Insect pest invasions cause significant damage to crop yields, and the resultant economic losses are truly alarming. Climate change and trade liberalization have opened new ways of pest invasions. Given the consumer preference towards organic agricultural products and environment-friendly nature of natural pest control strategies, biological control is considered to be one of the potential options for managing invasive insect pests. *Drosophila suzukii* (Drosophilidae) is an extremely damaging fruit pest, demanding development of effective and sustainable biological control strategies. In this study, we assessed the potential of the parasitoid *Leptopilina japonica* (Figitidae) as a biocontrol agent for *D. suzukii* using ecological niche modeling approaches. We developed global-scale models for both pest and parasitoid to identify four components necessary to derive a niche based, target oriented prioritization approach to plan biological control programs for *D. suzukii*: (i) potential distribution of pest *D. suzukii*, (ii) potential distribution of parasitoid *L. japonica*, (iii) the degree of overlap in potential distributions of pest and parasitoid, and (iv) biocontrol potential of this system for each country. Overlapping suitable areas of pest and parasitoid were identified at two different thresholds and at the most desirable threshold ($E = 5\%$), potential for *L. japonica* mediated biocontrol management existed in 125 countries covering 1.87×10^7 km², and at the maximum permitted threshold ($E = 10\%$), land coverage was reduced to 1.44×10^7 km² in 121 countries. Fly pest distributional information as a predictor variable was not found to be improving parasitoid model performance, and globally, only in half of the countries, >50% biocontrol coverage was estimated. We therefore suggest that niche specificities of both pest and parasitoid must be included in site-specific release planning of *L. japonica* for effective biocontrol management aimed at *D. suzukii*. This study can be extended to design cost-effective pre-assessment strategies for implementing any biological control management program.

10 **ABSTRACT**

11 Insect pest invasions cause significant damage to crop yields, and the resultant economic losses
12 are truly alarming. Climate change and trade liberalization have opened new ways of pest
13 invasions. Given the consumer preference towards organic agricultural products and
14 environment-friendly nature of natural pest control strategies, biological control is considered
15 to be one of the potential options for managing invasive insect pests. *Drosophila suzukii*
16 (*Drosophilidae*) is an extremely damaging fruit pest, demanding development of effective and
17 sustainable biological control strategies. In this study, we assessed the potential of the
18 parasitoid *Leptopilina japonica* (*Figitidae*) as a biocontrol agent for *D. suzukii* using ecological
19 niche modeling approaches. We developed global-scale models for both pest and parasitoid to
20 identify four components necessary to derive a niche based, target oriented prioritization
21 approach to plan biological control programs for *D. suzukii*: (i) potential distribution of pest *D.*

22 *suzukii*, (ii) potential distribution of parasitoid *L. japonica*, (iii) the degree of overlap in potential
23 distributions of pest and parasitoid, and (iv) biocontrol potential of this system for each
24 country. Overlapping suitable areas of pest and parasitoid were identified at two different
25 thresholds and at the most desirable threshold ($E = 5\%$), potential for *L. japonica* mediated
26 biocontrol management existed in 125 countries covering $1.87 \times 10^7 \text{ km}^2$, and at the maximum
27 permitted threshold ($E = 10\%$), land coverage was reduced to $1.44 \times 10^7 \text{ km}^2$ in 121 countries.
28 Fly pest distributional information as a predictor variable was not found to be improving
29 parasitoid model performance, and globally, only in half of the countries, >50% biocontrol
30 coverage was estimated. We therefore suggest that niche specificities of both pest and
31 parasitoid must be included in site-specific release planning of *L. japonica* for effective
32 biocontrol management aimed at *D. suzukii*. This study can be extended to design cost-effective
33 pre-assessment strategies for implementing any biological control management program.

41

42 INTRODUCTION

43 Over recent decades, the world has witnessed significant increases in agricultural
44 production, but increases in crop yields have often been reduced by diverse insect pests
45 (Vreysen et al., 2007; Savary et al., 2019). Assessment of all of the components of agricultural
46 productivity and food security must include consideration of insect pests, as they are an
47 integral part of anthropogenic crop ecosystems (Food and Agriculture Organization, 2013;
48 Savary et al., 2019). Global warming and economic globalization accelerate development of
49 new routes of pest invasion (Girod et al., 2018), presenting new challenges. As pests pose
50 serious threats in the functioning of global food systems (Savary et al., 2017), various strategies
51 have been developed for insect pest management, each with its own advantages and
52 disadvantages (Dara, 2021). Improvement in the management of invasive pest populations
53 includes consideration of sustainable and eco-friendly approaches, with the goal of achieving
54 long-term benefits (Bernaola & Holt, 2021).

55 A broad (fruit) host range (Lee et al., 2011; Bellamy, Sisterson & Walse, 2013), combined
56 with an ability to infest ripening soft fruits (Gabarra et al., 2015), has made *Drosophila suzukii*
57 (Matsumura) (Diptera: Drosophilidae) an economically damaging, globally invasive fruit pest of
58 serious concern (Walsh et al., 2011). Preference for not-quite-ripe or just-ripe fruits over
59 damaged or decaying fruits (Mitsui, Takahashi & Kimura, 2006), and the presence of a
60 sclerotized ovipositor of females (Kienzle & Rohlf, 2021) with serrations to pierce undamaged
61 fruit epicarps for laying eggs, are two notable traits (Walsh et al., 2011) that contribute
62 significantly to economic threats imposed by *D. suzukii*. Bacterial and fungal pathogens can

63 cause secondary infections in fruits after infestation by *D. suzukii*, augmenting economic losses
64 (Molina et al., 1974; Louis et al., 1996; Walsh et al., 2011).

65 *Drosophila suzukii* is native to eastern and southeastern Asia (Bolda et al., 2010); it was
66 initially detected in Japan in 1916 (Kanzawa, 1935) and described as a distinct species in 1931
67 (Hauser, 2011). In 2008, *D. suzukii* was identified as an invasive species for the first time with
68 populations in both North America (Hauser, 2011) and Europe (Calabria et al., 2012). Its host
69 range covers 13 angiosperm families (Cloonan et al., 2018), and its invaded geographic range
70 has now extended to South America (Deprá et al., 2014; Andreatza et al., 2017) and Africa
71 (Kwadha et al., 2021). As *D. suzukii* larvae feed inside of fruits (Fanning, Grieshop & Isaacs,
72 2018), and the fruit export trade strictly follows zero-tolerance towards infestations (Tait et al.,
73 2021), much high-value fruit is rendered unsellable every year. Economic impact assessments
74 in the United States (Bolda, Goodhue & Zalom, 2010; Walsh et al., 2011; Goodhue et al., 2011;
75 Farnsworth et al., 2017; DiGiacomo et al., 2019; Yeh et al., 2020), Europe (Knapp et al., 2021),
76 and South America (Benito, Lopes-da-Silva & Santos, 2016), have indicated losses on the order
77 of US\$550M per year.

78 Various preventive and post-infestation control measures (Lee et al., 2011; Landolt,
79 Adams & Rogg, 2012; Haye et al., 2016; Schetelig et al., 2018; Shower et al., 2018; Tait et al.,
80 2021) have been developed so far, but none with complete efficacy (Kehrli et al., 2017; Knapp,
81 Mazzi & Finger, 2019). Management strategies for *D. suzukii* can be classified broadly into four
82 categories: (1) chemical control (Beers et al., 2011; Van Timmeren & Isaacs, 2013; Shower et al.,
83 2018; Shower, 2020), (2) microclimate manipulation (Lee et al., 2016; Rendon et al., 2020), (3)
84 RNA interference biopesticides (Murphy et al., 2016), and (4) biological control (Chabert et al.,

85 2012; Daane et al., 2016; Mazzetto et al., 2016; Knoll et al., 2017; Daane et al., 2021). Extensive
86 use of chemical methods to control *D. suzukii* infestations can lead to increased pest resistance,
87 and concerns regarding food and environmental safety (Santoemma et al., 2019). Microclimate
88 manipulation approaches to control *D. suzukii* are more likely to perform well in hot and dry
89 regions (Schöneberg et al., 2022), as *D. suzukii* is sensitive to high temperatures and low
90 humidity (Rendon et al., 2020). RNA interference methods involve higher development costs
91 and involve much labor (Bramlett, Plaetinck & Maienfisch, 2020). Finally, biological control
92 involves release of enemies of *D. suzukii* from the region of its origin (Asia) in invaded areas, as
93 a means to reduce its population growth (Girod et al., 2018). This method is recommended
94 (Cock et al., 2010; van Lenteren, 2012) in view of improved food safety, environment-friendly
95 characteristics, economic feasibility, and long-term control solutions that are established
96 (Kruitwagen, Beukeboom & Wertheim, 2018).

97 Parasitoid wasps of the genera *Asobara* (Braconidae), *Ganaspis* (Figitidae), and
98 *Leptopilina* (Figitidae) have been studied extensively as biological control agents with potential
99 to suppress growth of *D. suzukii* populations (Kacsoh & Schlenke, 2012; Rossi Stacconi et al.,
100 2015; Daane et al., 2016; Giorgini et al., 2019; Wang et al., 2019; Biondi, Wang & Daane, 2021).
101 In particular, the species *A. japonica*, *G. brasiliensis*, and *L. japonica* are potential biocontrol
102 agents (Wang et al., 2019). However, some researchers do not recommend *A. japonica* for
103 biological control programs aimed at *D. suzukii* (Daane et al., 2016; Girod et al., 2018; Abram et
104 al., 2020), owing to its broad host range (Ideo et al., 2008; Furihata et al., 2016). Indeed, given
105 its host specificity, *G. brasiliensis* has been proposed as a candidate for biological control of *D.*
106 *suzukii* (Wang et al., 2020), yet, in a scenario when these three wasps coexist, *L. japonica* is

107 unique in being able to outcompete the other two species thanks to its relatively faster egg-
108 hatching potential (Wang et al., 2019). Relatively high host specificity (Wang et al., 2020),
109 demonstrated competence in multi-parasite systems (Wang et al., 2019), and recent range
110 expansions into areas invaded by *D. suzukii* in Europe (Puppato et al., 2020) and North America
111 (Abram et al., 2020, 2022), make *L. japonica* a particularly promising biocontrol agent of *D.*
112 *suzukii*.

113 Ecological niche modeling (ENM) has been used extensively to identify potential
114 distributions of species for a variety of purposes (Raxworthy et al., 2007; Escobar, 2020;
115 Kolanowska & Jakubska-Busse, 2020; Wan et al., 2020; Valencia-Rodríguez et al., 2021; Agboka
116 et al., 2022; Demján et al., 2022; Outammassine, Zouhair & Loqman, 2022). In pest-parasitoid
117 systems, identifying and comparing relative habitat suitability of pest and parasitoid can help to
118 guide effective biological control programs (Pérez-de la O et al., 2020; Tapa-Yotto et al.,
119 2021a,b). The utility of ENM in applications to biological control of pests can be attributed to
120 two factors: alien parasitoid species must survive and reproduce in the geographic regions
121 where they are released (Mills, 2018; Schulz, Lucardi & Marsico, 2019), and unfavorable abiotic
122 factors can reduce the long-term efficacy of biological control measures (Olfert et al., 2016).
123 Modeling climatic preferences of deliberately introduced parasitoid species can also provide
124 insights into possible range expansions, an important aspect to be tested in improving
125 effectiveness of classical biological control programs (Pérez-de la O et al., 2020).

126 In this study, we used ENM approaches to explore, discuss, and highlight five aspects of
127 a biological control strategy for *D. suzukii* that can directly benefit producers, extension agents,
128 and policy makers. (1) We estimated the potential distribution of the invasive pest *D. suzukii*,

129 and (2) that of the parasitoid *L. japonica*. (3) We assessed the degree of overlap in the potential
130 distributions of *D. suzukii* and *L. japonica*, and (4) estimated the biocontrol potential of this
131 system for each country. Finally, (5) we assessed parasitoid model performance to see if
132 incorporating distributional information for the pest improves model performance for the
133 parasitoid.

134

135 **METHODS**

136 **Occurrence data**

137 Occurrence records of *D. suzukii* were downloaded from five online biodiversity data
138 portals: Global Biodiversity Information Facility (GBIF; www.gbif.org, accessed on 2 August,
139 2022), Biodiversity Information Serving Our Nation (BISON; www.gbif.us, accessed on 2 August,
140 2022), Berkeley Ecoinformatics Engine (Ecoengine; ecoengine.berkeley.edu, accessed on 2
141 August, 2022), iNaturalist (www.inaturalist.org, accessed on 2 August, 2022), and Integrated
142 Digitized Biocollections (iDigBio; www.idigbio.org, accessed on 2 August, 2022) using Spocc
143 version 1.2.0 R package (Chamberlain, Ram & Hart, 2021); occurrence data were also drawn
144 from the Centre for Agriculture and Bioscience International (CABI; www.cabi.org, accessed on
145 3 August, 2022). This initial harvest of occurrence data yielded an initial total of 2369 records.

146 A five-step data cleaning process was adopted: (1) removal of records with no date of
147 observation, (2) removal of incomplete coordinates (*i.e.*, lacking valid latitude and longitude),
148 (3) removal of unlikely coordinates (e.g., 0.00°N, 0.00°E), (4) removal of duplicated coordinates,

149 and (5) removal of coordinates with fewer than two decimal places. Data cleaning was
150 performed using *scrubr* version 0.1.1 R package (Chamberlain, 2016). The cleaned dataset
151 (1385 records) was overlaid on climatic raster layers (5' or ~10 km spatial resolution, see below)
152 to remove points falling outside the raster boundaries. The resulting occurrence dataset (1377
153 records) was subjected to visual inspection to detect clusters of points (often related to points
154 of access or concentrations of people), and eliminate disproportionate data density at random,
155 maintaining a minimum distance of ≥ 30 km among points, to avoid model overfitting (Raghavan
156 et al., 2019). The final dataset of 314 points (Figure 1; Supplementary file 1) showed no
157 excessive clustering of occurrences across the known distribution of *D. suzukii*. Spatial filtering
158 was performed using *spThin* R package (Aiello-Lammens et al., 2015).

159 Occurrence records of *L. japonica* were sourced from published literature (Beers et al.,
160 2022; Abram et al., 2020; Puppato et al., 2020; Giorgini et al., 2019; Girod, 2018; Novković et
161 al., 2011), as online data portals held few or no records. A distance filter of 12 km was applied
162 to the occurrences extracted, and the final dataset comprised 31 points (Figure 1;
163 Supplementary file 2). *Leptopilina japonica* has two subspecies: *L. japonica japonica* and *L.*
164 *japonica formosana*, occurring in Japan and Taiwan respectively (Novković et al., 2011); both
165 have the ability to parasitize *D. suzukii* (Kimura & Novković, 2015). Our final dataset included
166 mostly the nominate subspecies, and only a single occurrence record of *L. j. formosana*
167 (Novković et al., 2011).

168

169

170

171 **Environmental data**

172 Bioclimatic raster layers at 5' spatial resolution (~10 km at the Equator) were
173 downloaded from WorldClim 2.1 for present conditions (1975-2000; Fick and Hijmans, 2017).
174 Variables combining temperature and precipitation measurements (*i.e.*, mean temperature of
175 wettest quarter, mean temperature of driest quarter, precipitation of warmest quarter, and
176 precipitation of coldest quarter) were excluded (Escobar et al., 2014) owing to discontinuous
177 patterns of those variables in many areas (Booth, 2022).

178 To define the set of limits and conditions for ENM, identification of areas accessible to
179 species over relevant time periods (Soberón & Peterson, 2005; Peterson & Soberón, 2012) is
180 essential to development of robust models (Barve et al., 2011) . The development of a
181 hypothesis of accessible area **M** is crucial for rigorous characterization of niche characteristics
182 of species (Barve et al., 2011; Machado-Stredel, Cobos & Peterson, 2021). Considering the near-
183 global distribution of *D. suzukii* and *L. japonica*, the entire world (excluding Antarctica) was
184 defined as the accessible area for the two species. The 15 climatic data layers were clipped to
185 the extent of this area. Multi-collinearity and dimensionality among the clipped bioclimatic
186 layers were minimized using principal components analysis, in effect transforming correlated
187 climatic variables into fewer, uncorrelated principal components (PCs), and these multivariate
188 environmental variables were used as the independent variables in ENM. Principal components
189 analysis of raster variables was done using the `kuenm_rpca` function of the `kuenm` R package
190 (Cobos et al., 2019).

191

192 **Ecological niche modeling**

193 In separate ENM analyses, occurrences of each species (pest and parasitoid) were
194 partitioned randomly into training and testing data in two different proportions: 70:30 for *D.*
195 *suzukii*, and 50:50 for *L. japonica*. Considering the small number of records, data-splitting ratio
196 was reduced to 0.5 for *L. japonica* to maintain a balance between predictive accuracy and
197 performance estimation of models as very low sample size for testing can cause errors in
198 estimating predictive accuracy (Peterson, Ball & Cohoon, 2002). Modeling experiments were
199 performed using six combinations of three feature classes (l-linear, q-quadratic, p-product; l, q,
200 lq, qp, lp, and lqp; product response types were not used in isolation owing to occasional
201 problems that result), 10 regularization multipliers (0.1, 0.3, 0.6, 0.9, 1, 2, 3, 4, 5, 6), and nine
202 sets of principal components summarizing climate data. The first 10 PCs accounted for >99% of
203 the total variation: set 1 (PCs 1 and 2), set 2 (PCs 1-3), etc., up to set 9 (PCs 1-10). Best models
204 were selected by applying three criteria sequentially (Cobos et al., 2019): (1) choosing
205 statistically significant models using partial ROC tests, (2) filtering statistically significant models
206 to those with < 5% omission error (*E*), and (3) ranking all remaining models based on Akaike
207 information criterion (AICc) values; the subset of significant, low-omission models within 2 AICc
208 units of the minimum were selected as the best models (Warren & Seifert, 2011). Top models
209 were replicated 10 times using the bootstrap method to produce final models, and the median
210 of the median outputs across all replicates was used to interpret results for each species.

211 To assess the potential role of fly distributional information in improving the
212 performance of the parasitoid model, the final *D. suzukii* model output was added to each
213 multivariate environmental variable set. We then re-calibrated the *L. japonica* model using the
214 same set of feature class types and regularization multiplier values to develop a two-species
215 model for the wasp (see Ashraf et al., 2021). We compared models with and without the fly
216 distributional information using the same 3 criteria described above. Occurrence data
217 partitioning exercises were done using caTools R package (Tuszynski, 2021). All modeling
218 experiments were performed using maximum entropy approaches (Maxent) (Phillips, Anderson
219 & Schapire, 2006), as implemented in the kuenm R package (Cobos et al., 2019).

220 To represent suitable and unsuitable regions for the pest and the parasitoid, Maxent
221 models in the form of continuous logistic outputs were transformed into binary presence-
222 absence models by applying two different least-training presence thresholds (*i.e.*, allowable
223 omission $E = 5\%$ and $E = 10\%$). These two thresholds were chosen as indices of most desirable
224 ($E=5\%$) and maximum permitted ($E = 10\%$) omission rates to represent relative habitat
225 suitability, and also to avoid overinterpretation of predictions (Ashraf, Chaudhry & Peterson,
226 2021). These thresholds were applied using QGIS Tisler desktop version 3.24.3 (QGIS
227 Geographic Information System, 2022).

228 For both thresholds, overlapping potential habitats of *D. suzukii* and *L. japonica* were
229 identified. The ratio between the land areas of predicted potential distribution of parasitoid
230 and pest in each country was estimated to determine the country-wise biocontrol coverage
231 potential percentage, for both thresholds. Identification of overlapped area and estimation of
232 land area in terms of biocontrol coverage were done in QGIS Tisler desktop version 3.24.3 (QGIS

233 Geographic Information System, 2022). All models were represented in an Eckert IV equal-area
234 map projection (Qiao et al., 2019).

235 RESULTS

236 For each of the two species, we developed 540 candidate models, of which 510 models
237 for *D. suzukii* and 533 models for *L. japonica* were statistically significantly better than random
238 expectations according to the partial ROC tests ($P < 0.05$). Of the statistically significant models,
239 53 models for *D. suzukii* and 11 models for *L. japonica* were also acceptable in having low (<5%)
240 omission. Finally, based on low model complexity (*i.e.*, low AICc value), our top model for *D.*
241 *suzukii* included linear and quadratic feature classes, a relatively low regularization multiplier
242 value (0.6), and four multivariate environmental variables (PC 1–PC 4) (Table 1). Our best model
243 for *L. japonica* had a higher regularization multiplier value (2.0), and included more multivariate
244 environmental variables (PC 1–PC 7), also with linear and quadratic feature types (Table 1). In
245 the two-species modeling experiment, we developed 540 models, and all models were
246 statistically significantly better than random expectations ($P < 0.05$). However, none of the
247 models met the omission rate threshold ($E = 5\%$). We found that, even relaxing the threshold (E
248 = 7%) did not result in the selection of any of the two-species models as best model for
249 parasitoid. We therefore confirmed that inclusion of pest model as a predictor variable did not
250 improve model performance for the parasitoid.

251 Our model for *D. suzukii* predicted potential distributional areas in southern and eastern
252 China, with some extensions towards central Asian regions (Figure 2). Farther north in Asia,
253 Japan and the Korean Peninsula were predicted to hold broad suitable areas for *D. suzukii*.

254 Predicted suitable areas covered seven nations [Afghanistan, Pakistan, India, Nepal, China
255 (Tibetan Autonomous Region), Bhutan, and Myanmar] across the entire northwest-southeast
256 spread of the Himalayas. In Oceania, southeastern Australia and much of New Zealand were
257 predicted to hold suitable conditions for *D. suzukii* invasion.

258 Already-invaded parts of western Europe and the southeastern United States were
259 identified as highly suitable for *D. suzukii* populations, which is logical given that occurrences
260 there were part of the model training data. In South America, the entire geographic extent of
261 Uruguay, known to hold invasive populations, was identified as suitable for *D. suzukii*; parts of
262 other known-invaded countries (Chile, Argentina, Brazil) were also identified as suitable:
263 eastern and northeastern Argentina, southern Brazil, and western and southern Chile. Peru is
264 the only country in South America predicted to hold suitable areas for *D. suzukii* invasion for
265 which no invasive populations are known; predicted potential distributional areas spanned the
266 Andean Cordillera.

267 The modeled potential geographic distribution for *L. japonica* was broad and continuous
268 in Asia, covering southern and northeastern Asian countries (India, China (Tibetan autonomous
269 region), Nepal, Bhutan, North Korea, South Korea, and Japan). Other potential distributional
270 areas were more sparse, in northwestern Europe, western North America, and in western and
271 southern Chile in South America.

272 **Binary models and biocontrol coverage estimation**

273 Binary model outputs were developed for *D. suzukii* and *L. japonica* (Figure 3) to identify
274 presence or absence of the two species in the area of interest. At the 5% threshold, potential

275 presence of *D. suzukii* was predicted in 162 countries (Supplementary file 3), covering a total
276 area of $\sim 4.82 \times 10^7$ km². Potential presence of *L. japonica* was predicted in 148 countries
277 (Supplementary file 3), covering a total area of 2.71×10^7 km². At the 10% threshold, total
278 coverage of predicted area was reduced to 3.44×10^7 km² in 152 countries for *D. suzukii*, and
279 2.46×10^7 km² in 146 countries for *L. japonica* (Supplementary file 3).

280 Overlapping suitable areas of *D. suzukii* and *L. japonica* to identify possible biocontrol
281 regions for both thresholds (Figure 4) showed that potential for *L. japonica*-mediated biocontrol
282 management of *D. suzukii* existed in 125 nations at $E = 5\%$, and 121 nations at $E = 10\%$ (Table
283 2). At a global level, the total possible biocontrol area was estimated to range 1.44×10^7 km²-
284 1.87×10^7 km² based on the different thresholds. Country-wise biocontrol coverage estimation
285 revealed that about half of the countries (65) had more than 50% biocontrol potential (*i.e.*, area
286 suitable for both fly and wasp; Table 2), with broadest areas in China ($\sim 4.4 \times 10^6$ km²), India
287 ($\sim 1.1 \times 10^6$ km²), Zambia (4.5×10^5 km²), and Angola ($\sim 4.2 \times 10^5$ km²).

288

289 DISCUSSION

290 Extremely fast range expansion as a consequence of globalization (Iacovone et al.,
291 2015), with severe economic damage to the fruit trade industry (Bolda, Goodhue & Zalom,
292 2010; Gabarra et al., 2015), has led to efforts to model ecological niches and predict potential
293 distributions for *D. suzukii* both locally (Castro-Sosa et al., 2017; de la Vega & Corley, 2019) and
294 globally (Santos et al., 2017; Ørsted & Ørsted, 2019; Reyes & Lira-Noriega, 2020). Comparing
295 with previous global-scale models, our models predicted highly suitable areas for *D. suzukii*

296 most similar to the model developed by Ørsted and Ørsted (2019), and less similar to those of
297 Santos et al (2017) and Reyes and Lira-Noriega (2020). Relatively broad geographic areas in the
298 southern part of central and eastern Africa were predicted to be suitable in the models
299 developed by Santos et al (2017) and Reyes and Lira-Noriega (2020) compared to our model
300 and that of Ørsted and Ørsted (2019). Unlike the predictions of Santos et al (2017) and Reyes
301 and Lira-Noriega (2020), Patagonian region of Argentina was not included as suitable habitat for
302 *D. suzukii* in our model and that of Ørsted and Ørsted (2019). Another major difference
303 between our model and those of Santos et al (2017) and Reyes and Lira-Noriega (2020) is that
304 their models predicted a large extent of eastern India as suitable habitats for *D. suzukii*.
305 However, according to our model, the suitability was more prominent in far north, and also in
306 some parts of Western Ghats in southern India. Although similar in many aspects of predicted
307 distributions, our model differed notably from that of Ørsted and Ørsted (2019) in predicting
308 the east-west continuity of potential distribution of *D. suzukii* in United States as our model
309 showed a discontinuous distribution of potential habitats.

310 For obvious reasons, choosing biological control agents for *D. suzukii* that have niche
311 preferences similar to those of the fly will be helpful (Robertson, Kriticos & Zachariades, 2008;
312 Olfert et al., 2016; Tapa-Yotto et al., 2021a,b) in the global-scale biological control challenge.
313 Matching the climatic niche requirements of pest and parasitoid will increase chances of long-
314 term establishment of the parasitoid across key regions (Robertson, Kriticos & Zachariades,
315 2008), resulting in more successful management via biological control. Despite various previous
316 studies modeling the climatic niche of *D. suzukii*, to the best our knowledge, no effort has been

317 made so far to study the potential distribution of climatic niches of any parasitoid of *D. suzukii*
318 in combination with analyses of the climatic niche of the fly pest.

319 Range expansion of *D. suzukii* in Europe and North America occurred after initial
320 outbreaks in California, Spain, and Italy, all in 2008 (Rota-Stabelli, Blaxter & Anfora, 2013;
321 Asplen et al., 2015). Niche filling related to absence of competitors or natural enemies, high
322 adaptability to temperate climates, high dispersal ability, and high reproductive output, are
323 major factors contributing to the unprecedented invasion of *D. suzukii* (Rota-Stabelli, Blaxter &
324 Anfora, 2013). As niche filling is an important factor, assessing the geographic distribution of
325 climatic niches of *D. suzukii* becomes an indispensable step in biological control programs, as it
326 can provide an initial estimate of the geographic limits for successful parasitoid release
327 (Puppato et al., 2020). Development of niche models for parasitoids, and identification of
328 geographic regions exhibiting overlapping climatic niches between pest and parasitoid, further
329 delimits regions for parasitoid release, making field trials involving elaborate and time-
330 consuming experiments more economical (Sun et al., 2017).

331 In its native distributional areas, *Leptopilina japonica* is one of most abundant potential
332 parasitoids of *D. suzukii* (Kimura & Novković, 2015; Puppato et al., 2020); its occurrence in
333 Europe (Puppato et al., 2020) and North America (Abram et al., 2020, 2022; Beers et al., 2022)
334 was identified only recently. Previous laboratory experiments in the United States indicated
335 that South Korean *L. japonica* strains attacked the North American strains of *D. suzukii* readily
336 (Daane et al., 2016), supporting at least in part the suitability of *L. japonica* as a biocontrol
337 agent for *D. suzukii*. Although occurrence records of *L. japonica* were scarce, our modeled
338 climatic niche for *L. japonica* overlapped broadly with that of *D. suzukii* in known-invaded

339 regions (Figure 2-4), meeting one of the major ecological requirements for a ‘natural enemy
340 species’ to be a candidate biological control agent (Robertson, Kriticos & Zachariades, 2008;
341 Olfert et al., 2016). The two-species model developed for gaining insight into the biotic
342 interactions shaping the potential geographic distribution of *L. japonica* underperformed
343 compared to the climate-only model. These results thus contrasted with previous findings
344 highlighting the importance of including biotic predictors in ecological niche modeling
345 procedures to improve model performance (Araújo & Luoto, 2007; Giannini et al., 2013;
346 Dormann et al., 2018; Simões & Peterson, 2018; Bebber & Gurr, 2019; Ashraf, Chaudhry &
347 Peterson, 2021).

348 We recommend a niche-based, target-oriented prioritization approach in designing
349 biological control programs aimed at *D. suzukii*. In Europe, three interlinked factors, (1) recently
350 recorded occurrences (Puppato et al., 2020), (2) predicted suitability in 17 European countries
351 (~39% of European countries) with biocontrol coverage of >80% at both thresholds ($E = 5\%$ and
352 $E = 10\%$) (Table 2), and (3) increasing consumer preference towards organic fruits (Murphy et
353 al., 2022), make *L. japonica* a promising parasitoid for control of *D. suzukii*. In the remaining
354 European countries, in particular those exhibiting biocontrol coverage <50%, we suggest extra
355 care in defining appropriate geographic boundaries for *L. japonica* release plans (Table 2). In the
356 United States and Canada, the potential distribution of *L. japonica* overlapped only one-third of
357 *D. suzukii*'s potential distributional area, demanding strict site-specific release planning. Site-
358 specific pest management utilizing pest distributional information is preferred over uniform
359 pest management (Park, Krell & Carroll, 2007). However, for effective site-specific biological
360 control of pests, not only the pest distributional information but also the niche overlap

361 between pest and parasitoids must be taken into account. Irrespective of the biocontrol
362 coverage in *D. suzukii* invaded regions, any *L. japonica* release strategy has to rely strictly on
363 specific details of both site and niche considerations.

364 In conclusion, this study illustrates a cost-effective pre-assessment strategy that can be
365 applied to any biological control management program before beginning the labor-intensive,
366 time-consuming, and expensive field experiments. Availability of a greater number of
367 occurrence records of *L. japonica* would further enhance the understanding of the
368 distributional potential of this potential biocontrol agent worldwide.

369

Figure 1

Distributional information

Representation of the known distribution of the pest *Drosophila suzukii*, and parasitoid *Leptopilina japonica* based on occurrence databases and published literature.

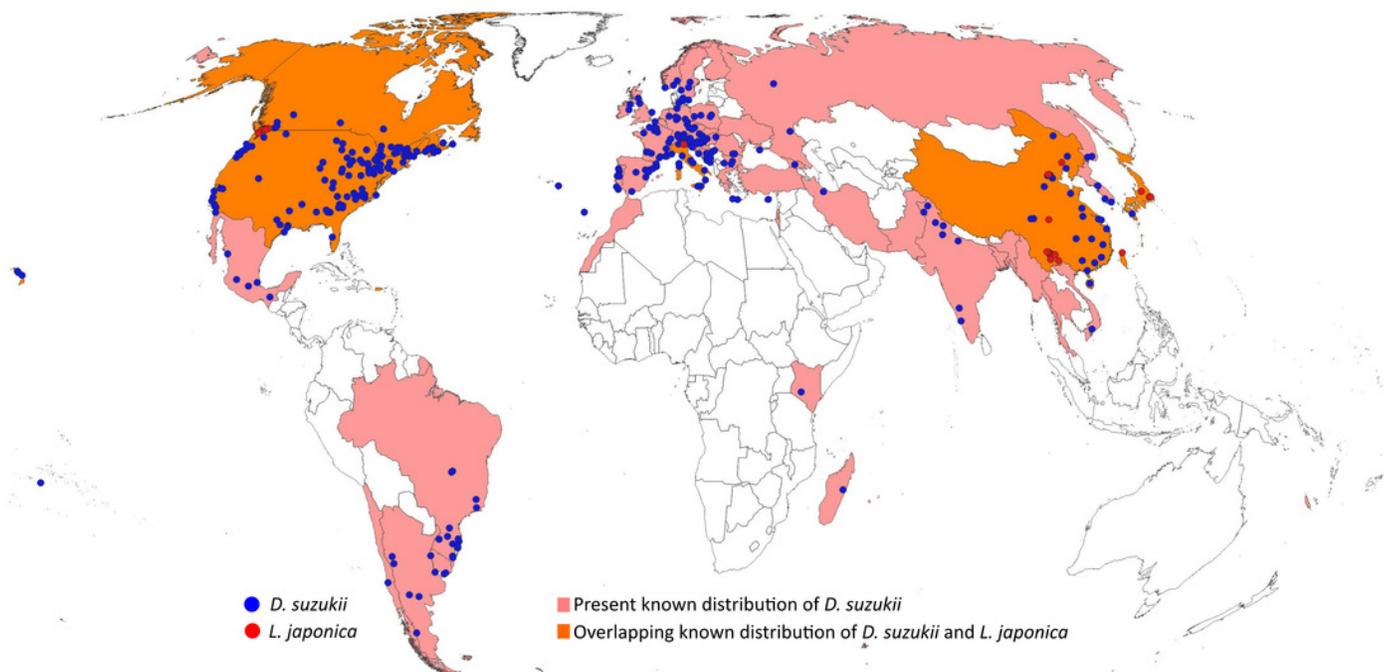

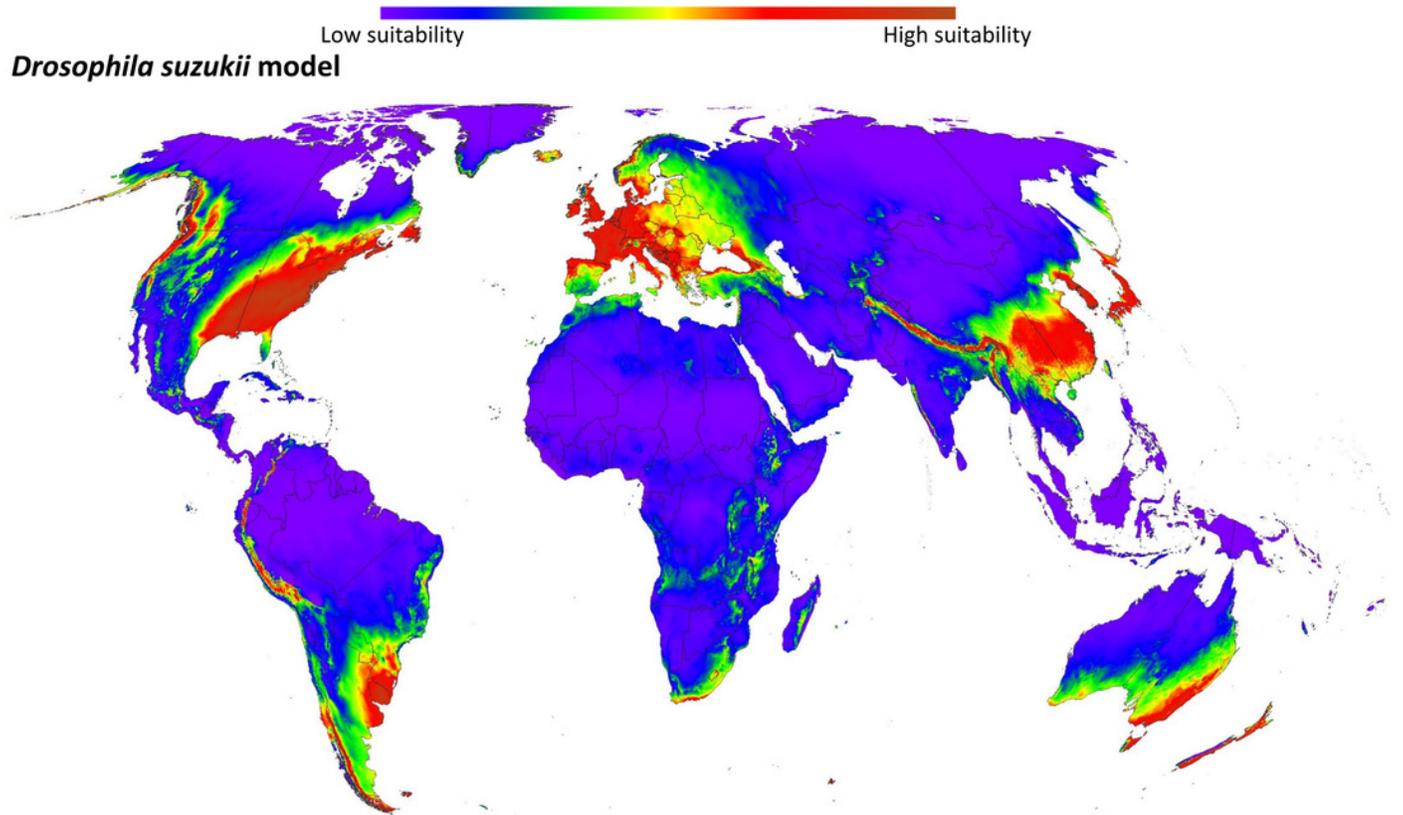

Figure 2

Ecological niche models

Predicted distribution of potential distributional areas of *Drosophila suzukii* and *Leptopilina japonica* across the world

***Leptopilina japonica* model**

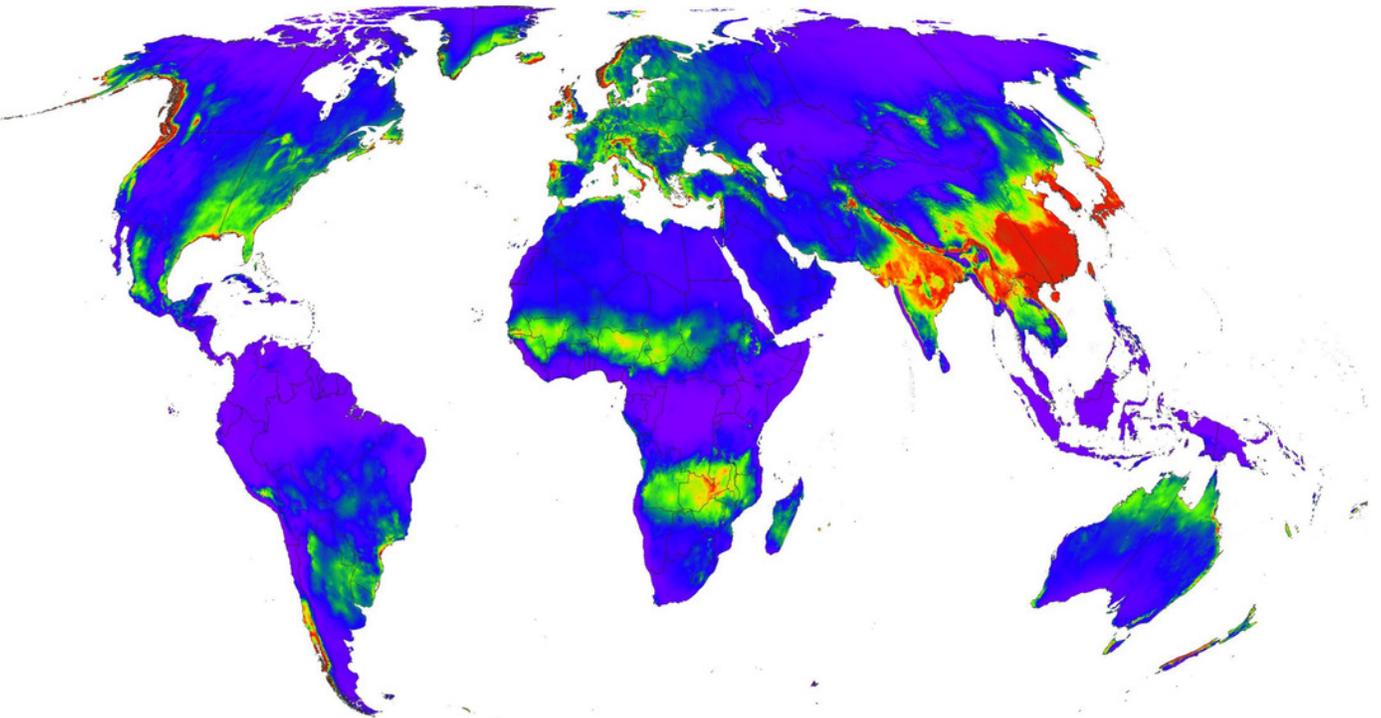

Figure 3

Binary models

Modeled suitable areas for *Drosophila suzukii* and *Leptopilina japonica* based on thresholding at $E = 5\%$ and $E = 10\%$

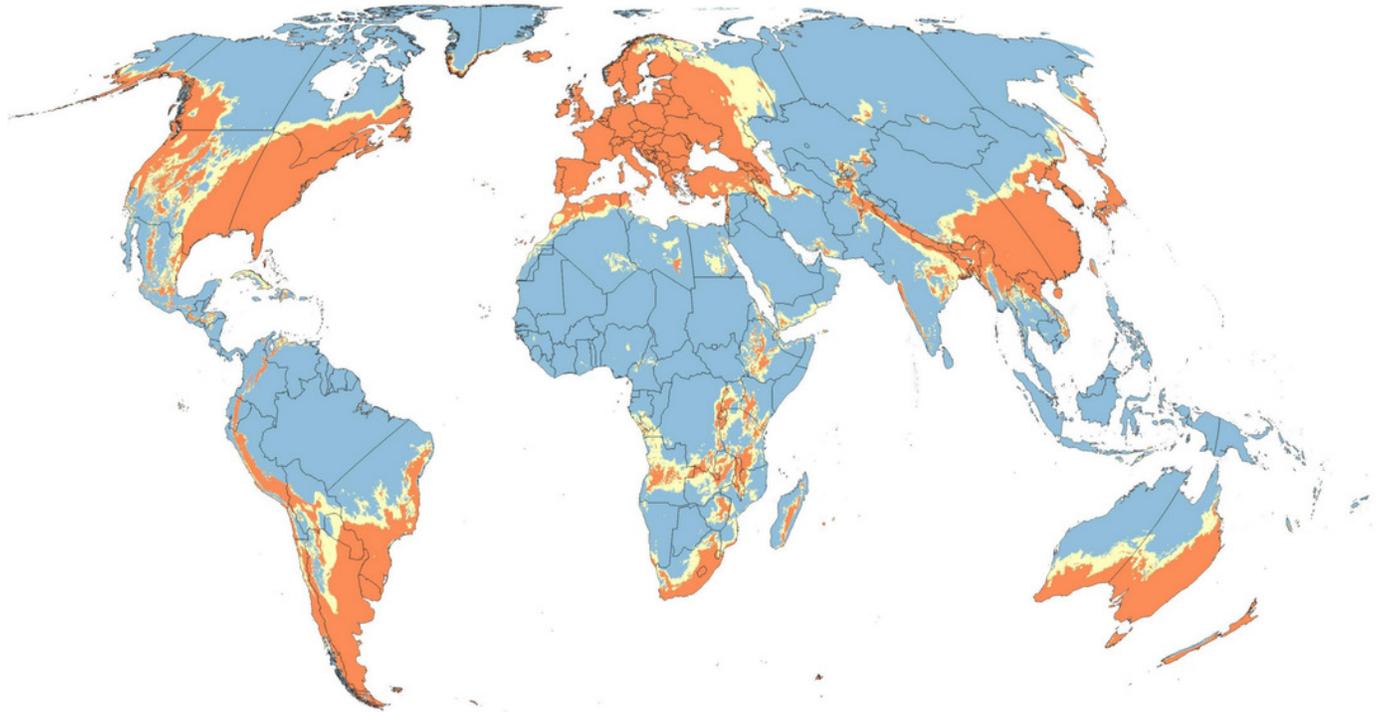

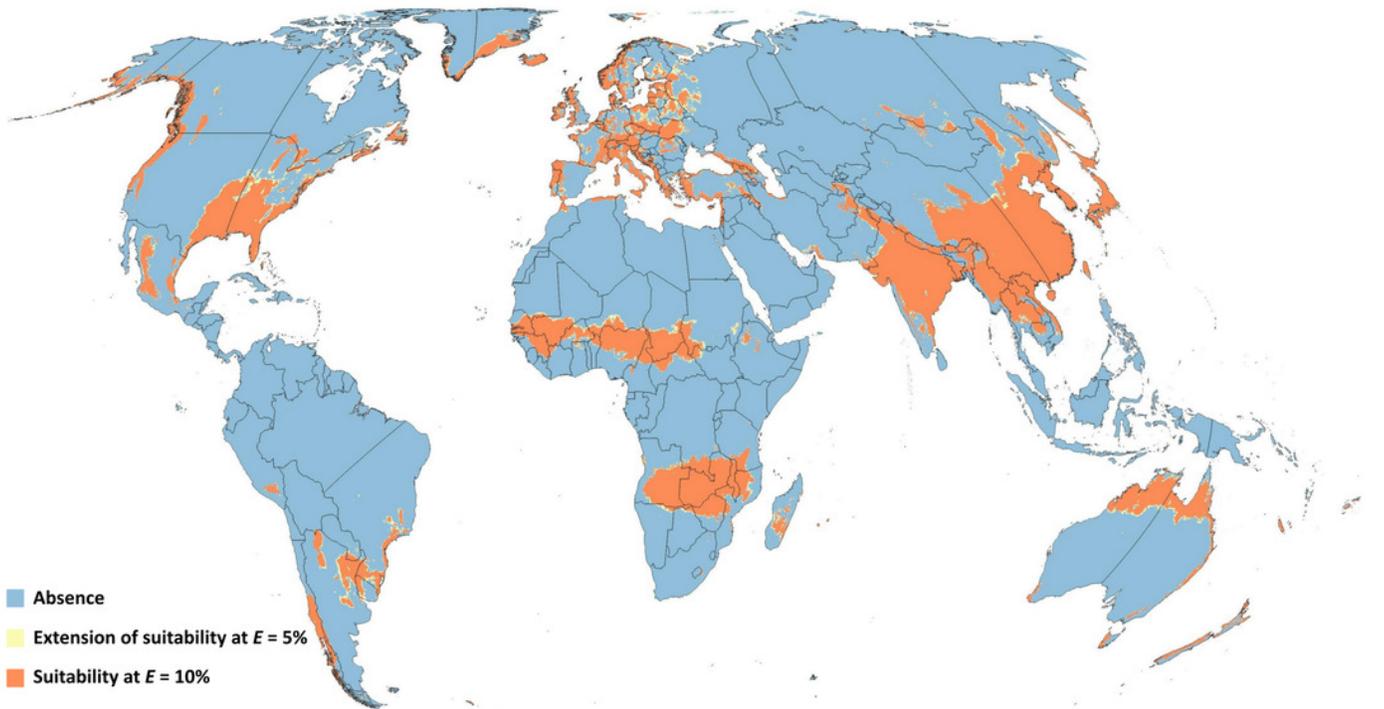

Drosophila suzukii* binary model**Leptopilina japonica* binary model**

Figure 4

Overlapped niches

Representation of modeled suitable biocontrol areas in terms of overlapping climatic niches of *Drosophila sukuzii* and *Leptopilina japonica*

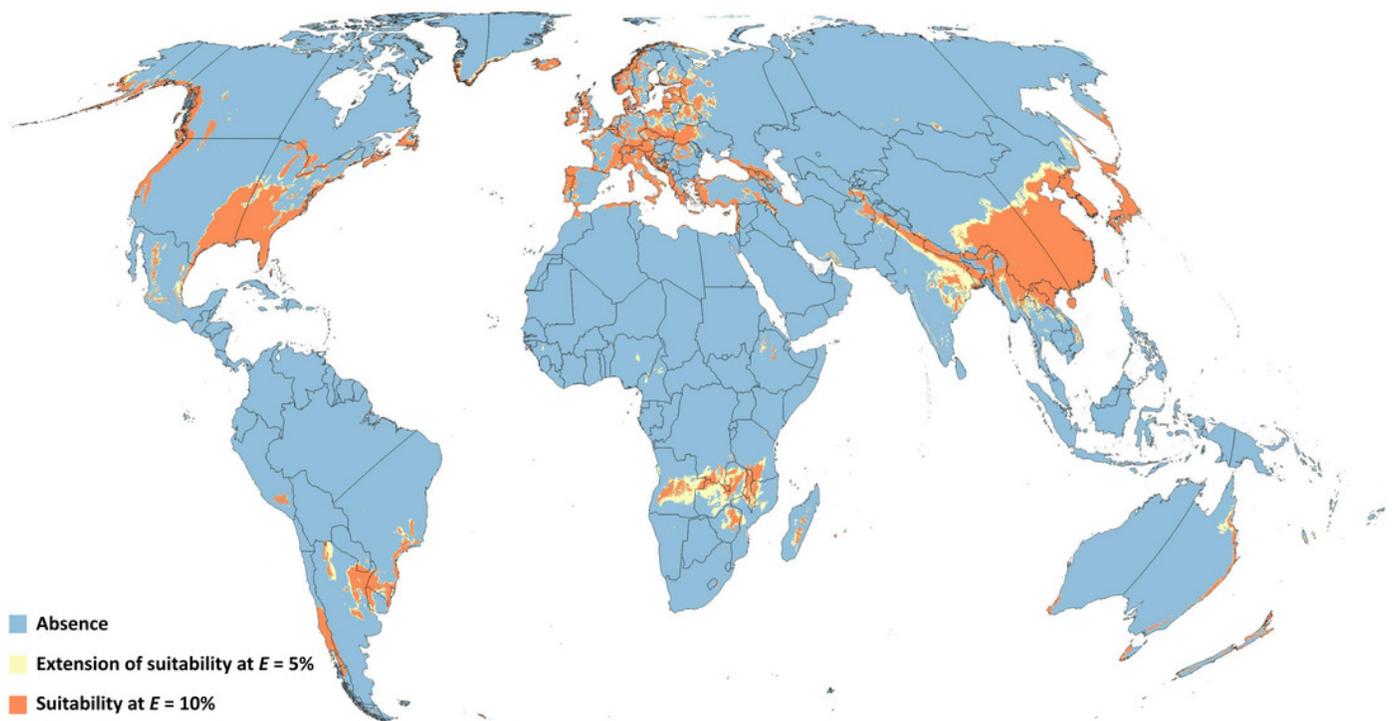

Table 1 (on next page)

Model evaluation

Performance summary of pest, parasitoid, and two-species parasitoid models

Species	Models	Mean AUC ratio	OR	AICc
<i>Leptopilina japonica</i>	M_2.0_F_lp_Set_7	1.76	0.00	839.55
<i>Drosophila suzukii</i>	M_0.6_F_lq_Set_4	1.47	0.04	8365.78
Two-species	M_1.0_F_l_Set_6	1.79	0.07	798.08

OR-Omission rate. Name of models indicates the details of regularization multiplier value, feature class and environmental dataset.

Table 2 (on next page)

Biocontrol coverage

Modeled potential for biocontrol coverage corresponding to the potential distribution of pest (*Drosophila suzukii*) and parasitoid (*Leptopilina japonica*). E indicates thresholding level

Country	Pest distribution (km ²)		Overlapping wasp distribution (km ²)		Biocontrol coverage (%)	
	<i>E</i> = 5%	<i>E</i> = 10%	<i>E</i> = 5%	<i>E</i> = 10%	<i>E</i> = 5%	<i>E</i> = 10%
