ABSTRACT

Background. *Bupleuri Radix* (Chaihu) is a famous traditional Chinese medicine derived from *Bupleurum*, Apiaceae. The origin of cultivated Chaihu germplasm in China is unclear, which has led to unstable Chaihu quality. In this study, we reconstructed the phylogeny of the main Chaihu germplasm species in China and identified potential molecular markers to authenticate its origin.

Methods. Three *Bupleurum* species (eight individuals), *B. bicaule*, *B. chinense*, and *B. scorzonerifolium*, were selected for genome skimming. Published genomes from *B. falcatum* and *B. marginatum* var. *stenophyllum* were used for comparative analysis.

Results. Sequences of the complete plastid genomes were conserved with 113 identical genes ranging from 155,540 to 155,866 bp in length. Phylogenetic reconstruction based on complete plastid genomes resolved intrageneric relationships of the five *Bupleurum* species with high support. Conflicts between the plastid and nuclear phylogenies were observed, which were mainly ascribed to introgressive hybridization. Comparative analysis showed that noncoding regions of the plastomes had most of the variable sequences. Eight regions (*atpF-atpH*, *petN-psbM*, *rps16-psbK*, *petA-psbJ*, *ndhC-trnV/UAC* and *ycf1*) had high divergence values in *Bupleurum* species and could be promising DNA barcodes for Chaihu authentication. A total of seven polymorphic cpSSRs and 438 polymorphic nSSRs were detected across the five Chaihu germplasms. Three photosynthesis-related genes were under positive selection, of which *accD* reflected the adaptation fingerprint of *B. chinense* to different ecological habitats. Our study provides valuable genetic information for phylogenetic investigation, germplasm authentication, and molecular breeding of Chaihu species.

INTRODUCTION

Bupleuri Radix (Chinese name: Chaihu), the dried root of *Bupleurum* species, has been used to treat cold, fevers, influenza, menstrual disorders, and hepatitis for more than 2,000 years (Yang et al., 2017; Zhu et al., 2017). Its primary use is as the main constituent of Chinese medicine prescriptions for soothing the liver and relieving depression, such as the Xiaochaihu Decoction, Chaihu Liver-soothing Powder, and Xiaoyao Pill (Yang et al.,

OPEN ACCESS

2017; Zhu et al., 2017). *Bupleurum chinense* DC. and *B. scorzonerifolium* Willd. have been authenticated as the official botanical origin of Chaihu in the Chinese Pharmacopoeia (National Pharmacopoeia Committee, 2020), and are referred to as “Bei Chaihu” and “Nan Chaihu”, respectively. More than 20 *Bupleurum* species are habitually utilized as Chaihu due to their morphological similarity (Pan et al., 2002). As one of the most popular medicines in China, the demand for Chaihu in prescriptions and exports is enormous, while the supply of wild *Bupleurum* herb is limited. Artificial planting of Chaihu has become the dominant agriculture industry in some regions, such as the Chencang district in Shaanxi Province (Ma et al., 2020). However, the use of multiple *Bupleurum* species in different districts has also contributed to the complexity and diversity of cultivated Chaihu germplasms.

Based on plantation surveys, the cultivated germplasms of Chaihu in China are mainly from five species, *B. bicaule* Helm, *B. chinense*, *B. falcatum* L., *B. marginatum* var. *stenophyllum* (Wolff) Shan et Y. Li, and *B. scorzonerifolium* (Xu et al., 2014; Zhang et al., 2021; Zhang et al., 2022). Among these species, *B. chinense* is the most common species cultivated in China (Ma et al., 2020; Zhang et al., 2021). As a widespread species, *B. chinense* exhibits broad intraspecific morphological variation and different levels of medicinal quality under different growing conditions. The unclear origins of wild and cultivated Chaihu resources result in somewhat unstable Chaihu qualities in the Chinese market. Previous studies have greatly improved our understanding of *Bupleurum* based on morphology (Pan et al., 2002; Sheh & Watson, 2005), chromosome counts (Ma et al., 2015), nuclear ribosomal internal transcribed spacer (nrITS) (Chao et al., 2014; Neves & Watson, 2004; Xie et al., 2009), and plastid DNA markers (Wang et al., 2008; Wang, Ma & He, 2011). However, because of limited genetic information, relationships among some closely related species could not be fully resolved, such as *B. bicaule* and *B. scorzonerifolium*.

With the development of high-throughput sequencing technologies, genetic information from both nuclear and organellar DNA has provided an opportunity for addressing problems that have remained unresolved using traditional molecular systematics approaches (Liu et al., 2021a; Liu et al., 2021b). Chloroplast, the plant organelle for photosynthesis and carbon fixation, provides valuable genetic information for phylogenies of plants due to its low nucleotide substitution rates and uniparental inheritance (Davis, Xi & Mathews, 2014; Delsuc, Brinkmann & Philippe, 2005; Thode, Lohmann & Sanmartín, 2020). Compared to plastid barcodes, whole-plastome sequences could generate higher phylogenetic resolution and improve species identification (Fu et al., 2022; Meng et al., 2021; Wikström, Bremer & Rydin, 2020). Considering conflicts between chloroplast and nuclear phylogenies, complementary phylogenetic trees inferred with different datasets are necessary (Meng et al., 2021). Some regions of the nrDNA repeat, like ITS are widely used as phylogenetic markers for lower-level plant identification (Baldwin et al., 1995; Liu et al., 2021a; Liu et al., 2021b; Yao et al., 2010). Genome skimming, which relies on next generation sequencing, is a kind of shallow genome sequencing that could capture the plastome, nuclear repeat, and mitogenome regions (Dodsworth, 2015). Benefitting from abundant datasets and cost-efficiency, genome skimming has been used successfully in

phylogenetic reconstruction at various levels, especially for taxonomically complex groups (Dodsworth, 2015; Straub et al., 2012).

In this study, we used the genome skimming approach to obtain the complete chloroplast genomes and nrDNA of *B. bicaule*, *B. chinense*, and *B. scorzonerifolium*, together with published genomes of two other *Bupleurum* species for comparative analysis. We aimed to: (1) explore the phylogenetic relationships of the five *Bupleurum* species that are the germplasm sources for Chaihu in China; and (2) select potential markers for authentication of Chaihu germplasm by comparative analysis. This study will provide valuable genetic information and potential markers for authentication of cultivated *Bupleurum* species, which will be helpful for cultivation and quality control of Chaihu.

MATERIALS & METHODS

Sample material

Three wild *Bupleurum* species, *B. bicaule* (one, BB01), *B. chinense* (five, BC01-05), and *B. scorzonerifolium* (two, BS01-02) were collected from different districts in China (Table 1). Field experiments were approved by the Research Council of Xianyang Normal University (project number: 2019012). Fresh and healthy leaves were dried with silica gel, and then stored at -80°C for DNA extraction. All species were authenticated by Director Xue Li (Xianyang Food and Drug Administration) and deposited at the Herbarium of Xianyang Normal University (<http://www.xysfxy.cn/>) accession Nos. XSYH202000101-XSYH202000801 (Table S1). Sampling information is shown in Table 1. To obtain the sequences of *B. falcatum* and *B. marginatum* var. *stenophyllum* for a broader comparison, we retrieved their raw sequenced reads from GenBank (*B. falcatum*, BF01: [SRR12513791](#) and *B. marginatum* var. *stenophyllum*, BM01: [SRR13195839](#)), and used them for genome assembly and annotation as with the accessions sequenced in the study.

DNA extraction and sequencing

Total DNA was extracted using the CTAB method. Then, the extracted DNA (about 1 μg) was randomly sheared by Covaris (Brighton, UK), yielding fragments with an average size of 200–400 bp for library construction. Genome skimming sequencing was performed on the BGISEQ-500 platform with paired-end runs (BGI, Shenzhen, China).

Genome assembly and annotation

High-throughput sequencing produced approximately 2 Gb raw data per sample. Raw reads were filtered and then assembled *de novo* into contigs using SOAPdenovo2 (Luo et al., 2012). To isolate plastid sequences, the generated contigs were pooled and mapped to the reference plastome (*B. chinense*: [MN337347](#)) using Bowtie2 (Langmead & Salzberg, 2012), then assembled to scaffolds by SPAdes v.3.11.1 (Bankevich et al., 2012). Geneious Prime (Kearse et al., 2012) was used to align the scaffolds with the aforementioned reference, resulting in the final plastid genomes. Annotation of the assembled sequences was also performed in Geneious Prime with *B. chinense* ([MN337347](#)) as a reference. All plastomes were deposited in GenBank with the accession numbers shown in Table S1.

Comparative analysis and sequence divergence analysis

For comparative analysis, MAFFT v.7 (Kato et al., 2002) was used to align the plastomes of *Bupleurum* individuals. The nucleotide substitution numbers and sequence identities of *Bupleurum* plastomes were calculated with Geneious Prime. The IR expansion/contraction of five *Bupleurum* species was tested by comparing the IR borders and neighboring genes of ten chloroplast genomes using an IRscope online program (Amiryousefi, Hyvönen & Poczai, 2018). To detect and characterize the divergence hotspots, mVISTA (Frazer et al., 2004) was used to compare the complete plastid genomes of five *Bupleurum* species with *B. chinense* (BC01) as a reference. The nucleotide diversity (P_i) among the plastid genome sequences was calculated using sliding window analysis in DnaSP v.5 (Librado & Rozas, 2009). The window size was 600 bp, and the step size was 200 bp. The single nucleotide polymorphisms (SNPs) and insertions-deletions (InDels) were identified using MEGA v.6 (Kumar et al., 2018) and visualized using Circos 0.64 (Krzywinski et al., 2009).

Simple sequence repeats in the chloroplast genome sequences (cpSSRs) were identified via Perl script in MISA (Thiel et al., 2003) with respective thresholds of 10, 5, 4, 3, 3, 3 for mono-, di-, tri-, tetra-, penta-, and hexanucleotides. The candidate polymorphic cpSSRs and nuclear SSRs (nSSRs) were identified using CandiSSR (Xia et al., 2016). The nuclear contigs were used to generate nSSRs by removing the plastid and mitochondrial contigs from the original contigs using Bowtie2 with *B. chinense* as a reference (GenBank accession numbers MN337347 and OK166971 for chloroplast and mitochondrial genomes, respectively). The parameters implemented in CandiSSR were as follows: flanking sequence length of 100, blast e-value cutoff of $1e^{-10}$, BLAST identity cutoff of 95, and BLAST coverage cutoff of 95.

Gene selective pressure analysis

To detect whether plastid genes were under selection pressure, the ratio of the non-synonymous (K_a) to the synonymous substitution rate (K_s) was calculated for all protein-coding genes by DnaSP. Genes were considered to undergo positive selection when the value of K_a/K_s was higher than 1, while $K_a/K_s < 1$ indicated that the genes were under neutral selection (Yang & Nielsen, 2002).

Phylogenetic analysis

For phylogenetic inference, maximum likelihood (ML) and Bayesian inference (BI) analyses were performed for three different datasets: (1) complete plastome sequences, (2) all shared protein-coding sequences (CDS), and (3) nrDNA sequence data (ITS). For phylogenetic analysis based on plastid data, we selected 32 plastid genomes, including eight accessions of three species we sequenced, two accessions (MT797174 and MT075712) we reassembled and reannotated, 20 *Bupleurum* accessions retrieved from NCBI, together with two accessions as outgroups (*Chamaesium paradoxum* MK780227, *Pleurospermum rivulorum* MW147504).

To obtain nrDNA data, the original contigs of the accessions studied in the plastid phylogeny were mapped to the ITS sequence of *B. chinense* (MH710800) and extracted by Bowtie2. The species used in the plastid and nrDNA datasets were kept largely consistent.

For species without nrDNA data, the ITS sequences were downloaded according to Wang, Ma & He (2011). Finally, 49 nrITS sequences of *Bupleurum* accessions, together with *Pleurospermum hookeri* var. *thomsonii* HQ824799 and *P. rivulorum* HQ824798, were selected for the phylogenetic reconstruction.

The software jModelTest v.2.1.4 (Posada, 2008) was used to determine the best-fit nucleotide substitution model, resulting in GTR+I+G for the plastid datasets and GTR+G for the nrITS data under the Akaike Information Criterion (AIC). ML analyses were conducted using RAxML v.8.2.11 (Stamatakis, 2014) with 1,000 bootstrap iterations. BI analyses were performed in MrBayes v.3.2.6 (Ronquist & Huelsenbeck, 2003). Four Markov chains starting with a random tree were run simultaneously for 5,000,000 generations, followed by a sampling point at every 1,000 generations. The resulting trees were visualized using FigTree v.1.4.4 (Rambaut, 2018). Bootstrap support (BS) value and posterior probability (PP) were used to evaluate the feasibility of each branch for ML and BI, respectively.

RESULTS

Chloroplast genome structure and characteristics analyses

Plastid sequences were successfully assembled for ten accessions, of which *B. falcatum* (MT797174, BF01) and *B. marginatum* var. *stenophyllum* (MT075712, BM01) were reassembled. For *Bupleurum* species sequenced in this study, the complete plastomes ranged from 155,540 bp in BC04 to 155,866 bp in BB01. Sequences of the *B. chinense* plastomes ranged from 155,540 bp to 155,659 bp, while those from *B. scorzonrifolium* ranged from 155,828 bp to 155,848 bp. All chloroplast genomes exhibited a typical quadripartite structure, consisting of a large single-copy (LSC) region (85,426–85,630 bp) and a small single-copy (SSC) region (17,492–17,602 bp) separated by two inverted regions (IRs, each with 26,289–26,326 bp) (Table 1, Fig. 1). The overall GC content of each plastome was 37.7%, whereas the GC contents in the LSC, SSC, and IR were 35.8%, 31.3–31.4%, and 42.8%, respectively.

Each *Bupleurum* chloroplast genome encoded a total of 132 genes, of which 113 were unique, containing 79 protein-coding genes (CDS), 30 transfer RNA genes (tRNA), and four ribosomal RNA genes (rRNA). The different functional genes were divided into three categories, namely self-replication, photosynthesis, and other (Table S2). A total of 19 genes were duplicated in the IRs, including six CDSs (*rps* 12, *rps* 7, *ndh* B, *ycf* 2, *rpl* 23, and *rpl* 2), seven tRNAs (*trn* N-GUU, *trn* R-ACG, *trn* A-UGC, *trn* I-GAU, *trn* V-GAC, *trn* L-CAA, and *trn* I-CAU), four rRNAs (*rrn* 4.5, *rrn* 5, *rrn* 23, and *rrn* 16), and two pseudogenes (*ycf* 1 and *rps* 19) with incomplete copies. The *rps* 12 gene was a particular trans-splicing gene with the 5'-end exon located in the LSC region, while two copies of the 3'-end exon were situated in the IR. There were 18 genes containing introns, including six tRNAs and 12 CDSs. Among these, *ycf* 3, *clp* P, and *rps* 12 had two introns. The gene *trn* K-UUU had the largest intron with 2,531 bp, where the *mat* K gene was located.

Figure 1 An overview of gene distribution and genome variation among *Bupleurum* plastomes using Circos. Genes located outside and inside of the outer layer circle represent clockwise and counterclockwise transcription, respectively. The inner circles exhibit the SNPs and InDels every 600 bp across five *Bupleurum* species with *B. chinense* (BC01) as a reference. The histograms of SNPs are outside the circles, while the histograms of InDels are inside the circles.

Full-size DOI: 10.7717/peerj.15157/fig-1

Comparisons of the *Bupleurum* plastomes

Differences and evolutionary divergences were tested based on ten *Bupleurum* plastomes, including five *B. chinense*, two *B. scorzonerifolium*, one *B. bicaule*, one *B. falcatum*, and one *B. marginatum* var. *stenophyllum*. The ten *Bupleurum* plastomes exhibited a high level of sequence similarity and structure (Table 2). The percentage of identity was 96.72–99.97%, with 49–5,160 nucleotide differences. Among *B. chinense* plastomes, the identity narrowly ranged from 99.4% to 99.81%. At the interspecies level, *B. chinense* (BC01) and *B. marginatum* var. *stenophyllum* (BM01) exhibited the most significant sequence difference with 96.72% identity (Table 2).

To further observe the contraction and expansion of IR, the exact IR border positions and their adjacent genes among the *Bupleurum* plastomes were compared (Fig. 2). Genes *rps* 19, *rpl* 2, and *trn* H were in the junctions of LSC/IR, while *ycf* 1, *ndh* F, and *trn* N flanked the junctions of SSC/IR. Genes in the junction regions were the same length, except the *ycf* 1 gene, which ranged from 5,483 bp to 5,490 bp. In all ten *Bupleurum* plastomes, *rps* 19 crossed the LSC/IRb region with 279 bp in length, of which 70 bp occurred in the

Table 2 Numbers of nucleotide substitutions (upper) and sequence identity (lower) in ten plastomes of five *Bupleurum* species.

IRb region. The pseudogene fragment of *rps* 19 was located aside the IRa/LSC junction with 70 bp. The *rpl* 2 gene was separated from the LSC/IRb junction with 126–127 bp in *B. chinense*; 127 bp in *B. bicaule*, *B. falcatum*, and *B. scorzonifolium*; and 130 bp in *B. marginatum* var. *stenophyllum*. The *trn* H gene was 4 bp away from the IRa/LSC region in all ten *Bupleurum* plastomes. In the SSC/IR junctions, *ycf* 1 crossed the SSC/IRa junction, and the pseudogene fragment narrowly ranged from 1,876–1,877 bp in IRb. The length of the *ycf* 1 gene was 5,484 bp in *B. chinense* and *B. falcatum*, while it was 5,483 bp in *B. bicaule* and *B. scorzonifolium*, and 5,490 bp in *B. marginatum* var. *stenophyllum*. The *ndh* F gene was 26–34 bp away from the IRb/SSC junction, and the *trn* N gene was 2,204–2,228 bp away from the SSC/IRa junction.

Sequence variation analysis

Abundant polymorphic sites were observed among the five *Bupleurum* species. In addition, *B. chinense* sequences also exhibited intraspecies divergence. With *B. chinense* (BC01) as a reference, the mVISTA result indicated that noncoding sequences exhibited a higher level of divergence than CDS, and most of the sequences were situated in the LSC and SSC regions (Fig. 3). We characterized genomic polymorphisms of the *Bupleurum* plastomes, including SNPs and InDel-variable loci (Fig. 1, Table S3). At the interspecies level, the number of SNPs varied from 420 (BF01 vs. BC01) to 2,091 (BM01 vs. BC01), and the InDel loci varied from 163 (BF01 vs. BC01) to 340 (BM01 vs. BC01). At the intraspecies level, the numbers of SNPs and InDels among *B. chinense* plastomes ranged from 70–303 and 39–114, respectively. The LSC regions harbored the largest number of genomic polymorphism sites, followed by SSC regions (Fig. 4). The IRs were conserved among *Bupleurum* species. The nucleotide diversity (P_i) of the chloroplast genomes was calculated to assess the sequence divergence level. Among all ten *Bupleurum* species, *atp* F-*atp* H, *pet* N-*psb* M, *rps* 16-*psb* K, *pet* A-*psb* J, *ndh* C-*trn* V/UAC, and *ycf* 1 had relatively higher divergence values ($P_i > 0.015$). Chloroplast genome diversity at the intraspecies level of *B. chinense* was also detected, of which *rps* 16 intron, *ccs* A-*ndh* D, *rbc* L-*acc* D, *rps* 16-*psb* K, and *ndh* C-*trn* V/UAC had high P_i values.

Figure 2 Comparison of the IR border regions among the ten plastid genomes of five *Bupleurum* species.

Full-size DOI: [10.7717/peerj.15157/fig-2](https://doi.org/10.7717/peerj.15157/fig-2)

Simple sequence repeats (SSRs) analysis showed that the total number of cpSSR loci in plastomes ranged from 57 (BC05) to 81 (BM01) (Fig. 5A, Table S4). As shown in Fig. 5A, the SSRs were mainly located in the intergenic spacer (IGS), followed by CDS and intron regions. Monomers were the primary type, accounting for 60–68.9% of the SSRs in ten *Bupleurum* plastomes. As the patterns of SSR distribution were similar among the ten *Bupleurum* plastomes, BC01 was chosen as an example to exhibit the SSR characters. A total of 60 SSRs were detected in BC01, of which 58.3% were monomers, 18.3% were dimers, 13.4% were trimers, 6.7% were tetramers, 3.3% were pentamers, and no hexamers were present. Hexamers were only found in BF01 and BM01. Moreover, 65% of the SSRs were located in the IGS region, followed by the CDS region (20%) and the intron (15%). The genes *rps16-psbK*, *rps2-rpoC2*, *trnT/GGU-psbD*, and *ycf1* harbored more than two SSRs in each *Bupleurum* plastome. By comparing the cpSSRs across the five *Bupleurum* species using CandiSSR, a total of seven polymorphic cpSSRs were identified (Fig. 5B, Table S5). Specifically, four were dimers, two were trimers, and one was a pentamer. All polymorphic cpSSRs were detected in noncoding regions, of which *trnT/GGU-psbD* harbored two

Figure 3 MVISTA-based sequence identity among the plastid genomes of five *Bupleurum* species with *B. chinense* (BC01) as a reference.

The y -axis represents nucleotide diversity of the alignment of five *Bupleurum* species (in black) and the *B. chinense* alignment (in blue), while the x -axis represents the position of the window midpoint.

Full-size [DOI: 10.7717/peerj.15157/fig-4](https://doi.org/10.7717/peerj.15157/fig-4)

polymorphic cpSSRs. Additionally, 438 candidate polymorphic nSSRs were identified from the nuclear contigs of the five *Bupleurum* species (Fig. 5C, Table S6). More specifically, dimers were the primary type of polymorphic nSSR (55%), followed by trimers (22.6%) and tetramers (18%). Polymorphic pentamers and hexamers accounted for 3% and 1.4%, respectively.

Selective pressure analysis

To pinpoint whether genes underwent adaptive evolution in *Bupleurum* plastomes, the K_a/K_s values of the protein-coding genes were calculated. At the interspecies level, the K_a/K_s values of *psa J* and *ndh B* were greater than 1, indicating that the corresponding genes experienced positive selection (Fig. 6). The K_a/K_s values of the photosynthetic genes and self-replication genes were 0.1853 ± 0.3804 and 0.1926 ± 0.2377 , respectively. Both

Figure 5 Analysis of SSRs in the five *Bupleurum* species. (A) Number and location of six types of cpSSRs in ten plastomes of the five *Bupleurum* species. (B) Seven polymorphic cpSSRs across five *Bupleurum* species identified using CandiSSR. (C) Polymorphic nSSRs across five *Bupleurum* species identified using CandiSSR.

Full-size DOI: 10.7717/peerj.15157/fig-5

were lower than those of other genes (0.4127 ± 0.2489). Among the *B. chinense* plastomes, *acc D* related to the subunit of acetyl-CoA-carboxylase had the highest of *Ka/Ks* (1.076), followed by *rpo C2* (*Ka/Ks* = 0.827) which is related to self-replication (Fig. 6).

Phylogenetic analysis

Phylogenetic trees based on complete plastid genomes and the CDS showed the same topology, therefore, only the tree based on the complete plastid genomes with a slightly higher bootstrap support value was shown. All *Bupleurum* accessions were clustered into two main groups with absolute support (Fig. 7). *B. marginatum* var. *stenophyllum* (MT075712) and the other three congeneric species that are mainly distributed in Southwestern China formed a monophyletic group, appearing as an early branching clade within *Bupleurum* (Clade I). The remaining accessions could be divided into two subgroups, Clade II and Clade III (Fig. 7). *B. chinense* accessions and the *B. falcatum* accession were both in Clade II. *B. chinense* grouped with *B. commelynoideum* and *B. yinchowense* forming a clade with absolute support. Within Clade III, morphologically similar species *B. angustissimum*, *B. bicaule*, and *B. scorzoniferolium* were clustered together, sister to *B. rockii* and *B. euphorbioides*.

Figure 6 *Ka/Ks* values of 79 shared coding genes in the alignment of five *Bupleurum* species (in black) and the *B. chinense* alignment (in blue). The genes with *Ka/Ks* values larger than one are in grey.

Full-size [DOI: 10.7717/peerj.15157/fig-6](https://doi.org/10.7717/peerj.15157/fig-6)

Figure 7 Phylogenetic tree reconstructed using maximum likelihood (ML) and Bayesian inference (BI) based on 32 complete plastid genomes. Numbers shown at the corresponding nodes represent ML bootstrap support (BS) values and Bayesian posterior probabilities (PP), respectively.

Full-size [DOI: 10.7717/peerj.15157/fig-7](https://doi.org/10.7717/peerj.15157/fig-7)

The *Bupleurum* accessions were also clustered into two groups based on ITS data (Fig. 8). Though some of the branch nodes were poorly supported, each *Bupleurum* species studied formed a monophyletic lineage with high support, except for *B. chinense*, *B. angustissimum*, and *B. scorzonifolium*. However, incongruences were observed between the phylogenies

Figure 8 Phylogenetic tree reconstructed using maximum likelihood (ML) and Bayesian inference (BI) based on ITS. Numbers shown at the corresponding nodes represent BS/PP.

Full-size  DOI: [10.7717/peerj.15157/fig-8](https://doi.org/10.7717/peerj.15157/fig-8)

based on nuclear ITS and chloroplast datasets. Based on ITS data, *B. chinense* and its forms were nested with *B. yinchowense*, while distinct from *B. falcatum*. The *B. scorzoniferifolium* accessions from northwestern China were grouped with *B. angustissimum* as shown in the tree based on the chloroplast dataset. *B. bicaule* represented an independent lineage in the nuclear dataset.

DISCUSSION

Infrageneric relationships within *Bupleurum* and taxonomic implications

Bupleurum L. is one of the largest genera in Apiaceae, represented by 150–180 species, of which nearly 50 species occur in China (Sheh & Watson, 2005). Due to the similar morphological characteristics and broad intraspecific morphological variation under different ecological habitats, species delimitation based on traditional classification systems is extremely difficult in this genus. The complicated infrageneric relationships also result in problems with cultivation. Based on more extended sampling, Wang, Ma & He (2011) proposed to divide the Chinese *Bupleurum* into two groups. Specifically, one group contained species from the southwest, while another consisted of the species mainly distributed in northern China. However, the statistical support of the main clade was relatively low based on the combined dataset of *mat* K and *trn* H-*psb* A. In this study, the phylogenetic topology based on complete chloroplast genomes was congruent to the framework of Wang, Ma & He (2011), but with much higher internal resolution. Among

the five Chaihu germplasm resources, *B. marginatum* var. *stenophyllum* clustered in the early branching group of the phylogenetic trees, separated from the other four *Bupleurum* species. Due to the high yield and high content of saikosaponins, *B. marginatum* var. *stenophyllum* was introduced from Tibet to Gansu and Shanxi Provinces in China with widespread planting (Liu et al., 2021a; Liu et al., 2021b). Modern pharmacological studies have shown that saikosaponins are not only the main bioactive components of Chaihu, but also the main toxic components (Huang & Sun, 2010; Lv et al., 2009; Zhou et al., 2021). Wang et al. (2020) demonstrated that *B. marginatum* var. *stenophyllum* contained higher content of saikosaponins A and D, and had a higher level of acute toxicity. Xia et al. (2021) compared the overall chemical components of *B. marginatum* var. *stenophyllum* and *B. chinense*, and showed clear species-clustering. Thus, the use of *B. marginatum* var. *stenophyllum* as Chaihu should be done with caution.

In the plastid and ITS trees, *B. chinense* accessions were clearly distinct from those of *B. scorzonerifolium*. Morphologically, the two species are distinguished by a combination of characteristics, including leaf veins, fibrous remnant sheaths, and color of the root bark. Notably, phylogenetic trees based on complete plastid genomes and nuclear ITS datasets both supported close affinities of *B. yinchowens* and *B. chinense*, and *B. angustissimum* and *B. scorzonerifolium*. The delimitation confusion has long been an issue in these species (Wang, Ma & He, 2011). Based on similar morphology and overlapping ecological distributions (Sheh & Watson, 2005), we proposed *B. yinchowens* as conspecific to *B. chinense*, and *B. angustissimum* as conspecific to *B. scorzonerifolium*, but more evidence was needed. *B. falcatum* showed a closer phylogenetic relationship with *B. chinense* in the plastid trees, while the species was resolved as a distinct clade not closely related to *B. chinense* and *B. scorzonerifolium* but to *B. bicaule*. *B. falcatum* is a cultivated species originating from Japan, where it is the official botanical origin of *Bupleuri Radix* in the *The Society of Japanese Pharmacopoeia* (2011). Consequently, we speculated that introgressive hybridization during years of cultivation might contribute to the conflicts between plastid and nuclear ITS phylogenies. Theoretically, evolutionary processes including incomplete lineage sorting, introgressive hybridization, and paralogy conflation might contribute to phylogenetic incongruence among different datasets (Liu et al., 2020; Wendel & Doyle, 1998). Many studies suggested that introgressive hybridization was a prominent factor for phylogenetic incongruence at lower taxonomic levels. Based on the plastid datasets, *B. bicaule* and *B. scorzonerifolium* were clustered with *B. angustissimum*. Morphologically, these three species are highly similar, with fibrous remnant sheaths around the stem. However, *B. bicaule* accessions did not cluster with *B. angustissimum* and *B. scorzonerifolium* in the nrDNA tree. Considering the corresponding node had low support, we cannot exclude the possibility that insufficient information from ITS sequences resulted in the incongruence. Moreover, *B. bicaule* was considered to be involved in hybridization events to coexist with other *Bupleurum* species. The delimitation of *B. bicaule* needs further study.

Conserved plastid genome structure

For the five *Bupleurum* species examined here, the chloroplast genomes displayed a typical quadripartite structure, as in most angiosperms (Palmer, 1985). The chloroplast genome structures were found to be largely conserved with lengths varying from 155,540 bp to 155,866 bp. Previous studies have reported that gene loss (Wakasugi et al., 1994; Wolfe, Morden & Palmer, 1992), expansion and contraction of the IRs (Lin et al., 2003; Parks, Cronn & Liston, 2009), and intergenic region variation (Tang et al., 2004; Wu et al., 2011) are three important factors driving size variation in the plastid genome. Across the five *Bupleurum* species in this study, the genes distributed around the junction boundaries slightly varied in length. Among these, the SSC/IR borders showed a higher level of differences than LSC/IR, in contrast to the study of Huang et al. (2021) in a broader comparison of *Bupleurum* species. As expected for the intraspecific divergence inferred from plastid genomes, the junction boundaries in *B. chinense* accessions were more convergent. We proposed that size variations in the chloroplast genome within *Bupleurum* were due to variation of intergenic regions.

Variable regions for potential molecular markers

In this study, abundant sequences with SNPs and SSRs were detected across the five *Bupleurum* species. As expected, large-scale sequencing provided abundant variable sequences, which could be used for species authentication and phylogenetic inference. Our results showed that the majority of variable sequences were located in noncoding regions at either the interspecific level or the intraspecific level. Previous studies have demonstrated that noncoding sequences of the chloroplast genome perform well as phylogenetic markers, and in phylogenetic construction and population genetic studies (Shaw et al., 2007; Borsch & Quandt, 2009). In addition, the majority of noncoding sequences with high nucleotide diversity were situated in single-copy regions. Perry & Wolfe (2002) showed that the nucleotide mutation rate of single-copy regions was 2.3 times higher than that of the inverted repeats.

In this study, *atp F-atp H*, *pet N-psb M*, *rps 16-psb K*, *pet A-psb J* *ndh C-trn V/UAC*, and *yef 1* regions had high values of nucleotide diversity across the five *Bupleurum* species. *Atp F-atp H* has been proposed as a potential DNA barcode for identifying plant taxa at the species level (Lahaye et al., 2008; Thakur et al., 2019). The high nucleotide diversity of the remaining five genes has been reported in *Bupleurum* before (Huang et al., 2021; Li et al., 2020; Xie et al., 2021). In particular, *yef 1* has been proposed as the most promising plastid DNA barcode of land plants (Dong et al., 2015). The Pi values of the corresponding genes were slightly lower than that in Huang et al. (2021), mainly because of the limited *Bupleurum* species involved in our study.

Repeat units, distributed in genomes with high frequency, are essential in the rearrangement and divergence of the genome (Weng et al., 2014). Microsatellites (SSRs), containing repetitive sequences of 1–6 bp in length, are used as molecular markers for population genetics, phylogeography, and systematics (George et al., 2015). Owing to the rapid development of next-generation sequencing, abundant genomic microsatellites with a high level of polymorphisms are available for plant species (Xia et al., 2016). Based on

complete plastomes, numerous cpSSRs were detected for the five Chaihu germplasm resources, varying from 51 (*B. chinense* BC05) to 81 (*B. marginatum* var. *stenophyllum*). The mononucleotide category was the most abundant, followed by di-, tri-, tetra- and pentanucleotides. Further, seven cpSSRs were found to be polymorphic across the five *Bupleurum* species, and were located in noncoding regions. One polymorphic cpSSR was located in *ndh C-trn V/UAC*, which also exhibited high nucleotide diversity. We propose that *ndh C-trn V/UAC* might be candidate molecular markers for cultivated *Bupleurum* species. At the same time, a total of 438 candidate polymorphic nSSRs were detected, most of which were dimers. Among polymorphic cpSSRs and nSSRs, the di- and trinucleotide repeats were dominant categories and no monomers were detected, consistent with the characteristics of the identified polymorphic SSRs in other taxonomic studies (Bhandari et al., 2020; Dabral et al., 2021). Notably, all regions with high variability possessed SSRs. The identified SSRs are helpful in intraspecific phylogeographic and population-level genetic studies of Chaihu germplasms as in *Angelica heterocarpa* (Revardel & Lepais, 2022), *Grevillea robusta* (Dabral et al., 2021), and *Erysimum teretifolium* (del Valle, Herman & Whittall, 2020).

Adaptive evolution among *Bupleurum* species

Plants might leave fingerprints in plastid genomes in response to environmental changes, within which some genes exhibit positive selection. The value of Ka/Ks is used to measure the selective pressure of the coding genes in angiosperms (Yang & Nielsen, 2002). The chloroplast functions directly in photosynthesis and carbon fixation, and three genes with essential roles in photosynthesis showed positive selection in this study. Among five *Bupleurum* species, the Ka/Ks values of *psa J* and *ndh B* were greater than one. Among the plastomes of *B. chinense*, we identified *acc D* as a positively selected gene. The substitution rates of the functional genes at intraspecies and interspecies levels were different, which might be caused by the diverse evolutionary history of *Bupleurum* species. Interestingly, the nucleotide diversity of *psa J*, *ndh B*, and *acc D* in coding regions was not significant (Figs. 3 and 4), presumably due to the close affinity among the *Bupleurum* species. Similar results were found in Huang et al. (2021) and Li et al. (2020). The *psa J* gene is involved in the excitation of photosystem I, which has been essential during the life history of plants (Schöttler et al., 2007). The *ndh B* gene encodes for the subunits of NAD(P)H dehydrogenase complex involved in photosystem I cyclic and chlororespiratory electron transport in higher plants (Martín & Sabater, 2010). Horváth et al. (2000) showed that *ndh B*-inactivated tobacco plants cause a moderate decline in photosynthesis via stomatal closure under humidity stress conditions. The *acc D* gene, encoding the β -carboxyl transferase subunit of acetyl-CoA-carboxylase, has been demonstrated as an essential gene in plastid genome evolution (Kode et al., 2005). Madoka et al. (2002) confirmed that *acc D* affected leaf longevity and seed yield.

B. chinense is a widespread species in China, within which three forms were recognized by Sheh & Watson (2005) with differences in leaves and bracteoles. Environmental variation drives leaf morphology variation within species (Byars, Papst & Hoffmann, 2007). We also observed leaf variations in the *B. chinense* populations under different ecological conditions

during field sampling. *Han et al. (2006)* identified three types of *B. chinense* based on leaf shapes, namely broad, long, and medium. The mutation accumulation of functional genes affects photosynthesis efficiency, which may cause ecological diversity of plants (*Zheng et al., 2017*). Consequently, positively selected genes provide important insights into adaptive molecular evolution of *Bupleurum* species.

CONCLUSIONS

In this study, the complete chloroplast genomes and nuclear ITS of five *Bupleurum* Radix germplasm resources, namely *B. bicaule*, *B. chinense*, *B. falcatum*, *B. marginatum* var. *stenophyllum*, and *B. scorzonerifolium*, were obtained using genome skimming. All plastomes we sequenced were conserved and exhibited a typical quadripartite structure, encoding 113 identical genes including 79 protein-coding genes, 30 tRNA genes, and four rRNA genes. Phylogenetic analysis inferred using the chloroplast genomes and nrITS resolved the relationships of the five *Bupleurum* species and their closely related species. *B. marginatum* var. *stenophyllum* was separate from the other four *Bupleurum* species studied. *B. chinense* and *B. scorzonerifolium*, which are the official botanical origins of Chaihu in the Chinese Pharmacopoeia, were in two separate clades. However, the phylogenetic delimitation of *B. bicaule* and *B. falcatum* needs further study, because introgressive hybridization might be involved. By comparison analysis, molecular markers, including plastid hotspots and polymorphic SSRs, were generated for authentication of Chaihu germplasms. Photosynthesis related genes *psa J*, *ndh B*, and *acc D* were found to be under positive selection as a response to adapting to diverse environments.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

The study was financially supported by the TCM Public Health Service Subsidy Special “National Chinese Medicine Resource Census Project” (Caishe (2018) No. 43), the Natural Science project of Shaanxi Science and Technology Department (2021JQ-821), the Natural Science project of Xianyang Science and Technology Department (2018k02-107), and the Natural Science project of Xianyang Normal University (XSYK19029). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.
