Running title: Urine complements of IgAN patients

Abstract

Aim: IgA nephropathy (IgAN) is one of the leading causes of end-stage renal disease (ESRD). Urine is a source of noninvasive biomarkers of body fluids that are used for measuring renal injury. This study aimed to analyse the complements during IgAN progression by quantitative proteomic strategy.

Methods: In the discovery phase, we analysed 22 IgAN patients who were divided into three groups (IgAN 1-3) according to the estimated glomerular filtration rate. The other 8 patients with primary membranous nephropathy (pMN) were set as controls. Isobaric tags for relative and absolute quantitation (iTRAQ) labelling coupled with liquid chromatography-tandem mass spectrometry was applied to analyse global urinary protein expression. In the validation phase, Western blotting and parallel reaction monitoring (PRM) were used to verify the iTRAQ results in an independent cohort (N=64).

Results: In the discovery phase, 747 proteins were identified in the urine of IgAN and pMN patients. There are different urine protein profiles in IgAN and pMN, and the bioinformatics analysis revealed that the complement and coagulation pathways were most activated. We totally identified 27 urinary complements related to IgAN. The relative abundance of C3, the membrane attack complex (MAC) and the complement regulatory proteins of the alternative pathway (AP),

MBL and MASP1 of the lectin pathway (LP) were increased during IgAN progression, especially MAC, which was found to be involved prominently in disease progression. Alpha-N-acetylglucosaminidase (NAGLU) and α -galactosidase A (GLA) were validated by Western blot and consistent with iTRAQ. By PRM analysis, 10 proteins with significant differences were validated, and these results were consistent with the iTRAQ results. Complement (CFB) and complement component C8 alpha chain (C8A) presented increasing abundance with the progression of IgAN. The combination of CFB and MAdCAM-1 showed excellent area under the curve values to discriminate the progression of IgAN.

Conclusion: There were abundant complement components in the urine of IgAN patients, indicating that the activation of AP and LP is involved in IgAN progression. Urinary complements may be used as biomarkers for evaluating IgAN progression in the future.

Keywords: Complement proteins; IgA nephropathy; α -N-acetylglucosaminidase; Proteomics; Urine;

1. Introduction

IgA nephropathy (IgAN) is the most common primary glomerulonephropathy worldwide, and 20-30% of patients with IgAN progress to end-stage renal disease within 10 years of disease onset [1]. The four-hit hypothesis of IgAN pathogenesis [2] involves elevated serum galactose-deficient IgA1 (Gd-IgA1), IgG or IgA antibody specific to Gd-IgA1, formation of immune complexes (ICs) and IC deposits predominantly on the glomerular mesangium, leading to inflammation,

complement activation, mesangial hypercellularity and glomerulosclerosis.

Activation of the complement cascade is involved in the pathogenesis of IgAN. The alternative and lectin pathways dominate the complement activation of IgAN [3]. However, previous studies have not revealed the role of complement proteins in IgAN progression. Data from mass spectrometry (MS) analysis in kidney biopsy samples have demonstrated that the complement pathways are involved in IgAN [4].

As a noninvasively accessible, low background and relatively stable biofluid, urine is an ideal source for biomarker discovery via proteomic approaches. Urinary proteomics could be used to analyse protein profiles and assess pathogenetic mechanisms in an overall view involved in disease progression. Previously, some urinary proteomic studies in IgAN have been devoted to candidate biomarker discovery [5,6], but there is no study on urinary proteomic profile changes during IgAN progression.

The proteomic study usually includes two phases, discovery and validation. In the discovery phase, the samples were analysed by an untargeted proteomics approach to identify the differentially expressed proteins, which may be related to disease mechanisms, drug targets or disease biomarkers [7]. In the validation phase, the differential proteins were analysed by targeted methods, including Western blotting, ELISA, and PRM, in another cohort to validate the results of the discovery phase [8].

The use of isobaric tags for relative and absolute quantification (iTRAQ) is a new technique in quantitative proteomics to identify and quantify protein expression levels. Parallel reaction monitoring (PRM) can distinguish between interference information and real signals and has greater selectivity to detect target proteins, often used for verification of iTRAQ differential proteins.

In this study, urine samples were collected from IgAN patients with different disease severities and primary membranous nephropathy (pMN) patients. After removing fourteen highly abundant proteins, urine samples of IgAN and pMN patients were analysed by iTRAQ labelling coupled with liquid chromatography-tandem mass spectrometry (2D-LC/MS/MS) for quantitative proteome analysis. Furthermore, PRM was also used to validate the differentially expressed proteins. The aim of this study was to analyse the entire urinary protein profiles in IgAN patients with different disease stages to assess whether the overall urinary complement expression profile changes with disease progression.

2. Materials and Methods

2.1 Reagents and instruments

HPLC-grade acetonitrile (ACN), trifluoroacetic acid, formic acid, ammonium bicarbonate, iodoacetamide (IAA), and dithiothreitol (DTT) were all purchased from Sigma (St. Louis, MO, USA). Sequencing-grade trypsin was purchased from Promega (Madison, WI, USA). The 4-plex iTRAQ reagents were purchased from ABsciex (Framingham, MA, USA). An Orbitrap Fusion Lumos Tribrid mass spectrometer coupled with an EASY-nLC 1000 HPLC system was purchased from Thermo (Thermo Fisher Scientific, MA, USA) and then applied for proteome analysis in both discovery and validation phases. For Western blotting, primary antibodies against α -N-acetylglucosaminidase (NAGLU, ab72178) and α -galactosidase A (GLA, ab168341) were purchased from Abcam (Cambridge, UK).

2.2 Patients and urine samples

All the patients enrolled in this study were diagnosed with IgAN by kidney biopsy. Fresh urine samples were collected on the morning of kidney biopsy. For the discovery cohort, the sample collection duration was from August 2014 to January 2017, and the sample collection of the

validation cohort was from November 2019 to July 2021. The urine was centrifuged at $3000 \times g$ for 30 min. The sediment was discarded, and the supernatant was stored at -80°C . This study was approved by the Ethics Committee of Peking Union Medical College Hospital (approval number: JS-2573), and the enrolled patients signed informed consent forms. The amount of 24-h urine proteins (24hUP), serum creatinine (SCr), and estimated glomerular filtration rate (eGFR) of patients were evaluated. The CKD-EPI equation was used to estimate the eGFR as described previously [9]. The clinical characteristics of the patients in the discovery and validation phases are shown in Table 1. The pMN was diagnosed by renal pathology (light microscopy, immunofluorescence and electron microscopy). Secondary MN due to infection, malignant neoplasms, rheumatologic disease, drugs, and other systemic causes was ruled out. In both the discovery and validation phases, IgAN patients were divided into three subgroups based on the eGFR, namely, IgAN-1 (eGFR: $> 90 \text{ ml/min/1.73 m}^2$), IgAN-2 (eGFR: $60\text{-}90 \text{ ml/min/1.73 m}^2$) and IgAN-3 (eGFR: $30\text{-}60 \text{ ml/min/1.73 m}^2$). Two nephropathologists evaluated renal biopsy samples independently according to the Oxford Classification of IgA nephropathy from the IgA Nephropathy Classification Working Group in 2016 [10].

2.3 Urinary protein extraction

The urine supernatants were precipitated by ethanol overnight at -20°C . After centrifugation at $12,000 \times g$ for 30 min, the pellets were resuspended in lysis buffer (7 M urea, 2 M thiourea, 0.1 M DTT, 50 mM Tris). The protein concentration of each sample was measured using the Bradford method. In the discovery phase, highly abundant proteins were removed from urine protein samples using an Agilent Mars14 chromatography column following the manufacturers' protocol (Agilent, Palo Alto, CA, USA). Equal amounts of total urine protein from each individual patient within one patient group were pooled together. Finally, four pooled protein samples were formed

from IgAN 1-3 and pMN patients for proteomic analysis.

2.4 Protein digestion and iTRAQ labelling

Each sample was digested using the filter-aided sample preparation method (FASP) [11]. Protein samples were denatured with 20 mM DTT at 37 °C for 1 h and alkylated with 50 mM IAA in the dark for 45 min. Then, the samples were loaded onto filter devices with a cut-off of 10 kD (Pall, Port Washington, NY, USA) and centrifuged at 14,000 g at 18 °C. After washing twice with UA (8 M urea in 0.1 M Tris-HCl, pH 8.5) and twice with 25 mM NH_4HCO_3 , the samples were redissolved in 25 mM NH_4HCO_3 and digested with trypsin (enzyme to protein ratio of 1:50) at 37 °C overnight. The digested peptides were collected as a filtrate and desalted using Oasis HLB C18 cartridges (Waters, Milford, MA). The IgAN 1-3 and MN samples were individually labelled with 114, 115, 116 and 117 4-plex iTRAQ chemistry according to the manufacturer's protocol (ABSciex, USA).

2.5 2D-LC/MS/MS

2D-LC–MS/MS detection was performed as described previously [12]. The pooled mixture of iTRAQ-labelled samples was fractionated using a high-pH RPLC column from Waters (4.6 mm × 250 mm, Xbridge C18, 3 μm). The samples were loaded onto the column in buffer A1 (H_2O , pH = 10) and then eluted under a gradient of 5–25% buffer B1 (90% ACN, pH = 10) for 60 min with flow rate at 1 mL/min. The eluted peptides were collected at fractions by minute and dried by vacuum evaporation for further redissolution. As Guo et.al proposed previously, the 60 dried fractions were resuspended in 0.1% formic acid and then pooled into 20 samples with certain regularity, for example, combining fractions 1, 21, 41 and 2, 22, 42 and so on. Eventually, 20 fractions from urinary peptide mixtures were analysed by LC–MS/MS.

Each fraction was analysed with a reversed-phase C18 capillary column (75 μm × 100 mm).

An Orbitrap Fusion Lumos Tribrid mass spectrometer was used to analyse the mixed peptides fractions by two times. A high-sensitivity mode was applied for the acquirement of MS data. Detailed parameters of PRM mode were as followed: data-dependent MS/MS scans per full scan with top-speed mode (3 s), full scans (resolution = 60,000) and MS/MS scans (resolution = 15000), 38% HCD collision energy, charge-state screening (charge state of precursors: from +2 to +6), dynamic exclusion (exclusion duration1: 30 s), and maximum injection time (60 ms).

2.8 Western blot analysis

Two candidate proteins associated with glycosylation, NAGLU and GLA, were selected for WB validation in individual urine samples from IgAN and MN patients. Thirty micrograms of urinary protein from each sample was loaded onto 10% SDS–PAGE gels and transferred to PVDF membranes. After blocking in 5% milk for 1 h, the membranes were incubated with primary antibodies at 4 °C overnight. Then, the membranes were washed with TBST four times and incubated with secondary antibodies (diluted 1:5,000 in 5% milk solution) for 1 h at room temperature. The blots of NAGLU and GLA were visualized using enhanced chemiluminescence reagents (Thermo Scientific, USA). The intensity of blots were scanned with an ImageQuant 400TM Imager (GE Healthcare Life Sciences, Piscataway, NJ, USA) and protein signals were quantified using the AlphaEaseFC system.

2.6 Parallel reaction monitoring (PRM) analysis

For PRM validation, the different proteins from LC–MS/MS analysis were evaluated in validation cohort consist of 64 IgAN patients. Each sample was analysed in schedule mode. The mixed sample were analysed as quality control (QC) to ensure the availability of data and the stability of the instrument signal for the PRM validation.

An Orbitrap Fusion Lumos Tribrid mass spectrometer (Thermo Fisher Scientific, MA, USA)

was used for PRM analysis. An RP C18 self-packing capillary LC column (75 mm × 100 mm) was applied to separate the peptides. The elution gradient was 5-30% buffer B1 (0.1% formic acid, 99.9% ACN; flow rate, 0.5 ml/min), and peptides were eluted for 45 minutes. The MS data were achieved under the PRM mode with parameters as followed: full scans acquired (resolution: 60,000), MS/MS scans (resolution: 15,000), 32% collision energy, dynamic exclusion (30 s), MS/MS scan range (100-1800 m/z), scan time (100 ms), isolation window at 4 Da and schedule window (7 minutes).

2.7 Data processing

Proteome Discover (Thermo Fisher, Waltham, USA; version 2.1) was used for database searching. Proteome data were searched by comparing with the SwissProt human database (20,227 entries) assuming trypsin digestion (<http://www.ebi.ac.uk/swissprot/>). The parent and fragment ion mass tolerances were 10 ppm and 0.05 Da. Carbamidomethyl cysteine was specified as a fixed modification, with two miscleavage sites accepted. Proteins were available with false discovery rate (FDR) lower than 1.0% and also at least two unique peptides identified. The acquired intensities were generally normalized across all runs. The normalization of reference channels were also used to determine a 1:1-fold change. All normalization processing was achieved with medians in multiplicative manner.

For the PRM mode, Skyline 21.1 software was used for the selection of the suitable m/z precursor ion to m/z fragment ion transition thereby determining candidate peptides of potential biomarkers. Required data was imported into Skyline software, where the proper data were chosen manually, and the results of peptides from all samples were finally exported. For each sample, total ionic chromatography (TIC) of ions with +2 - +5 charge was settled by Progenesis software. The normalization of each peptide by TIC strength was performed to adjust the errors caused by

the quality of sample loading and the intensity of MS signal. The quantitation of the peptides was subsequently analysed.

2.8 Statistical analysis

Continuous data are performed with the mean \pm standard deviation or median. Categorical data are performed with absolute frequencies and percentages. The Kolmogorov–Smirnov test was performed to evaluate the normality of the distribution. For the quantitative data, one-way analysis of variance (ANOVA) was used to compare the differences for normally distributed data, and non-parametric test was performed for non-normally distributed data. For the categorical variables, chi-square test was used for the comparison among groups. *P* values < 0.05 were considered as statistically significance. Above data were analysed with SPSS version 26.0 software (SPSS Inc., Chicago, IL, USA).

Receiver operating characteristic (ROC) curves of all the significantly different proteins were achieved by Metaboanalyst software (<http://www.metaboanalyst.ca>). The combination ROC analysis was analysed with linear SVM algorithm, and the area under the ROC curve (AUC) was also calculated by separately comparing IgAN-2 and IgAN-3 with the IgAN-1 during the validation phase to identify candidate diagnostic markers.

2.9 Bioinformatics analysis

Mfuzz analysis was performed to detect different clustering models of protein expression among IgAN groups of different CKD stages in the discovery phase. We applied pathway enrichment analysis to determine the different pathways of the proteins with statistics significance according to the KEGG (Kyoto Encyclopedia of Genes and Genomes) database. Protein interaction networks were constructed to demonstrate the potential association among different pathways. The data analysis was performed in the OmicsBean workbench (<http://www.omicsbean.cn>). An adjusted *P*

value < 0.05 was considered statistically significant.

3. Results

3.1 Clinical and pathological characteristics of the patients

In this study, a total of 30 patients were included in the discovery phase, and another independent cohort including 26 and 64 patients was enrolled for WB and PRM validation. The clinical data and pathological characteristics of the patients are summarized in **Table 1**. In the iTRAQ, WB and PRM phases, there were significant differences in SCr and eGFR among the IgAN 1-3 and pMN patient groups. There were significant differences in the T-score of the Oxford classification in the IgAN-3 group compared with the IgAN-1/2 groups in the discovery phase and significant differences in the T-scores of the Oxford classification between the IgAN-3 and IgAN-1 groups in the validation phase ($P < 0.05$) (**Table 1**).

3.2 Bioinformatics analysis of urine proteomes in IgAN and MN patients

The workflow of the urine proteomics analysis is shown in **Figure 1**. Urine samples of IgAN-1, IgAN-2, IgAN-3 and pMN were pooled, and an antibody column was used to remove 14 high-abundance proteins from urine samples prior to proteomic analysis. A total of 747 urinary proteins were identified with at least two unique peptides in both technical replicates using 2D-LC-MS/MS and iTRAQ quantification (**Table S1**). Western blotting for NGALU and GLA was applied in IgAN and MN patients. Furthermore, PRM was used for the targeted quantification of unique peptides from differentially expressed proteins (DEPs) in another IgAN 1-3 cohort.

After hierarchical clustering analysis of all urinary proteins identified, it was found that in IgAN 1-3 and pMN, there were different urine protein expression patterns (**Figure 2A**). Mfuzz analysis of 747 urinary proteins in three IgAN subgroups is shown in **Figure 2B**. Among the 4 clusters, Cluster 1, consisting of 120 urinary proteins, was increased with IgAN progression, and

the main enrichment pathways included complement and coagulation pathways and *Staphylococcus aureus* infection (**Figure 3A**). Protein–protein interaction (PPI) analysis showed that three pathways are mainly related to complement C3, C5-9, complement lectin pathway (LP), mannan-binding lectin (MBL) and alternative pathway (AP) complement regulatory proteins (**Figure 3B**).

The expression of 194 proteins in Cluster 2 gradually decreased with decreasing eGFR. Further pathway enrichment analysis showed that Cluster 2 was involved in cell adhesion molecules, ECM-receptor interactions, regulation of the actin cytoskeleton and the PI3K-Akt signalling pathway (**Figure 3C**). PPI analysis demonstrated that collagen and fibronectin in these pathways were downregulated (**Figure 3D**).

Both IgAN-1 and pMN patients in this study had similar eGFRs. We compared the urinary proteins of the IgAN1 group with those of the pMN group according to a cut-off value of fold change >1.50 or <0.67 , used to indicate differentially expressed proteins. There were 150 differentially expressed proteins between the IgAN-1 and pMN groups, 107 of which were upregulated. A clustering analysis of 107 proteins revealed that the main enrichment pathways were regulation of actin cytoskeleton, focal adhesion, protein digestion and absorption. PPI analysis showed that structural proteins, such as collagen 4-6, nectin1 and nectin2, were relatively more highly expressed in abundance than pMN. Moreover, as shown in Table S1, 17 urinary proteins showed differential abundances between pMN and IgAN patients (15 proteins were expressed at higher levels in pMN than in IgAN1-3 patients).

3.3 Urinary complement pattern analysis in IgAN and MN patients

Among the 747 proteins identified in urine, 27 were complement proteins. The urinary complements were divided into 5 categories: the classical pathway (C1 s, C1rL, C1qR, C1 inhibitor

SERPING1, C2 and C4), the lectin pathways (MBL, MASP1, MASP2 and Ficolin2), the AP complement regulatory proteins (CFB, CFD, CFH, CFHR2, CFHR4, CFI, DAF and properdin), the membrane attack complex (MAC) in the terminal pathways (C5, C6, C7, C8A, C8B, C8G, C9 and MCP) and C3. The abundance of urinary C3, MAC and complement regulatory proteins was increased during the progression of IgAN. MAC compositions increased most significantly, while the classical pathway proteins did not increase with the progression of IgAN. It was noted that for proteins in the LP of the complement cascade, as eGFR declined, MASP1 and MBL were upregulated, while MASP2 and Ficolin2 were downregulated. The abundance of five categories of urinary complement proteins in IgAN-1 patients was similar to that in pMN patients (**Figure 4, Table 2**).

3.4 Western blot validation of glycosylation-related proteins

Two proteins involved in glycosylation and glycan modifications (alpha-N-acetylglucosaminidase, NAGLU and alpha-galactosidase A, GLA) were further validated by Western blot in another patient group, including IgAN 1-3 and pMN (**Figure 5, Figure S2**). The expression level of NAGLU gradually decreased among IgAN 1-3 patients, and the expression level of NAGLU in IgAN-3 patients was significantly lower than that in IgAN-1 and MN patients ($P < 0.05$). The ratio of NAGLU abundances among IgAN-1, IgAN-2, IgAN-3 and pMN in the MS experiment was 1:0.52:0.48:0.82. This result was consistent with the MS results. GLA also showed gradually decreased expression among IgAN 1-3 patients. This result was also consistent with its decreasing levels in the MS experiment (IgAN-1: IgAN-2: IgAN-3: pMN, 1:0.70:0.52:0.81). GLA also showed different expression between IgAN-3 and pMN patients ($P < 0.05$).

3.5 PRM validation of IgAN markers

To validate the iTRAQ results, 64 urinary samples were collected, including 14 from IgAN-1 (eGFR: > 90 ml/min/1.73 m²), 29 from IgAN-2 (eGFR: 60-90 ml/min/1.73 m²) and 21 from IgAN-3 (eGFR: < 60 ml/min/1.73 m²).

To evaluate LC–MS/MS system stability, a mixture of all urine samples was pooled as quality control (QC) samples. The correlation map of QC samples showed that QC samples were highly positively correlated, with an average Pearson correlation coefficient of 0.966 (**Fig. S3**). The above results showed the good repeatability and stability of the LC–MS/MS platform.

According to PRM analysis, 17 peptides that corresponded to 10 proteins were validated, which showed the same trend as iTRAQ, including 2 upregulated proteins and 8 downregulated proteins (**Figure 6 and Table 3**). Complement Factor B (CFB) and complement component C8 alpha chain (C8A), as complements and related molecules, were verified to be upregulated. Among the downregulated proteins, plasma serine protease inhibitor (SERPINA5), lymphocyte function-associated antigen 3 (CD58) and mucosal addressin cell molecule 1 (MAdCAM1) presented a gradually downward trend with the progression of IgAN, indicating a potential contribution to monitoring the development of IgAN. DANSE2 and AXL were found to only significantly decrease at IgAN-3, which may be associated with kidney injury at the end stage of IgAN.

The diagnostic values of 10 proteins were evaluated using ROC analysis. There were 7 proteins, and 9 showed an AUC > 0.75 compared with IgAN-2 and IgAN-3 with IgAN-1 (**Table 3**). Meanwhile, the combination of CFB and MAdCAM1 showed an AUC of 0.963 (95% CI, 0.856-0.997)/0.915 (95% CI, 0.770-0.982) in distinguishing IgAN-2/3 from IgAN-1 (**Figure 7A and 7B**).

We further analysed whether these potential biomarkers correlated with the clinical test results of IgAN. Spearman's correlation analysis showed that the urinary excretion of CFB and

C8A was negatively correlated with eGFR decline, while the other 8 proteins presented a positive correlation with eGFR. The abundance of C8A, SERPINA5 and AXL also presented a stronger correlation with 24-h urinary protein (24hUP) ($|r| > 0.3$). The 10 candidates, except LRG1, all correlated with blood urea nitrogen (BUN) ($|r| > 0.2$), which indicated the occurrence of kidney injury. Seven of 10 proteins, including CFB, C8A, DNASE2, SERPINA5, AXL, and EGF, were also significantly associated with the evaluation of the MEST-C score ($|r| > 0.2$) and were most significantly correlated with the T-score, which indicated interstitial fibrosis/tubular atrophy (Figure 7C).

4. Discussion

The aim of this study was to evaluate urine proteomics of patients with different stages of IgAN, especially complements and complement-related proteins.

Activation of the complement pathway plays an important role in the pathogenesis of IgAN. Alongside the development of targeted complement inhibitors in glomerular diseases [13], it is necessary to better understand how the complement pathway is involved in IgAN progression. In this study, we found that the urinary complements C3, MAC, and complement regulatory proteins were increased with the progression of IgAN, indicating AP activation in the progression of IgAN.

In a previous urinary proteomic study of healthy individuals, Shao et al. [14] identified 1872 quantifiable proteins by 2D LC-MS/MS with the label-free quantitative method, including 26 of 27 complements reported in our study. In addition, Zhao et al. [15] identified all 27 complements found in our study from pooled urinary samples of healthy individuals using the same proteomic-based technology. In IgAN, IgA is mostly codeposited with C3 in the mesangium. MBL [16], properdin and CFH deposition [17] were also found in the mesangium. A recent proteomic study of microdissected glomeruli from progressive IgAN cases revealed significantly increased MAC

proteins, FHR5 and FHR2, compared with patients with stable clinical status [4]. In our study, 20 urinary complement proteins were found to be consistent with those previously found in the microdissected glomeruli; notably, we found eight differentially expressed proteins of LP and complement regulatory proteins that have not been identified in the microdissected glomeruli of IgAN patients (Table S2).

Previous studies suggested that overactivation of AP-dependent complement amplification could promote the formation of the MAC and lead to kidney injury in IgAN. According to the iTRAQ results, CFH, CFHR2 and CFHR4 were found to have the highest expression in IgAN-3 (CFH: (IgAN1: IgAN2: IgAN3) = 1: 1.14: 2.41; CFHR2: (IgAN1: IgAN2: IgAN3) = 1: 1.25: 3.06, CFHR4: (IgAN1: IgAN2: IgAN3) = 1: 1: 2.41). CFH is the major negative regulator of AP by binding with C3b and inhibiting the formation of C3 convertase, which normally functions to avoid excessive activation of the complement system. The CFHRs were sequentially similar to CFH and could compete with CFH for binding with C3b. These proteins have been studied as potential risk factors for IgAN [18]. Previous studies have reported that high levels of CFHR1, CFHR3 and CFHR5 could increase C3b binding capacity and AP activation, resulting in complement-mediated injury in IgAN [19,20]. Although there are fewer reports on urinary CFHR2 or CFHR4 in IgAN, the functions of these two proteins also indicate the facilitation of complement system activation. In vitro studies have demonstrated that CFHR4 initiates AP activation via the formation of active C3 convertases on CFHR4-bound C3b [21]. Compared with other CFHRs, CFHR2 has a lower affinity to compete with CFH in binding C3b or C3d but can form homologous dimers or heterodimers with CFHR1 and CFHR5 [19]. Complexes of CFHR1, CFHR2 or CFHR5 have been reported to increase the avidity for the ligands C3b, iC3b, and C3dg and enhance competition with complement Factor H (CFH), eventually promoting AP activation on certain surfaces [22,23]. The

significant increase in CFH, CFHR2 and CFHR4 in IgAN-3 may reflect the potential function at the end stage of IgAN.

There have been few studies on changes in serum or urinary LP proteins of the complement cascade in IgAN patients. In this study, we identified four urinary LP proteins in IgAN patients. Unlike MBL and MASP1, urinary MASP-2 and ficolin-2 gradually decreased with IgAN progression. MASP-2 could directly cleave C3 while bypassing the usual sequence to activate C4 and/or C2, therefore playing an important role in the LP activation of the complement system [24]. A pilot study recently showed that nasoplimab, a MASP-2 inhibitor, could reduce proteinuria in IgAN patients and maintain renal function, suggesting that MASP-2 activation may be involved in the pathogenesis of IgAN [25]. The reasons for the downregulation of MASP-2 and ficolin-2 in progressive IgAN patients are not fully understood. A British study compared levels of plasma LP proteins between stable and progressive IgAN patients; specifically, M-ficolin, L-ficolin, MASP1 and MAP19 were increased, but MASP3 was decreased, in progressive IgAN patients, and there was no difference in MASP-2 between IgAN and healthy controls [26]. These changes are thought to be secondary to LP activation, with MASP2 consumption at sites of disease activity. Further studies are required to assess the changes in urinary MASP2 and ficolin-2 in progressive IgAN patients. In this study, the urinary complement profile of pMN patients with eGFR>90 ml/min/1.73 m² was analysed as a control. pMN is caused by autoantibodies that bind to antigens expressed by podocytes. These autoantibodies, which are predominantly of the IgG4 subclass, mainly activate the LP and AP [27]. Therefore, the abundance of urinary complements in pMN patients with normal renal function was similar to that observed in IgAN-1 patients (Fig. 4). Meanwhile, 17 differential urinary proteins between pMN and IgAN were also identified in the discovery phase, and their significance should be further investigated.

The proteins in Cluster 1 were increased with eGFR reduction, indicating that these proteins were closely associated with disease severity in IgAN and could be used as noninvasive biomarkers of disease progression. In Cluster 1, KEGG pathway analysis showed that the complement and coagulation cascade pathways, immune disease pathway, and *Staphylococcus aureus* infection were significantly enriched. A cohort study including 116 IgAN patients and 122 non-IgAN patients revealed that 68% of IgAN patients presented with *Staphylococcus aureus* antigen, while non-IgAN patients had no *Staphylococcus aureus* antigen deposition [28]. Our study revealed that the *Staphylococcus aureus* pathway was significantly activated with IgAN progression and that *Staphylococcus aureus* interacted with MBL, C3, C4 and C5. Recently, a study [29] reported that *Staphylococcus aureus* could activate LP by acting on MBL through the glycol polymer wall containing teichoic acid on its surface.

Cluster 2 proteins were decreased with eGFR progression. Further pathway analysis revealed that the first three enrichment pathways were cell adhesion molecules, focal adhesion and the PI3K-Akt signalling pathway. Mesangial deposition of IgA and ECM expansion have been thought to be the initiating event in IgAN pathogenesis. Our results showed that the PI3K-Akt signalling pathway was significantly enriched at the early stage of IgAN. A gene array study [30] proposed that differentially expressed genes between IgAN patients and healthy volunteers were mainly involved in the PI3K-Akt signalling pathway, which is strongly related to cell proliferation.

As two glycosylation-related enzymes, NAGLU and GLA were also assessed by Western blotting in IgAN 1-3 and MN patients, and the WB results were consistent with those of iTRAQ quantitative proteomics. NAGLU is a type of glycosidase and is involved in the degradation of the polysaccharide heparan sulfate (HS) by removing the terminal N-acetylglucosamine (GlcNac) residue [31]. It has been reported that HS can promote fibrosis in the kidney [32]. The deficiency

of HS in mice was demonstrated to prevent profibrotic crosslinking of extracellular matrix and recruitment of TGF- β 1 [33,34], which was positively correlated with fibrotic area in renal tissue of IgAN patients [35]. Therefore, the decline in NAGLU could result in the accumulation of heparan sulfate (HS) [36] and may contribute to IgAN progression.

Alpha-galactosidase (GLA) is a lysosomal glycosidase and can catalyse the removal of α -linked galactose from oligosaccharides, glycoproteins, and glycolipids during the salvage pathway of galactose [37,38]. In humans, the deficiency of functional GLA could result in the accumulation of galactosylated substrates (Gb3) in tissues, leading to Fabry disease, which is often accompanied by a series of visceral diseases, including renal disease [39]. According to previous reports, IgAN and Fabry disease may coexist [40-42]. However, the definite mechanism of GLA in IgAN is still unknown. The WB results of NAGLU and GLA were consistent with their results based on iTRAQ quantitative proteomics. This is the first study showing the changes in these two proteins in the urine from IgAN patients, although their clinical significance remains to be further explored.

Among the DEPs validated in PRM, the increase in complement Factor B (CFB) and complement component 8 a chain (C8A), consistent with iTRAQ, confirmed the activation of the complement system in IgAN (**Figure 6**). CFB is an essential component of the alternative pathway, providing an active subunit associated with C3b to form the C3 convertase [43]. Previous studies have revealed increasing CFB or complement factor Bb (a fragment of CFB) in the circulation of patients with IMN or IgAN [44]. In our study, CFB exhibited a negative correlation with eGFR but a positive correlation with 24-h urine protein, which supports the association between urinary CFB and AP activation in IgAN progression. C8A, as a component of the MAC, was significantly increased in IgAN-2 and IgAN-3 compared with IgAN-1 in our study (**Figure 6**). The formation of MAC or C5b-9 was reported to induce kidney cell injury, inflammation, and fibrosis [45].

Meanwhile, the efficiency of C5b-9 was also evaluated as a prognostic marker for IgAN. Several studies on C5b-9 deposition demonstrated that almost all IgAN patients showed more intense and diffuse C5b-9 deposition in the glomerulus and tubules than healthy controls [45-47]. Urine-based proteomics studies have also suggested an increase in urinary C5b-9 levels in patients with IgAN. Urinary C5b-9 levels were found to be associated with disease severity and inversely correlated with eGFR [47-49]. The increase in CFB and C8A confirmed that the complement system, including the AP and MAC pathways, could participate in biological processes during the progression of IgAN at the urine level.

The combination of CFB and MAdCAM-1 was found to potentially distinguish IgAN patients at different stages from weaker controls (IgAN-1). MAdCAM-1, as a transmembrane protein with a complex structure, can combine three Ig domains and a mucin-like region between Ig domains 2 and 3. Moreover, there is also an IgA-like Ig domain in the MAdCAM-1 molecule, which could be correlated with its expression in the area where most IgA antibodies are secreted [50]. MAdCAM-1 can regulate both the passage and retention of leukocytes and function in chronically inflamed tissues [51]. Previous studies suggested that the tissue expression of adhesion molecules in IgAN reflects continuous inflammatory renal activity, including vascular cell adhesion molecule 1 (VCAM-1) and intercellular adhesion molecule 1 (ICAM-1) [52,53]. However, few studies have demonstrated the association between MAdCAM-1 and IgAN. A previous study detected soluble MAdCAM-1 in the serum and urine of healthy donors, and the expression levels of MAdCAM-1 were similar to those of CAM, ICAM-1, and VCAM-1 [54]. The deficiency of MAdCAM-1 in urine should be further studied for its potential diagnostic ability in the progression of IgAN.

After removing 14 highly abundant proteins in samples prior to quantitative proteomic analysis, this study identified abundant complements and complement-related proteins in the urine

of IgAN patients with different CKD stages. To our knowledge, this is the first study to identify an abundance of complements in the urine of IgAN patients. This is also the first study to demonstrate alterations in urinary complements of AP and LP, and among the complements, the major component involved in IgAN progression was MAC.

There are several limitations of this study. First, this study was a single-centre study with a limited number of patients. Thus, a large-scale analysis, including healthy controls, IgAN patients and patients with other related chronic kidney diseases, will be more comprehensive to confirm the conclusions. Second, although CFB and C8A were validated by PRM, more related complements, such as CFHR2 and CFHR4, should also be validated. IHC validations in IgAN tissues were necessary to validate the conclusions. Third, a study on the function and mechanism of the potential biomarkers for IgAN should be provided as well.

In conclusion, complement components were found in IgAN urine and increased with the progression of IgAN. These findings indicated that the urine proteome may reflect the changes in IgAN. In addition, a combination of CFB and MAdCAM-1 may be used as a potential urinary biomarker for monitoring the development of IgAN. The findings of our study provide useful information for future IgAN research and improve the understanding of the pathogenesis of IgAN.

Declarations

➤ Ethics approval and consent to participants

The research was conducted ethically in accordance with the World Medical Association Declaration of Helsinki. Patients have given their written informed consent. The study protocol has been approved by the Ethics Committee of Peking Union Medical College Hospital (Ethics approval number: JS-2573).

➤ Consent for publication

Not applicable.

➤ Availability of data and materials

All relevant data and its supplementary information files are included in the article. Besides, the raw data for LC-MS/MS analysis can be download from Figshare online (details showed at the supplemental files: 10.6084/m9.figshare.21685898, 21687299, 21688946, 21688979 and 21689000).

➤ Competing interests

The authors have no conflicts of interest to declare.

➤ Funding

This work was supported by the National Natural Science Foundation of China (No. 31200614), the Beijing Municipal Science and Technology Project (D181100000118004), Youth Fund of Peking Union Medical College Hospital (pumch201912152). The funders participated in the study design, while had no role in data collection and analysis, decision to publish, or preparation of the manuscript.

➤ Authors' contributions

Xia Niu analyzed PRM analysis, and wrote the draft manuscript. Shuyu Zhang analyzed clinical

data, performed statistical analysis, and wrote the draft manuscript. Jianqiang Wu performed the proteomic and western blot analysis. Jianling Tao participated in the study design and helped with drafting of the manuscript. Wenling Ye reviewed the pathological diagnosis. Chen Shao directed the study design. Guangyan Cai and Ke Zheng participated in the study design and coordination. Mingxi Li conceived the study, participated in its design, and helped with drafting of the manuscript. All authors read and approved the final manuscript.

Appendix

➤ Figure Legends

Fig.1. The workflow of differential urinary proteome analysis and western blot validation.

Fig.2. Hierarchical clustering analysis of 747 urinary proteins from 4 pooled samples. A: Heatmap of urinary proteins in IgAN subgroups and pMN group (two technical replicates). B: Mfuzz analysis of urinary proteins among IgAN subgroups.

Fig.3. Functional analysis of urinary proteins in cluster 1 and cluster 2 of IgAN patients. (A) KEGG pathway enrichment analysis of proteins in cluster 1. (B) Protein-protein interaction (PPI) networks were created for cluster-1 proteins. (C) KEGG pathway enrichment analysis of proteins in cluster 2. (D) PPI networks were created for cluster 2 proteins.

Fig.4. Comparison of urinary complements in IgAN 1-3 and pMN patients.

Fig.5. Western blotting validation of NAGLU and GLA in another patient cohort.

Fig.6. The PRM results of validated differential proteins.

Fig.7. The analysis of PRM results. (A) Receiver operating characteristic (ROC) analysis of IgAN-2 and IgAN-1; (B) ROC curve analysis of IgAN-3 and IgAN-1. (C) Heatmap of correlations between PRM results and clinical tests.

➤ Tables

Table 1. Clinical and histopathological characteristics of patients enrolled in discovery and validation phases.

Table 2. The relative abundance of all urinary complements in IgAN 1-3 and pMN patients.

Table 3. Validation proteins by parallel reaction monitoring.

➤ **Supplementary Materials**

Supplemental Table 1. Identification and quantitation details of urinary proteins in IgAN and pMN patients.

Supplemental Table 2. Differential complements between glomeruli and urine of IgAN patients.

Supplemental Figure 1. Functional analysis of urinary proteins upregulated in IgAN-1 patients compared to pMN patients. (A)KEGG pathway enrichment analysis of 107 upregulated proteins in IgAN-1 compared to pMN. (B)The PPI networks were created for 107 upregulated proteins in IgAN-1 compared to pMN.

Supplemental Figure 2. The raw image of western blotting of NAGLU and GLA in another patient cohort.

Supplemental Figure 3. Correlation of QC samples in PRM.

Figure 1

The workflow of differential urinary proteome analysis, western blotting and parallel reaction monitoring validation.

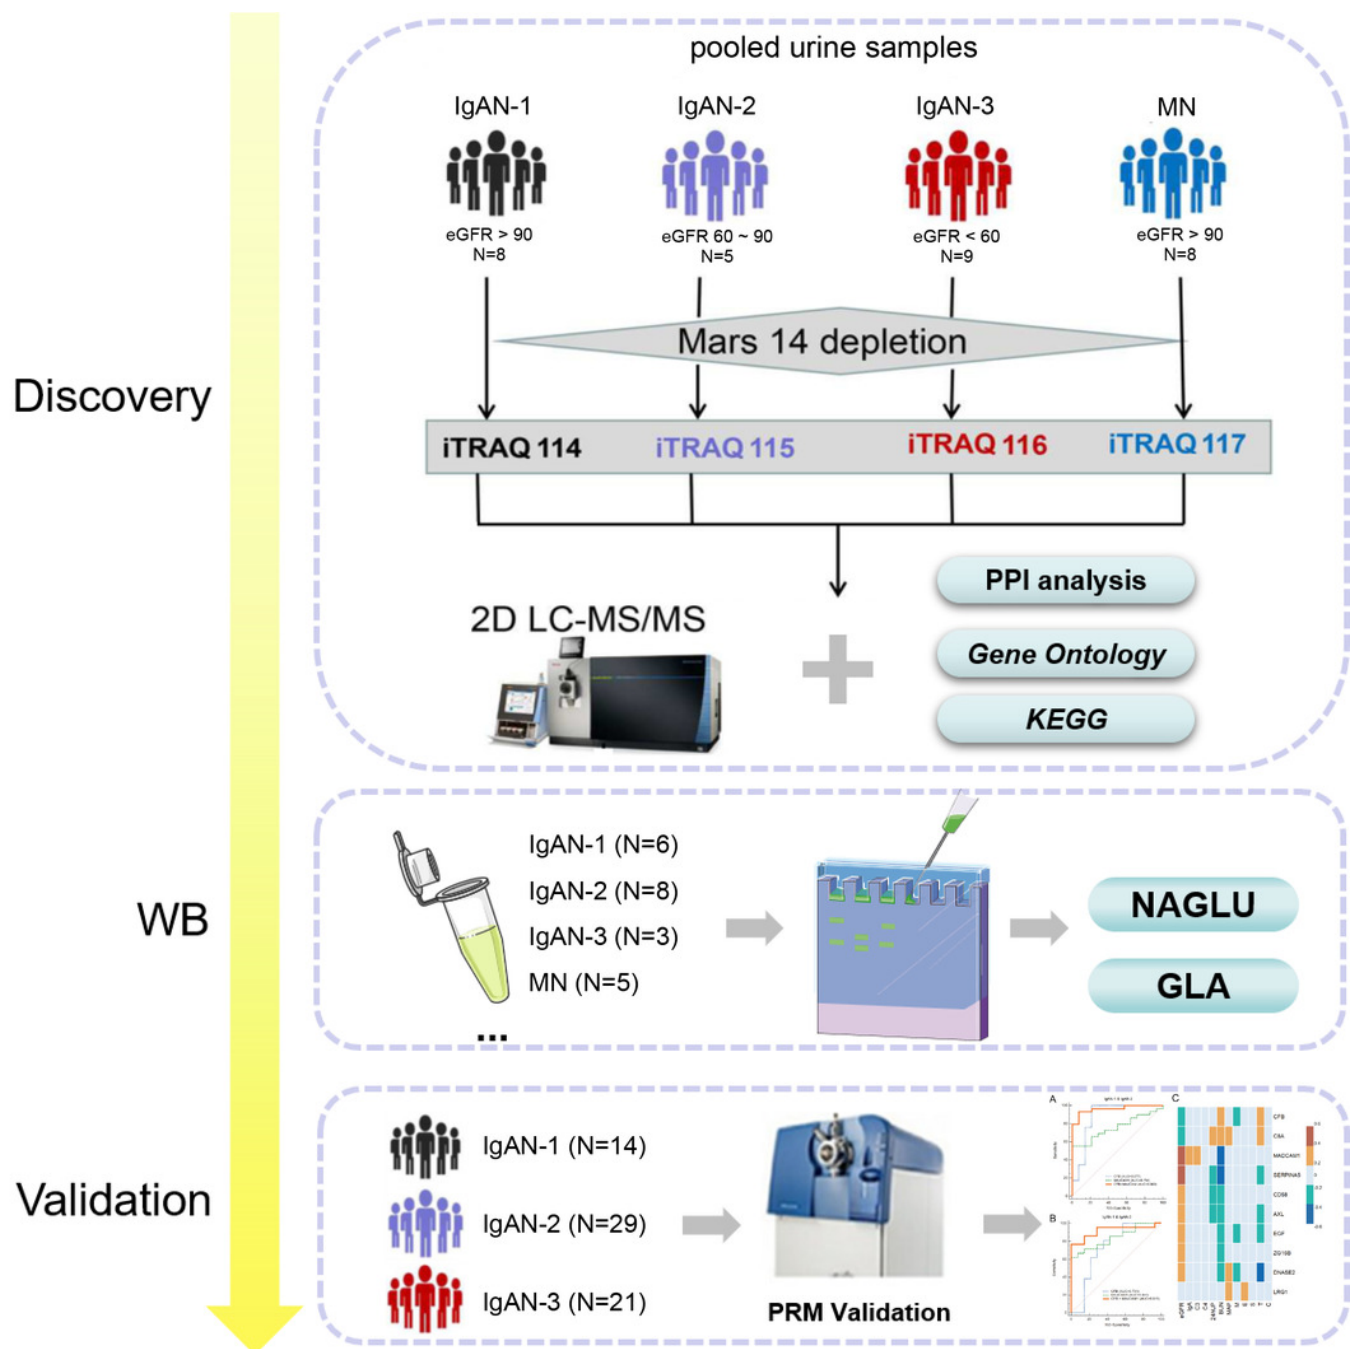

Figure 2

Hierarchical clustering analysis of 747 urinary proteins from 4 pooled samples.

(A) Heatmap of urinary proteins in IgAN subgroups and pMN group (two technical replicates). The color bar from orange to blue represented the fold change from increasing to decreasing of the proteins in four groups. **(B)** Mfuzz analysis of urinary proteins among IgAN subgroups. Proteins in cluster1 were increased with IgAN progression; Proteins in cluster2 were decreased with IgAN progression; Proteins cluster3(n=142) and Cluster4(n=291) showed no gradual changes with IgAN progression. Color bar represented Z-score change from -2 to 2.

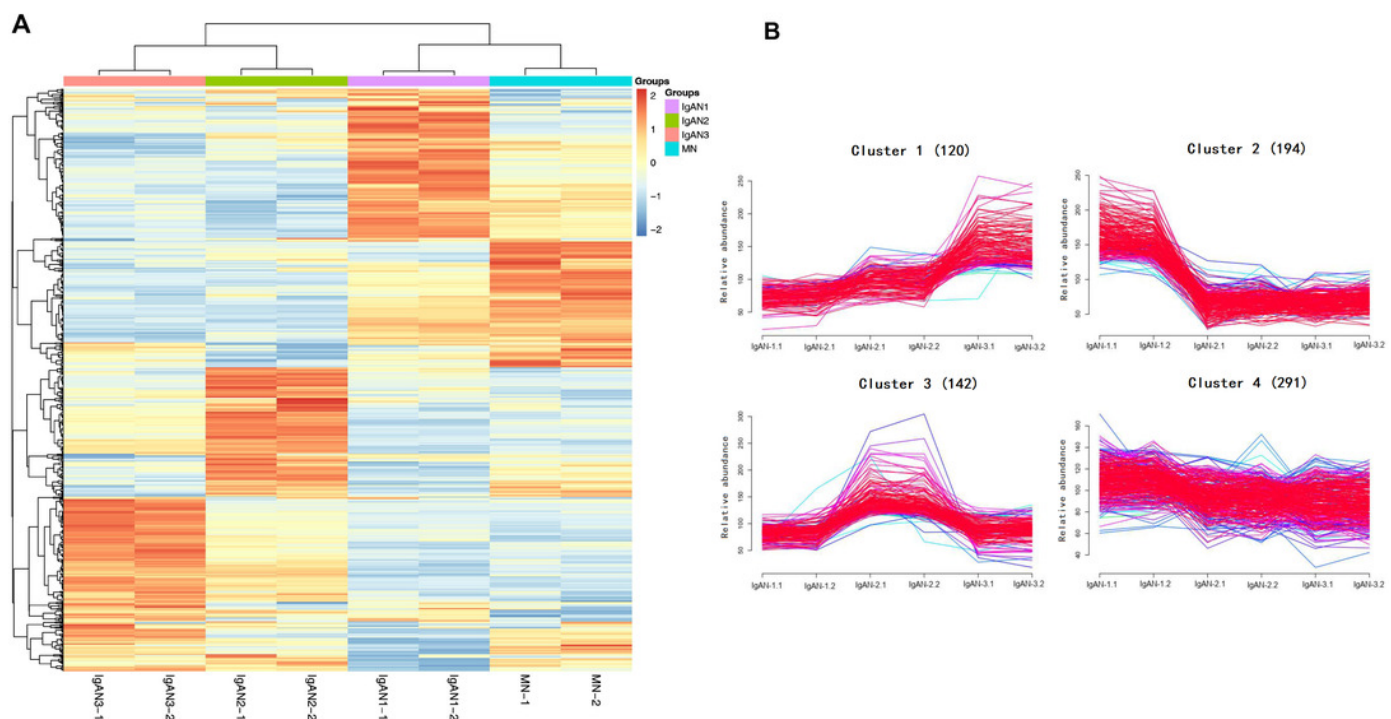

Figure 3

Functional analysis of urinary proteins in cluster 1 and cluster 2 of IgAN patients.

(A) KEGG pathway enrichment analysis of proteins in cluster 1. **(B)** Protein-protein interaction (PPI) networks were created for cluster 1 proteins. **(C)** KEGG pathway enrichment analysis of proteins in cluster 2. **(D)** PPI networks were created for cluster 2 proteins. In the KEGG enrichment analysis, the abscissa represented the percent of corresponding genes under each pathway classification (p value was noted in the bracket). The ordinate represented enrichment pathway. In the protein interaction networks, circle nodes represented for genes/proteins, rectangle for KEGG pathways. Green solid lines represented inhibition; red solid lines represented activation; blue dotted lines represented KEGG pathways. The significance of the pathways represented by $-\log(p \text{ value})$ was shown by color bar with dark blue as the most significant. The color of circle nodes from red to green represented the fold change from increasing to decreasing of the proteins.

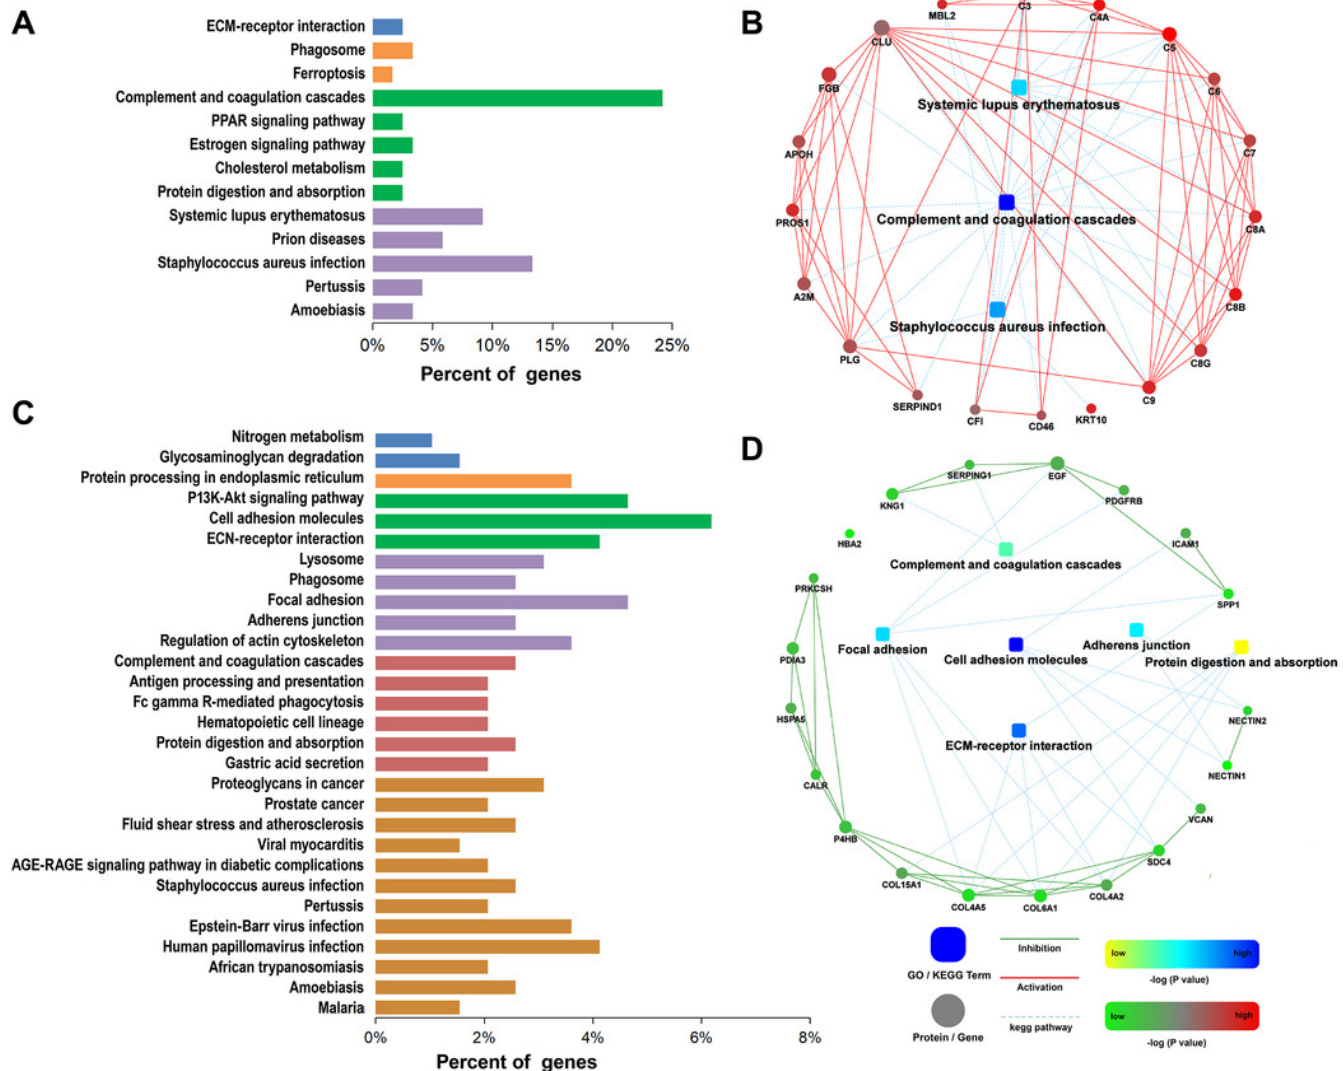

Figure 4

Comparison of urinary complements in IgAN 1-3 and pMN patients.

CP: Classical pathway; LP: Lectin pathway; AP: Alternative pathway; MAC: Membrane attack complex.

Figure 5

Western blotting validation of NAGLU and GLA in another patient cohort.

In the WB experiments, equal amount of urine protein from each individual sample was loaded. The validation set included IgAN-1 (n=6), IgAN-2 (n=8), IgAN-3 (n=3) and pMN (n=5) patients. Means and standard deviations were represented in the figure, and a nonparametric test were used to analysis the data. *Indicates a p value < 0.05.

Figure 6

The PRM results of validated differential proteins.

IgAN-1: eGFR > 90 ml/min/1.73m², IgAN-2: eGFR: 60-90 ml/min/1.73m², IgAN-3: eGFR: 30-60 ml/min/1.73m². CFB, complement factor B; C8A, complement component C8 alpha chain; SERPINA5, plasma serine protease inhibitor; CD58, lymphocyte function-associated antigen 3; MADCAM1, mucosal addressin cell adhesion molecule 1; AXL, tyrosine-protein kinase receptor UFO; ZG16B, zymogen granule protein 16 homolog B; EGF, pro-epidermal growth factor; DNASE2, deoxyribonuclease-2-alpha; LRG1, leucine-rich alpha-2-glycoprotein.

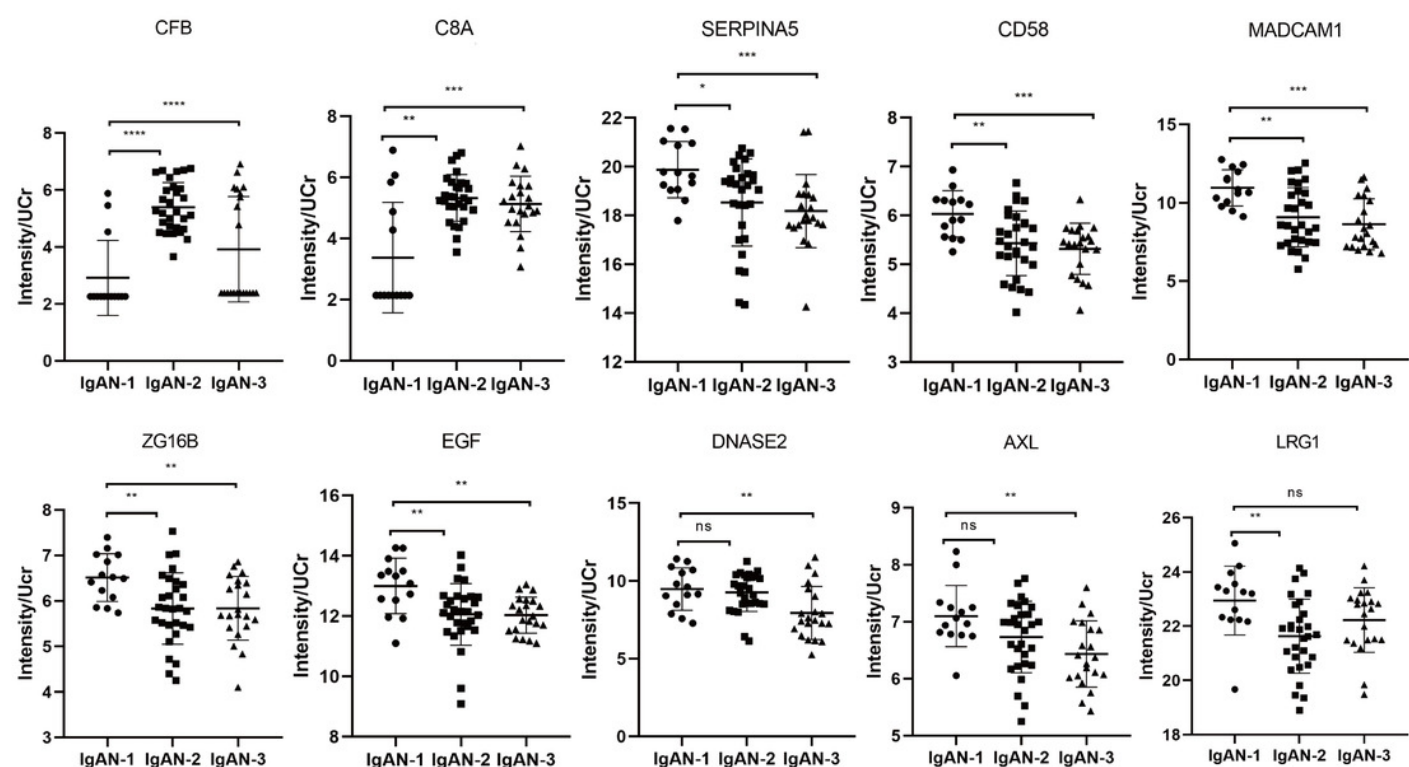

Figure 7

The analysis of PRM results.

(A) Receiver operating characteristic (ROC) analysis of IgAN-2 and IgAN-1; **(B)** ROC curve analysis of IgAN-3 and IgAN-1; **(C)** Heatmap of correlations between PRM results and clinical tests. eGFR, estimated glomerular filtration rate; C3: complement component 3; C4: complement component 4; 24hUP: 24-hours urinary protein; BUN, blood urine nitrogen; MAP, mean arterial pressure; M, mesangial hypercellularity; E, endocapillary cellularity; S, segmental sclerosis; T, interstitial fibrosis/tubular atrophy; C, crescents.

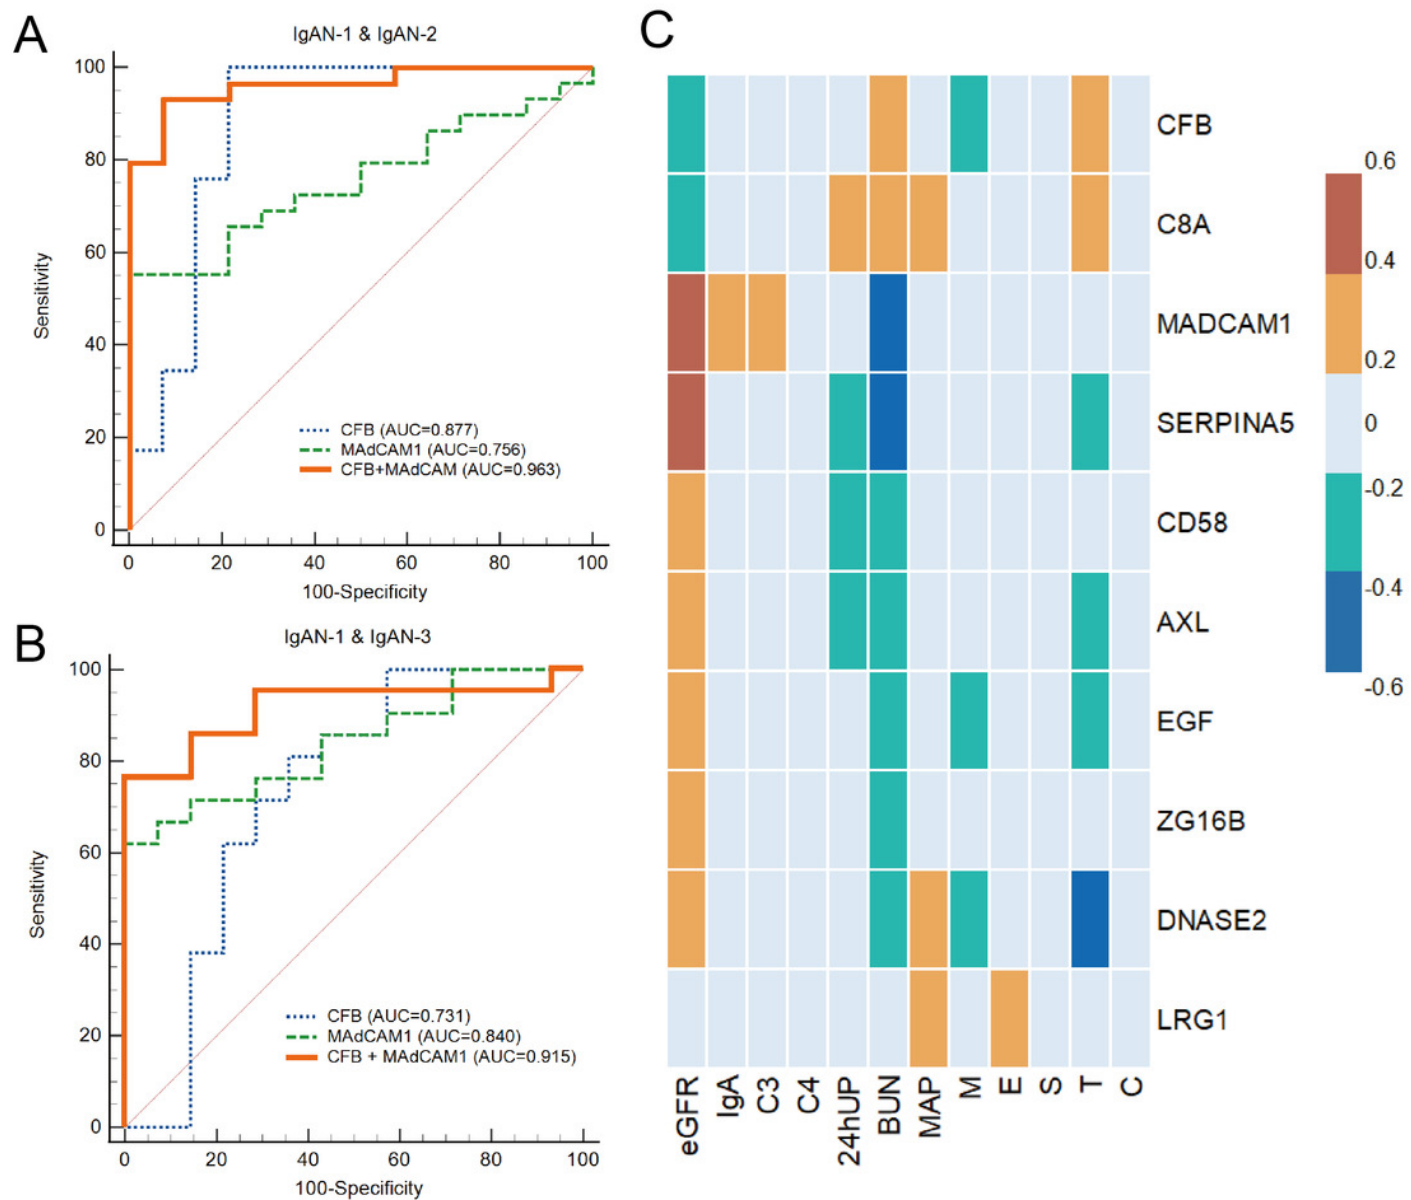

Table 1 (on next page)

Clinical and histopathological characteristics of patients in discovery and validation phase.

N: number; 24 h UP: 24 hr urinary protein; SCr: serum creatinine; C3: complement 3; C4: complement 4. The five pathological variables in Oxford classification were scored as follow: mesangial score ≤ 0.5 (M0) or ≥ 0.5 (M1), endocapillary hypercellularity absence (E0) or presence (E1), segmental glomerulosclerotic absence (S0) or presence (S1), tubular atrophy/interstitial fibrosis $\leq 25\%$ (T0) or $>25\%$ (T1+T2), crescent absence (C0) or presence (C1+C2). Pa < 0.05 indicated comparison with IgAN-1; Pb < 0.05 indicated comparison with IgAN-2; Pc < 0.05 indicated comparison with IgAN-3.

Group	N	Gender (M/F)	Age (year)	24 h UP (g)	SCr (mmol/L)	eGFR (ml/min/1.73m ²)	C3 (g/L)	C4 (g/L)	Histopathological Characteristic
