Declines of the Eastern oyster, *Crassostrea virginica*, and its numerous ecological benefits have spurred oyster restoration initiatives. Successful restoration of a self-sustaining oyster population requires evaluating the temporal and spatial patterns of recruitment (settlement and survival) of oyster larvae in the target waterbody. Restoration of the Eastern oyster population in the Maryland Coastal Bays (MCBs), U.S.A., a shallow lagoonal estuary, is of interest to federal and state agencies, but the location and timing of natural recruitment is not known.

Methods. We assessed the spatial and temporal variation in oyster larval recruitment throughout the MCBs using horizontal ceramic tiles and PVC plates. Newly settled oyster larvae (recruits) were monitored biweekly from June to September 2019 and 2020 at 12 sites in the MCBs and a comparison site in Wachapreague, Virginia. Water quality measurements collected included temperature, salinity, dissolved oxygen, pH, and turbidity. The objectives of this study were to determine 1) the most effective substrate design for monitoring oyster recruitment, 2) the spatial and temporal distribution of oyster larval recruitment in the MCBs, and 3) patterns in oyster larval recruitment that would be applicable to other lagoonal estuaries.

Results. 1) Ceramic tiles were more effective than PVC plates for recruiting oyster larvae, 2) Peak settlement began during the period from late June through July, and oyster recruitment was greatest at sites closest to the Ocean City and Chincoteague inlets, 3) Areas near broodstock that have slow flushing rates to retain larvae may provide the best environments for recruitment of oysters to lagoonal estuaries.

Discussion. As the first study on oyster larval recruitment in the MCBs, our results provide insight into their spatial and temporal distribution, methods that can serve as a foundation for future recruitment studies in other lagoonal estuaries, and baseline data that can be used to inform stakeholders and evaluate the success of oyster restoration projects in MCBs.

Keywords: Oyster, *Crassostrea virginica*, Larval recruitment, Settlement, Restoration, Ecosystem services, Lagoonal estuary, Maryland, Mid-Atlantic.

Introduction

Coastal lagoonal estuaries account for 13% of the coastline worldwide (McAvoy & Clancy, 1994). The Eastern oyster, *Crassostrea virginica* (Gmelin 1791), is an inhabitant and keystone species of coastal lagoonal estuaries along the Atlantic shoreline of the United States. Important ecosystem services (Sanjeeva Raj, 2008) provided by the Eastern oyster are water filtration (Wilber & Clarke, 2010), nitrogen cycling (Jiang et al., 2020), benthic-pelagic coupling (Maryland Department of Natural Resources, 2004), habitat formation (Harding & Mann, 2001), carbon and nitrogen sequestration (Smyth, Geraldi & Piehler, 2013; Fodrie et al., 2017), and shoreline protection (Piazza, Banks & La Peyre, 2005). Despite the Eastern oyster's ecological importance, anthropogenic stresses such as increased shoreline development, habitat destruction, pollution, water quality degradation (Lotze et al., 2006; Worm et al., 2006), overharvesting (Kirby, 2004), and disease (Harvell et al., 1999; Beck et al., 2011) have contributed to its decline.

Population declines and habitat losses of the Eastern oyster have inspired federal, state, and non-governmental agencies to pursue restoration efforts to reestablish the species in native waters (Chesapeake Bay Program, 2000). Successful oyster restoration projects have been conducted in lagoonal estuaries along the east coast of the United States at various scales and locations. For example, the restoration efforts in the Delaware Inland Bays, which encompass Rehoboth Bay, Indian River Bay, and Little Assawoman Bay, include smaller restoration projects. Volunteers in the Delaware Oyster Gardening Program grow oysters for two years on private docks to be utilized for research or restoration purposes (Reckenbeil & Ozbay, 2014). In Maryland and Virginia, federal and state agencies are restoring native Eastern oyster populations and habitats in 10 tributaries (by 2025) as part of the 2014 Chesapeake Bay Watershed

Agreement. Of the five tributaries targeted in Maryland, 788 acres of oyster reefs have been restored since 2014, with a goal of 1,439 acres by 2025. Restoration of Eastern oyster populations in the Maryland Coastal Bays (MCBs) have also been discussed among federal, state, NGO, and academic partners prior to 2013 (B. Stevens, 2018, pers. comm.). However, the spatial and temporal distribution of wild oyster larvae in the MCBs was not known.

Surveys on historical oyster bars and adult Eastern oyster populations in the MCBs have been conducted as part of the annual shellfish population surveys by the Maryland Department of Natural Resources (MD DNR) through their Shellfish Monitoring and Assessment Program. Remnant populations of wild Eastern oysters exist in intertidal areas of the MCBs, a two-inlet lagoonal estuarine system along the east coast of the United States in the Mid-Atlantic. The Eastern oyster populations have declined dramatically from historic levels due to overharvesting and lasting effects from the creation of the Ocean City Inlet during a hurricane in 1933. This inlet introduced changes in salinity and hydrodynamics within the MCBs as well as new diseases, predators, and competitors (Maryland Department of Natural Resources, 2004; Jesien et al., 2009; Kang et al., 2017). Shellfish surveys have never found natural oysters on the former oyster bars of the MCBs since 1993. Instead, oyster shells are deteriorating, becoming fouled, and buried in sediment (Maryland Department of Natural Resources, 2004). Although no viable natural oysters exist in subtidal areas of the MCBs, small populations have settled on anthropogenic structures in intertidal areas near Ocean City Inlet and southern Chincoteague Bay where subtidal oyster farms also exist (Maryland Department of Natural Resources, 2004; Jesien et al., 2009). Since the annual shellfish surveys only provide data on adult oyster populations, no information on the locations of settled oyster larvae exists, so the spatial and temporal distribution of wild oyster larvae still remains unknown in the MCBs.

Prior to restoration initiatives, it is crucial to evaluate the spatial and temporal recruitment patterns of wild oyster larvae and their growth and survival over multiple years to determine the feasibility, scale, and location of a restoration effort (Kennedy et al., 2011; Soniat et al., 2012; Casas, La Peyre & La Peyre, 2015). Additionally, mapping the locations of wild oyster larvae is important because natural recruitment supplements restoration efforts and aids in the success of restoration projects (Schulte & Burke, 2014). Therefore, we conducted the first study of recruitment of oyster larvae in the MCBs and assessment of the best methods for measuring recruitment to guide future studies in other waterbodies. From June to September in 2019 and 2020, we assessed the spatial and temporal distribution of recruitment using three sampler types (ceramic arrays, PVC arrays, and PVC collectors) that utilized PVC plates or ceramic tiles. Specific objectives were to 1) determine which sampler type was most effective for recruitment, 2) determine the spatial and temporal distribution of oyster larval recruitment in the MCBs, and 3) identify patterns in oyster larval settlement that would be applicable to other lagoonal estuaries. Identifying natural recruitment of wild oyster larvae can aid in restoration success by supplementing restoration efforts (Schulte & Burke, 2014). An oyster restoration project in the MCBs would help improve its poor water quality (Jesien et al., 2009), create hard substrate habitat, and provide additional ecosystem services (Maryland Department of Natural Resources, 2004; Jesien et al., 2009).

Materials & Methods

Study Area

This study was conducted throughout the MCBs, located along the Mid-Atlantic coast of the United States between the Delmarva Peninsula (spanning the states of Delaware, Maryland,

and Virginia) and the Atlantic Ocean (Dennison et al., 2016). The MCBs system is a shallow lagoonal estuary that encompasses a 453 km² watershed comprised of six bays ranging from north to south: Assawoman Bay, Saint Martin River, Isle of Wight Bay, Sinepuxent Bay, Newport Bay, and Chincoteague Bay (Maryland Department of Natural Resources, 2004; Krantz et al., 2009). The MCBs is a two-inlet system with Ocean City Inlet in the north and Chincoteague Inlet in the south. It has an average depth of 1.5 m, but approximately 3 m at Ocean City Inlet and 4 m at Chincoteague Inlet (Dennison et al., 2016; Kang et al., 2017; Oseji, Fan & Chigbu, 2019). As a shallow estuary, it is well-mixed and highly productive with little to no salinity or thermal gradients (Bricker et al., 2009; Oseji, Fan & Chigbu, 2019).

The MCBs have varied flushing rates, the amount of time it takes for water to be replaced by water exchange through the inlets and freshwater inputs, which range from 9 days in Isle of Wight Bay to 63 days in Chincoteague Bay (Pritchard, 1969; Thomas et al., 2009). Another characteristic of the MCBs is uneven circulation with high current velocities near the inlets that decrease with distance from the inlets (Krantz et al., 2009). The only sources of “new” water (inlets and freshwater input) account for approximately 7.5% of the volume in the MCBs daily (Pritchard, 1960). Well-circulated areas have better water quality than areas in or close to tributaries. The uneven distribution of well-circulated areas in combination with input from non-point sources can cause nutrient enrichment that leads to poor water quality (Bricker et al., 2009; Dennison et al., 2016; Oseji, Fan & Chigbu, 2019).

Site Selection

Historical water quality data from the National Park Service (NPS; 2016 – 2018), Maryland Department of Natural Resources (MDNR; 1999 – 2019), and Maryland Coastal Bays Program (MCBP; 2013 – 2015) were used to guide the selection of study sites. From the

historical water quality data, twelve sites in the MCBs (10 sites in Maryland and two in Virginia) were selected based on several factors including geographic location, proximity to inlets, salinity (18 – 39 ppt), bottom type, depth, historical water quality data, and expert recommendations (Fig. 1, Table S1). The study sites ($n = 12$) included three currently monitored for water quality by local agencies: DNR XDN4312 (site: St. Martin River), DNR TUV0021 (site: Turville Creek), and NPS ASSA 2 (site: Verrazano Bridge). Sites had a range of bottom sediments from coarse sand to silt (Mid-Atlantic Ocean Data Portal, 2021) and were defined as either Pier or Bay Sites depending on whether sampling equipment was attached to a shore-based pier or placed in open water. An additional study site for sampling gear comparison (substrate material and design) was established in Wachapreague, Virginia, at the Virginia Institute of Marine Science (VIMS) Eastern Shore Laboratory (ESL), where VIMS conducts a recruitment study on oyster larvae.

Sampler types

“Settlement” in this study is defined as an oyster larvae cementing itself to a substrate, thereby becoming sessile (Connell, 1985). “Recruitment” refers to settlement in addition to survival for a time frame defined by the investigator (Bushek, 1988; Roegner & Mann, 1995). We defined “recruitment” as recently settled oyster larvae or recruits that survived on settlement substrate for up to two weeks as described in Rimler (2014). Recruitment of oyster larvae was monitored using two different types of sampler designs (collectors or arrays) containing either PVC plates (12.70 cm x 13.97 cm) or ceramic tiles (10.16 cm x 10.16 cm).

PVC collectors consisted of a cage made of plastic-coated wire (22.86 cm x 22.86 cm x 53.34 cm) with 1.5 in² apertures containing PVC plates and built to our specifications by Ketcham Traps (New Bedford, MA). Each collector contained three PVC plates suspended

horizontally using bungee cords at 35.6 cm, 40.6 cm, and 45.7 cm above the substrate and was weighted with two bricks placed in the bottom (Fig. 2A). PVC plates were custom cut to be 12.70 cm x 13.97 cm but had an outer border that confined a counting area to 10.16 cm x 12.7 cm. Plates were drilled in four corners and sanded on both sides with 100 grit sandpaper in a cross-hatched pattern to simulate the rugosity of the outside of an oyster shell to enhance settlement (Beiras & Widdows, 1995). An outer border of 6.35 mm on two sides and 12.70 mm on two sides was scored to define a counting area of exactly 10.16 cm x 12.7 cm (129 cm²). The border was defined to ease plate removal and reduce the risk of dislodgement of organisms because the plates could not be picked up comfortably using one hand width.

Arrays consisted of a 30.5 cm nylon threaded rod (0.95 cm diameter) on which three center-drilled PVC plates or ceramic tiles (10.2 cm x 10.2 cm x 0.7 cm, or 103 cm²) were positioned and separated by 5 cm sections of 1.25 cm PVC pipe (Fig. 2B; Fig. 2C). Arrays did not have a surrounding wire mesh cage. Ceramic tiles were arranged with the unglazed side facing downwards. This design was similar to arrays used by VIMS (Ross & Synder, 2020) but modified with weights (two bricks) below, and a small float (buoy) above, to keep the plates suspended in the water column at a fixed height off the bottom. Ceramic tiles did not have a border, like the PVC plates, because they were smaller and could easily be picked up on the sides using one hand, without risk of dislodging organisms. PVC collectors were deployed in 2019 and 2020 and arrays (both ceramic and PVC) were deployed only in 2020. Because chemical cues have been suggested to induce settlement (Pawlik, 1986), approximately 90% of plates and tiles were conditioned in seawater for 8–24 hours prior to deployment; the remaining were not due to time constraints.

In 2019, we also carried out an observational study at site Wachapreague at the Virginia Institute of Marine Science (VIMS) Eastern Shore Laboratory to compare VIMS ceramic arrays and our PVC collector design. Three PVC collectors were suspended next to VIMS arrays made of ceramic tiles. This comparison was made to determine 1) if PVC plates were as effective as ceramic tiles and 2) if a potential lack of recruitment on the PVC plates was due to the presence of fewer oyster, collector design, or plate substrate. Due to the results of this study and low counts in 2019 on PVC plates vs. ceramic tiles we added ceramic array designs to six sites in 2020 as described below. Results from 2019 suggested that ceramic tiles were more effective for monitoring oyster larval settlement. Therefore, ceramic and PVC arrays employing the VIMS design were added in 2020 to the sites where oyster larval recruitment was observed during 2019. Although PVC collectors were less suitable for recruitment than ceramic tiles, they were deployed again in 2020 to compare spatial and temporal distribution between years and evaluate potential patterns.

Field Sampling

PVC collectors and arrays were either attached to lines suspended from a shore-based pier (Pier site) or attached to a surface line suspended by buoys between each collector (Bay site) (Fig. 3A; Fig. 3B). The PVC plates and ceramic tiles were replaced biweekly at the sites for a total of five times per site, or five “swaps” from June – September of 2019 and 2020. In 2019, three PVC collectors (three replicates), each containing three PVC plates ($n = 9$) were deployed at all 13 sites. At all 13 sites in 2019, PVC plates (total $n = 117$) were collected and replaced biweekly ($n = 531$ plates total). During 2020, PVC collectors ($n = 333$ plates), PVC arrays ($n = 225$ plates), and ceramic tiles ($n = 225$ ceramic tiles) could not be deployed at the same five swap

dates nor at all 13 sites from 2019 due to COVID-19 restrictions and transportation issues. Therefore, the “swap dates” typically occurred later and fewer sites were sampled in 2020 than in 2019.

In 2020, PVC collectors were deployed at 11 of the 13 sites, while three PVC arrays and three ceramic arrays were added to six of those sites (designated as “primary sites”). These six sites included four sites where oyster larvae settled in 2019 (Fig. S1), in addition to site Mills Island and Island Mark 12 that were recommended by watermen. Among the six primary sites (DNR Pier, Island Mark 12, Mills Island, Guys Point, Queen Sound, and Wachapreague), PVC plates ($n = 54$) in PVC collectors, PVC plates ($n = 54$) in PVC arrays, and ceramic tiles ($n = 54$) in ceramic arrays were collected and replaced biweekly. Only PVC collectors with PVC plates were used at the remaining sites including Greys Creek, Verrazano Bridge, South Point, Public Landing, and Taylor Landing. Not all plates and ceramic tiles could be retrieved, however, due to being lost in the field, removed etc.

Environmental data were also measured using a Xylem ProDSS Multiparameter Water Quality Meter (Xylem, Yellow Springs, OH) that was positioned above the sediment. Environmental parameters measured included temperature ($^{\circ}\text{C}$), salinity, dissolved oxygen (mg/l), pH, and depth (m). Turbidity was measured as secchi disk depth (m). Field experiments were approved by the Maryland Department of Natural Resources under Scientific Collection Permit numbers SCP201964 and SCP202091.

Laboratory processing

PVC plates and ceramic tiles collected in the field were transported to the laboratory at the University of Maryland Eastern Shore in CD containers to prevent abrasion among plates. Sediment on the plates was gently rinsed and brushed off and a dissecting microscope was used

to count oyster larvae. PVC material rugosity was consistent on both sides, while ceramic tiles had a smooth glazed top and a rough unglazed bottom. Oyster larvae were counted on the underside of the PVC plates and ceramic tiles to replicate the methods used by the Virginia Institute of Marine Science (VIMS; Gloucester, VA, USA; (Ross & Synder, 2020) and because of the texture differences. Oyster larvae identification was conducted after confirmation by P. Ross at VIMS.

Statistical Analysis

All statistical analyses were performed in R version 4.2.2 (R Core Team, 2022) and the graphics were generated using the “ggplot2” R package (Wickham, 2016). Histogram plots and the Shapiro-Wilk test for normality showed a non-normal distribution for the oyster larval count data. Kruskal-Wallis rank sum tests (R Core Team, 2022) followed by Dunn’s post hoc multiple comparison tests (Ogle et al., 2022) were used to determine differences ($\alpha = 0.05$) among sites and sampler types. Due to the high percentage of zeros in the larval counts during 2019 (95%) and 2020 (42%), the data was subset to counts ≥ 1 to determine statistical differences among sites and sampler types.

Densities of the larval counts (larval count per cm^2 = larval counts from each PVC plate or ceramic tile/area of PVC plate or ceramic tile) were calculated to generate density maps for spatial data visualization. Densities adjusted for plate size differences between ceramic (10.16 cm x 10.16 cm) and PVC plates (10.16 cm x 12.7 cm).

Larval counts and water quality measurements from all sites 2019 ($n = 496$) and 2020 ($n = 830$) were combined into one dataset to examine potential relationships. The larval counts from plates and sampler types were summed to obtain independent observations of larval counts and water quality measurements from sampling time points within each site ($n = 13$). The

correlations between the larval counts and water quality measurements in the combined ($n = 58$) and 2020 ($n = 47$) dataset were evaluated using principal component analysis (PCA). The significance of these correlations was tested using the Kendall Tau-b (τ_B) rank correlation method ($\alpha = 0.05$; McLeod, 2011). This correlation method is appropriate when data contains non-normal distributions, tied ranks, and outliers (Croux & Dehon, 2010; Alfons, Croux, & Filzmoser, 2017; Akoglu, 2018). The PCA plot was generated using the “prcomp” function in the FactoMineR package (Kassambara and Mundt, 2020), which uses singular value decomposition to examine covariances and correlations between the observations. The factoextra package (Lê et al., 2008) was used to evaluate the eigenvalues to determine the highest percentages of variance retained by each principal component.

To determine the influence of sampler type, site location, and sample timing on larval recruitment, the oyster larval counts from 2019 and 2020 were used to generate a generalized linear mixed model (GLMM) with the “glmmTMB” R package (Brooks et al., 2017). Models were run with a zero-inflated Poisson (ZIP) regression due to the high percentage of zeros (84.5%) in the dataset. The Akaike information criterion (AIC) values from each model (m_i) were used to calculate a second-order bias correction estimator (AIC_C). A model was chosen based on the AIC_C values and quality checks provided by the “DHARMA” R package (Fig. S2; Hartig, 2022).

Results

Sampler types

The presence of oyster larvae varied by sampler type and site during 2020 with many zero counts (absence) within sites (Fig. 4A). Ceramic arrays were the most effective sampler

type for assessing oyster larval recruitment at the six primary sites in the MCBs. Oyster larvae settled on 2% - 33% of the ceramic tiles and on 1% - 14% of the PVC plates (Fig. 4A). Additionally, the settlement of oyster larvae was observed more frequently on the ceramic arrays (116 times) than on the PVC arrays (65 times) among the sites (Fig. 4B; $H(2) = 7.054$, $p = 0.029$). The median larval counts were also significantly higher on ceramic arrays (13.5 ± 18.53 [MAD]) compared to PVC collectors (1 ± 0 [MAD]) and PVC arrays (3 ± 2.97 [MAD]; Fig. 5A; $H(2) = 34.393$, $p < 0.0001$). The ceramic arrays had larval counts up to 930 compared to the PVC collectors and arrays with counts up to 32 and 93, respectively (Fig. 5B). The oyster larvae on the ceramic arrays were observed most frequently at DNR Pier (18), Guys Point (24), Queen Sound (16), and Wachapreague (45; Fig. 4B). The median larval count (447 ± 189.78 [MAD]) was significantly higher at Queen Sound compared to the other five sites, but maximum larval counts >100 were observed at Queen Sound, DNR Pier, and Wachapreague (Fig. 5C, 5D; $H(5) = 68.855$, $p < 0.05$).

Spatial distribution

PVC collectors were deployed during 2019 and 2020 to compare distribution patterns in oyster recruitment between years. No oyster settlement occurred at sites other than the six primary sites during 2019 and 2020, except one occurrence at North Verrazano Bridge during August 2020 (Table 1). Of the six primary sites, oyster settlement occurred in both years at DNR Pier, Guys Point, Queen Sound, and Wachapreague. Little to no recruitment occurred at Island Mark 12 and Mills Island (Table 1). Spatial patterns of recruitment on PVC collectors were consistent between 2019 and 2020 because all sites with settlement in 2019 also received settlement in 2020 (Fig. 6A). Total settlement density from all sites on the PVC collectors was greater during 2020 (3.07 larvae per cm^2) than 2019 (0.37 larvae per cm^2). At DNR Pier,

settlement density was five times greater on the PVC collectors during 2020 (0.50 larvae per cm²) than 2019 (0.11 larvae per cm²; Fig. 6A). Additionally, total settlement density at Wachapreague (2.62 larvae per cm²) from 2019 and 2020 was almost 18 times greater than settlement at DNR Pier (0.61 larvae per cm²). Inter-annual differences were only significant at Wachapreague ($H(1) = 4.95, p = 0.0204$) but not at DNR Pier or the primary sites. No recruitment occurred at Island Mark 12 and Mills Island for PVC collectors during both years. Recruitment on the PVC collectors was low at Queen Sound in both years and recruitment was slightly less during 2020 (0.03 larvae per cm²) than 2019 (0.07 larvae per cm²; Fig. 6A). Recruitment at Guys Point (0.05 larvae per cm²) remained the same for both years.

The spatial distribution of settlement densities from the ceramic arrays were compared to the settlement densities from the PVC arrays, which were only deployed during 2020 at the six primary sites (Fig. 6B). Overall, total settlement density was greater on ceramic arrays (109 larvae per cm²) than PVC arrays (0.92 larvae per cm²; $H(1) = 96.291, p < 0.0001$). Within the MCBs, the greatest larval density on ceramic arrays occurred at Queen Sound (66.81 larvae per cm²), Wachapreague (29.31 larvae per cm²), and DNR Pier (11.73 larvae per cm²) in 2020 over the entire field season (Fig. 6B). Among the six primary sites, settlement density on the ceramic arrays was greatest at the sites closest to the inlets (DNR Pier and Queen Sound). Lastly, Island Mark 12 (0.01 larvae per cm²) and Mills Island (0.21 larvae per cm²) received little recruitment on both array types (Fig. 6B).

Temporal distribution

In 2019, settlement on PVC collectors began in early to mid-July at site Wachapreague and the MCBs sites, except Island Mark 12 (Fig. 7). In 2020, settlement at sites Wachapreague and Queen Sound occurred earlier than the remaining primary sites (3 July 2020; Fig. 7D, 7E).

At all sites in the MCBs, settlement in 2019 and 2020 generally began in early to mid-July, but settlement only occurred in late-July of 2019 at Island Mark 12 (Fig. 7). Settlement continued until late July and early August during both years. Earliest settlement within the MCBs occurred at site Queen Sound, but sampling equipment at that site disappeared after 30 July 2020 due to a storm, which prevented further data collection (Fig. 7D). Settlement began slightly earlier at site Wachapreague than in the MCBs, in late June (2019) and early July (2020), and extended longer, until late August in 2020 (Fig. 7E). At site DNR Pier, near Ocean City Inlet, two settlement peaks were observed in both 2019 and 2020 and occurred within approximately the same week of each year (Fig. 7A).

GLMM model for larval recruitment prediction

Several ZIP GLMMs were tested and compared against a null model to determine the best fit model for predicting larval counts based on sampler type (St), site location (Si), and sample timing represented as swap number (Sw; Table 2). The m_4 model contained sampler type, site location, and sample timing (swap number) as fixed effects but was eliminated due to a probability (w_i) < 0.05 , higher AIC_C value, and failing quality checks (outlier test and Kolmogorov-Smirnov test for uniformity of the residuals). Models m_6 and m_7 results had the lowest AIC_C values and uniquely contained the plate levels within the samplers and line number, the location of the sampler on the pier or buoy line, as a nested random effect. Model m_7 was chosen because it contained both site location and sample time as a fixed effects and resulted in the lowest AIC_C value, a probability > 0.05 , and passed model quality checks (Table 2; Fig. S2). The chosen model predicted the highest larval counts to occur at DNR pier, Queen Sound, and Wachapreague sites and during swaps 2 and 3 which represented the time period between late June and mid-August (Fig. S3).

Environmental effects

The Principal Component Analysis (PCA) plot showed potential relationships between oyster larval counts and water quality measurements of temperature, salinity, dissolved oxygen (DO), pH, and turbidity. The principal components (PC-1 and PC-2) calculated from the water quality variables and larval counts explained 59% of the variance observed in the dataset (Fig. 8). Results of the Kendall Tau-b (τ_B) rank correlation tests showed that larval counts had a significant positive correlation with salinity ($\tau_B = 0.49$, $z = 6.545$, $p < 0.0001$) and negative correlations with DO ($\tau_B = -0.17$, $z = -2.237$, $p < 0.05$) and pH ($\tau_B = -0.19$, $z = -2.453$, $p < 0.05$). Average salinity ranged from 24 - 32 ppt among sites and was highest (>30 ppt) at DNR pier, Mills Island, Guys Point, Queen Sound, and Wachapreague (Table 1). At these 5 sites, the average pH and DO were 7.6 - 8.1 and 4.6 - 6.6 mg O L⁻¹, respectively (Table 1). No correlations were found between the larval counts and temperature or turbidity in the PCA analysis. The average temperature and turbidity among these five sites ranged 22 - 30°C and 0.3 - 1 m, respectively (Table 1).

Discussion

Sampler types

Oyster larvae exhibit preferential settlement (Keough & Downes, 1982), indicated by significantly more counts on the ceramic arrays in 2020 than any other sampler type. Despite our PVC plates being sanded with 100 grit sandpaper, the ceramic tiles had greater rugosity, making it easier for oyster larvae to attach (Marques-Silva et al., 2006). In addition, ceramic tiles are alkaline (Reig et al., 2013) and oyster larvae are more likely to settle when exposed to ammonia, which is alkaline (Coon, Fitt & Bonar, 1990). Preferential settlement on ceramic tiles rather than PVC was also evident in the study by Chuku et al. (2020), who compared monthly recruitment of

the West African mangrove oyster *Crassostrea tulipa* among five substrates (coconut shell, oyster shell, nylon mesh, PVC slats, and ceramic tile) in four lagoonal estuaries in Ghana. Ceramic tiles had the greatest monthly settlement in three of the four estuaries, and PVC slats had the greatest in the fourth; recruitment on ceramic tiles was not significantly different than on PVC slats (Chuku et al., 2020). In addition, biofilms are effective at inducing oyster settlement (Tamburri, Zimmer-Faust & Tamplin, 1992; Zhao, Zhang & Qian, 2003; Su et al., 2007; Campbell et al., 2011), but the effect varies with length of conditioning and rugosity of the substrate (Taylor, Southgate & Rose, 1998; Devakie & Ali, 2002; Zhao, Zhang & Qian, 2003; Su et al., 2007; Tamburri et al., 2008; Bellou et al., 2020).

Spatial distribution

Although settlement and recruitment behaviors can be difficult to measure *in-situ*, our results show a spatial distribution trend of greater recruitment at sites near Ocean City (DNR Pier) and Chincoteague Inlet (Queen Sound), suggesting those are more attractive locations for oyster settlement than sites further away from inlets. Additionally, broodstock live close to those inlets. Settlement of both Sydney rock oyster *Saccostrea glomerata* and invasive Pacific oysters *Crassostrea gigas* in Port Jackson Estuary, Australia was greater at sites nearer the Pacific Ocean than in the upper channel (Scanes et al., 2016). Spatial distribution patterns in the Port Jackson Estuary were similar to those of the MCBs with more oyster larvae being observed closer to the interface between the estuary and ocean.

The MCBs have lower freshwater discharge, varied flushing rates, and high velocity water near Ocean City and Chincoteague inlets. Flushing rates in the individual sub-bays vary greatly, e.g. from 9 days in Isle of Wight Bay to 63 days in Chincoteague Bay (Pritchard, 1969; Lung, 1994). This implies that oyster larvae are retained longer, thus have a longer period of

time to settle in Chincoteague Bay than in Isle of Wight Bay. The longer retainment period in Chincoteague Bay supports the greater settlement observed near Chincoteague Inlet (Maryland Department of Natural Resources, 2004). Retention within a system correlates to recruitment success (Norcross & Shaw, 1984).

A hydrodynamic model by Kang et al. (2017) demonstrated that the northward flow of water through the MCBs is primarily wind-driven, except when wind speeds are weak (e.g., 3 m/s), at which times it becomes tidally driven. However, near Ocean City and Chincoteague inlets, tidal cycles drive circulation patterns (Wells, Hennessee & Hill, 2002). The MCBs have a distinct seasonal wind pattern, with prevailing winds blowing from the southwest in the summer due to the Bermuda High pressure system and winds blowing from the northeast in the winter. Circulation patterns in the MCBs may also be influenced by the shape of the estuary's basin and bathymetry, or depth (Lee & Valle-Levinson, 2012) since the shallow basin and winds in the MCBs can alter wave dynamics (Mao & Xia, 2018). Strong turbulence from waves can cue oyster larvae to sink, increasing their proximity to suitable substrate in which to attach (Fuchs et al., 2013). The strong turbulence at the inlets could be a reason for the observed spatial distribution near the inlets.

The MCBs are characterized as being “microtidal” since tidal exchange is limited to Ocean City Inlet and Chincoteague Inlet. Although the tidal excursion of the MCBs is unknown, similar lagoonal estuary systems have tidal excursions of 2.7 km in Haulover Canal connecting Mosquito Lagoon and Indian River lagoon (Smith, 1993), 2 km both for Little Egg Harbor and Barnegat Bays (Chant, 2001), and 1.02 km to 8.25 km depending on the site proximity to Fort Pierce Inlet within the Indian River lagoon (Smith, 1983). Tidal excursion refers to the distance between low water and high water in which a particle travels. It is a measurement to describe the

movement of particles such as larvae and pollutants within a tidal cycle (Ji, 2008). A coupled biological-physical transport model by Kim et al. (2013) simulated that larger tidal excursions during a tropic tide caused greater larval dispersion. We hypothesize that the spawning adult oysters are within a 1 km – 8 km range of settlement sites in the MCBs. Perhaps the coupling of flushing rates (slowest in Chincoteague Bay), proximity and tidal circulation through the inlets may have contributed to greater settlement.

Temporal distribution

The Eastern oysters in this study region typically spawn from June through October (Haven & Fritz, 1985). Samplers showed little variation in peak timing between 2019 and 2020 (< 10 days apart) and all settlement peaks began in July in both years. Our results showed that oyster larvae settled between late-June and mid-August, which was expected based on settlement timing reported by previous studies at similar latitudes in the Mid-Atlantic (Shaw, 1967; Kennedy, 1980; Haven & Fritz, 1985; Capelle et al., 2020; Ross & Synder, 2020). Although monitoring in our study did not continue into late September, it has been documented by other studies that peaks do occur during that time (Haven & Fritz, 1985).

Environmental effects

Temperature and salinity are known to have an influence on oysters throughout their life cycle (Hori, 1933; La Peyre et al., 2013). Although there was no correlation found between larval counts and temperatures, settlement was greatest between 22 and 26 °C at DNR Pier, Guys Point, Queen Sound, and Wachapreague (data not shown). These temperatures were within the optimal range (20 and 32.5 °C) for oyster larval growth (Calabrese and Davis 1970) and the ambient water temperatures (20 and 30 °C) that induce adult oysters to spawn (Horn Point Oyster Hatchery, 2021). Previous studies observed increased settling with thermal shock (Lutz, Hidu &

Drobeck, 1970; Hidu & Haskin, 1971). Perhaps the mixing and change in temperature between the warmer bay water and cooler ocean water from the inlets may have contributed to settlement.

The optimal salinity ranges of 12.00 – 28.00 (Dame, 1996) and 15.00 – 20.00 (Barnes et al., 2007) have been reported for oyster growth. Our results are consistent with Nelson (1923), who observed the greatest abundance of straight-hinge larvae at stations in the most saline and lower portion of Barnegat Bay, New Jersey. This is contrary to laboratory experiments by Hidu and Haskin (1971), in which oyster larvae were not stimulated to settle with an increase in salinity. Highest larval settlement occurred at sites with average salinities >30 ppt over the 2019-2020 period, which is just above the optimal range for oyster growth. Salinity had the strongest and most significant correlation with larval counts. Although these sites were also located closest to the inlets, where salinity is naturally higher, there are other factors such as current flow and/or tidal excursion that can influence settlement.

The negative correlations between larval counts, pH, and DO were significant, but the correlation coefficient was weak (<0.20). For oysters, the ideal range in pH and DO for growth is 6.75 to 8.75 (Calabrese & Davis, 1966; Clark & Gobler, 2016) and 7 mg O L⁻¹, respectively (Clark & Gobler, 2016). The average pH at sites DNR pier, Mills Island, Guys Point, Queen Sound, and Wachapreague fell within the desired range for oyster larvae, but not for DO. Interestingly, the site with the lowest average DO was at site Wachapreague (4.6 mg O L⁻¹), which had the second greatest larval counts. This further corroborates the negative correlation between larval counts.

Conclusions

This is the first recruitment study for oyster larvae in the MCBs, and the resulting spatial and temporal distribution patterns can provide insight into evaluating restoration initiatives and serve as a foundation for future recruitment studies in other lagoonal estuaries. We assessed the recruitment distribution of oyster larvae at 12 sites within the MCBs and a site for sampling gear comparison, using PVC plates and ceramic tiles that were monitored biweekly in summer 2019 and 2020. This study resulted in four significant findings: 1) ceramic tiles received significantly greater recruitment than PVC plates; 2) new recruits settled in the greatest numbers at sites that were closest to Ocean City and Chincoteague inlets, as opposed to sites further within the bays; 3) settlement occurred between late June and early July into mid-August, which was consistent with previous studies at similar latitudes (Shaw, 1967; Kennedy, 1980); and 4) the spatial and temporal patterns of settlement were essentially identical in both 2019 and 2020, although recruitment was four to five times greater in 2020. This study can supplement ongoing data collection (e.g., surveys of fish, shellfish, submerged aquatic vegetation, water quality, and current drift monitoring) to gain a broader understanding of the MCBs and provide baseline data upon which to build. Notably, it may guide stakeholders in evaluating the decision to potentially pursue an oyster restoration project within the MCBs and similar lagoonal estuaries.

Recommendations

For any oyster restoration project, monitoring is recommended prior, during, and after restoration to assess the reef habitat, the organisms living on the reef, and interactions among organisms (Thayer et al., 2005). This is important so adjustments can be made if needed and the progress of the restoration can be observed over time. Examples of restoration techniques used in the Mid-Atlantic and other areas include creating 3-dimensional structures with vertical relief that emulate natural oyster reefs. These consist of clutch, which is a material (e.g. shells, shell

fragments, limestone, concrete, etc.) in which oyster larvae settle (Kurz, 2012). Clutch is deposited on the sediment or a foundation then are piled to make the vertical structure (Luckenbach, Mann & Wesson, 1999; O’Beirn et al., 2000; Brumbaugh & Coen, 2009). Other methods include pre-cast limestone or concrete structures (e.g. oyster castles or oyster balls) and oyster shells in bags (Olander et al., 2020; Virginia Institute of Marine Science, 2023). Partnering with local agencies as well as oyster farmers and watermen would aid in the collection of necessary data.

For setting up a larval recruitment and settlement monitoring study, ceramic arrays would be the best sampler to use in the short term (a spawning season), prior to restoration -- to evaluate the location and time to establish a restoration project. The ceramic arrays should be utilized during at least two spawning seasons to determine if there are spatial and temporal patterns in settlement. However, oyster shells should be prioritized for use in restoration efforts over ceramic substrate, because of the protein periostracum that is present on oyster shells (Crisp, 1967), chemical cues released from conspecifics (Tamburri, Zimmer-Faust & Tamplin, 1992), and the contoured surface (Taylor, Southgate & Rose, 1998) but ceramic tile is an alternative if oyster shells are not readily accessible. Natural recruitment of wild oyster larvae aid in restoration success by supplementing restoration efforts (Schulte & Burke, 2014). Burke and Schultz (2014), concluded that restored reefs with planted spat and adults, recruited greater populations and in greater densities than unenhanced reefs because wild settlement rose two to three orders of magnitude. The additional larvae and adults provide additional substrate for wild oysters in which to settle (Southworth & Harding, 2014).

Based on the results of our study, we recommend the following for site selection prior to pursuing oyster restoration in the MCBs and other lagoonal estuaries: 1) selecting a restoration

site that is in close proximity to broodstock, has a slow flushing rate, and circulation patterns that retain larvae; 2) utilizing oyster shells as substrate for preliminary recruitment studies and/or restoration projects (if oyster shells are not accessible, a ceramic array design as seen in this study, can be used as an alternative); 3) establishing a restoration site prior to or in early June (in the Mid-Atlantic) to ensure wild oyster larvae settle during peak time; 4) conduct additional research on the current state of parasites, overwintering, and diseases to ensure survival and growth of oysters; and 5) establish a monitoring program to assess progress and address environmental changes (Recommendations further described in Kennedy et al., 2011).

Acknowledgements

This paper is in honor of Daniel Cullen, who was an incredible friend, mentor, and colleague. He is missed greatly.

We would also like to thank our boat Captains for their assistance in transportation to our study sites as well as the National Park Service, Maryland Department of Natural Resources, and Maryland Coastal Bays Program in guiding the location of study sites. We are grateful to Elizabeth North, Mitchell Tarnowski, and the anonymous reviewers for providing comments to improve this manuscript. Special thanks to Steve Doctor and Paige Ross for sharing their expertise and University of Maryland Eastern Shore students for assisting in the field and laboratory. Lastly, we thank Cara C Schweitzer at the NOAA NMFA-Office of Habitat Conservation for her feedback on the statistic models.

Figure 1

Study area map.

Map of study area depicting the locations of 12 coastal bay sites in Maryland and one in Virginia where three sampler types were deployed from June to September 2019 and 2020 to assess the distribution of oyster larvae. Circles indicate sites in which three collector types were suspended from a pier while squares indicate sites where three collector types were set on a floating buoy line. Inset shows the location of the study area within the Delmarva Peninsula (USA). Sites include Greys Creek (GC), St. Martin River (SM), Turville Creek (TC), DNR Pier (DP), Verrazano Bridge (VB), Island Mark 12 (IM), South Point (SP), Public Landing (PL), Taylor Landing (TL), Mills Island (MI), Guys Point (GP), Queen Sound (QS), and Wachapreague (W).

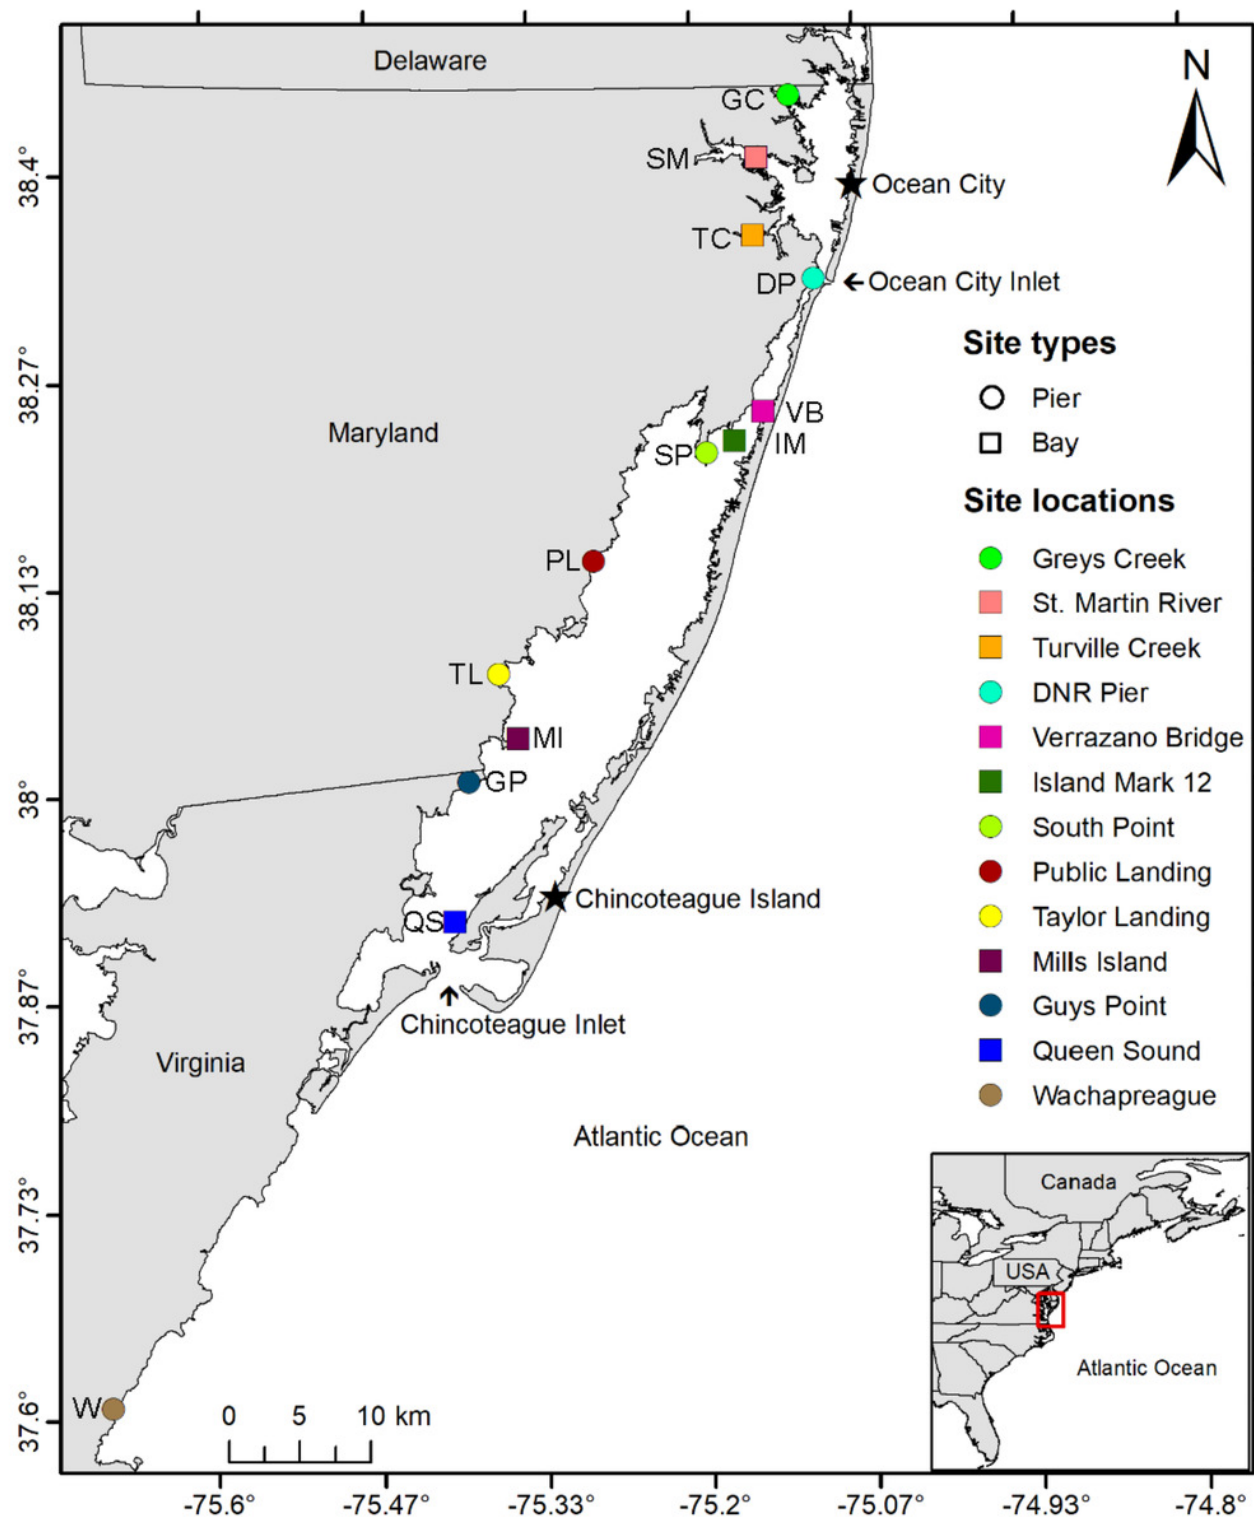

Figure 2

Sampler types used to monitor recruitment of oyster larvae at 13 sites to assess their distribution:

(A) PVC collector. (B) PVC array. (C) Ceramic array.

Figure 3

Diagrams of samplers deployed at coastal bay site locations.

(A) Pier site in which ceramic arrays (white), PVC arrays (black), and PVC collectors (black, in rectangles) were suspended from a shore-based pier. (B) Bay site in which samplers were suspended from a floating buoy line. At both site locations, each sampler type had three replicates that were positioned in random order. In 2019, all 13 sites included three PVC collectors. In 2020, six primary (sites DNR Pier, Island Mark 12, Mills Island, Guys Point, Queen Sound, and Wachapreague) included all three sampler types (ceramic arrays, PVC arrays, and PVC collectors), while the remaining sites included three PVC collectors.

Figure 4

The proportion of the absence and presence of oyster larvae and the number of times oyster larvae was present on the collection devices at each site during 2020.

The larval count data was used to calculate the presence and absence of oyster larvae on collection devices from each site. (A) The proportion of oyster larvae that was absent (gray) or present on ceramic arrays (CA; green), PVC arrays (PA; orange), and PVC collectors (PC; purple). Sites and total number of observations were DNR Pier (n = 127), Island Mark 12 (IM; n = 45), Mills Island (MI; n = 113), Guys Point (GP; n = 132), Queen Sound (QS; n = 72), and Wachapreague (W; n = 137). (B) The number of times (frequency) that oyster larvae was observed on the types of collection devices.

Figure 5

Comparison of median and maximum larval counts to sampler types and sites during 2020.

Data was pooled by either sites or sampler types to compare the median and maximum larval counts (≥ 1). (A-B) Counts from collection devices of ceramic arrays (CA; $n = 116$), PVC arrays (PA; $n = 27$), and PVC collectors (PC; $n = 38$). (C-D) Counts from sites of DNR Pier (DP; $n = 18$), Island Mark 12 (IM; $n = 1$), Mills Island (MI; $n = 12$), Guys Point (GP; $n = 24$), Queen Sound (QS; $n = 16$), and Wachapreague (W; $n = 45$). Bars above median counts represent standard error (SE). The letters above the SE bars denote significant differences ($p < 0.05$) between median larval counts.

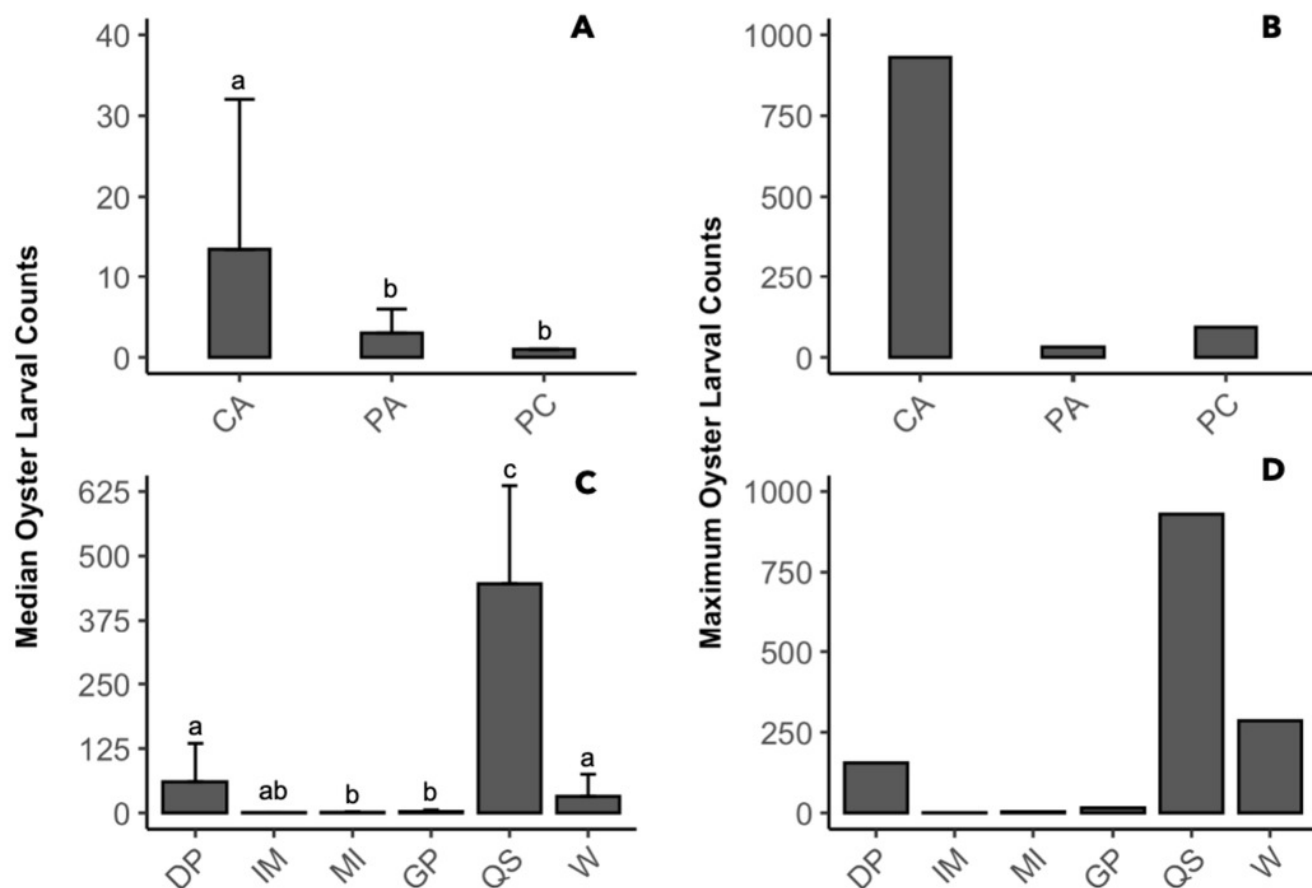

Figure 6

Map of spatial distribution of oyster larvae that settled on three sampler types at six primary coastal bay sites.

(A) Density of oyster larvae per plate over entire field season on PVC collectors in 2019 and 2020. (B) Density oyster larvae per plate over entire field season on PVC arrays and ceramic arrays in 2020. Values refer to density of median oyster larvae counts from the underside of a ceramic tiles or PVC plates. Six primary sites included DNR Pier (DP), Island Mark 12 (IM), Mills Island (MI), Guys Point (GP), Queen Sound (QS), and Wachapreague (W).

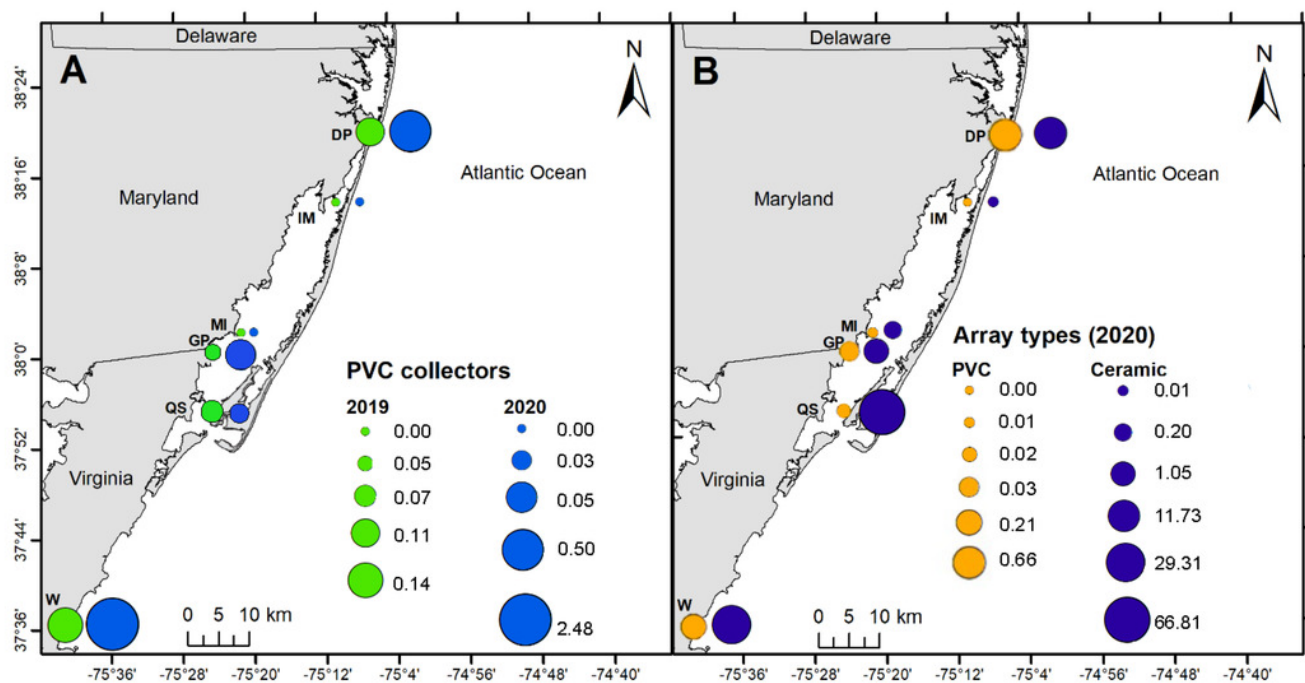

Figure 7

Temporal distribution of oyster larvae at coastal bay sites.

Comparison of recruitment on PVC collectors at five sites from June to September 2019 and 2020. Figures display raw counts of oyster larvae counted on the underside of PVC plates within PVC collectors. Sites (A) DNR Pier. (B) Island Mark 12. (C) Guys Point. (D) Queen Sound. (E) Wachapreague. Note scales of y-axes differ.

Figure 8

Principal component analysis (PCA) of oyster larval counts and water quality parameters.

PCA plot showing the potential correlations between oyster larval counts and water quality measurements of salinity, turbidity, dissolved oxygen (DO), pH, and temperature (°C). The correlations between larval counts and water quality measurements were obtained by combining the 2019 ($n = 58$) and 2020 ($n = 47$) datasets with all 13 sites.

Table 1(on next page)

Total oyster larval counts and water quality measurements of sites during 2019 and 2020.

Larval counts were summed to calculate totals and water quality measurements of depth, temperature, salinity, pH, dissolved oxygen, and turbidity. Values were averaged (mean \pm standard deviation) by site across years and time points.

1

Site	Site type	n	Total Larval Counts	Depth (m)	Temperature (°C)	Salinity (ppt)	pH	Dissolved oxygen (mg O L ⁻¹)	Turbidity (m)
Greys Creek	Pier	10	0	0.61 ± 0.09	28.80 ± 1.22	24.86 ± 2.09	7.65 ± 0.41	4.19 ± 2.80	0.44 ± 0.12

Table 2(on next page)

Comparison of ZIP generalized linear mixed models (m_0 - m_7) corresponding to the different variables tested for oyster larval settlement prediction.

Model	Variables	df	logLik	AIC _C	Δ_i	w_i
m ₀	L ~ 1	2	-18161.9	36327.9	+30624.8	0
m ₁	L ~ Sw + (1 ST) + (1 Si) + (1 N)	9	-3217.5	6453.1	+750.0	<0.001
m ₂	L ~ Si + (1 ST) + (1 Sn) + (1 N)	17	-3205.7	6445.9	+742.8	<0.001
m ₃	L ~ Si + Sw + (1 ST) + (1 N)	20	-3189.8	6420.2	+717.1	<0.001
m ₄	L ~ Si + Sw + ST + (1 N)	21	-3181.5	6405.6	+702.5	<0.001
m ₅	L ~ Si + Sw + (1 ST) + (1 N) + (1 L)	21	-3014.8	6072.3	+369.2	<0.001
m ₆	L ~ Si + (1 Sw) + (1 ST) + (L N)	22	-2842.0	5728.8	+25.7	<0.001
m₇	L ~ Si + Sw + (1 ST) + (L N)	25	-2826.1	5703.1	-	0.99

df = degrees of freedom; Loglik = log-likelihood; AIC_C = corrected AIC value; Δ_i = difference between each model and the best selected model; and w_i = probability that a given model provided is the best fit for the data. Variables: L = oyster larvae counts; Si = site; Sw = swap number represented sampling time; ST = sampler type; L= plate level on the sampler; N= line number represented the position of the sampler on the pier or buoy line. Model m₇ was selected to be the best fit model.
