The response of plants to waterlogging stress is a complex process, with ethylene playing a crucial role as a signaling molecule. However, it remains unclear how ethylene is initially triggered in response to waterlogging stress when plants are continuously waterlogged for less than 12 hours. Here, we have shown that ethylene-induced autophagy leads to the degradation of damaged mitochondria (the main organelles producing reactive oxygen species (ROS)) to reduce ROS production during oxidative stress in *Arabidopsis thaliana*, which improves the survival rate of root cells in the early stages of waterlogging stress. Waterlogging stress activated ethylene-related genes, including *ACO2*, *ACS2*, *ERF72*, *ERF73*, and *EIN3*, and ethylene content of plants increased significantly within 24 h of continuous waterlogging. As stress duration increased, increased amounts of ROS accumulated in *Arabidopsis thaliana* roots, and the activity of antioxidant enzymes initially increased and then decreased. Concurrently, the level of ethylene-induced autophagy, which participates in antioxidant defense, is higher in wild-type plants than in the octuple *acs* mutant *cs16651* (*acs2-1/acs4-1/acs5-2/acs6-1/acs7-1/acs9-1/amiRacs8acs11*). Exogenous application of 1-aminocyclopropanecarboxylic acid (ACC), resulted in a more pronounced manifestation of autophagy in the stele of *Arabidopsis* roots. Compared with the waterlogging treatment group or the ACC treatment group, the waterlogging + ACC treatment can induce autophagy to occur earlier and expand the autophagic range to the epidermis of *Arabidopsis thaliana* roots. Overall, our results provide insight into the important role of ethylene-induced autophagy in enhancing the antioxidative capacity of *Arabidopsis thaliana* during the early stages of waterlogging stress. Furthermore, we suggest ethylene as a potential candidate for mitigating the deleterious effects caused by waterlogging in *Arabidopsis thaliana*.

## Abstract

The response of plants to waterlogging stress is a complex process, with ethylene playing a crucial role as a signaling molecule. However, it remains unclear how ethylene is initially triggered in response to waterlogging stress when plants are continuously waterlogged for less than 12 hours. Here, we have shown that ethylene-induced autophagy leads to the degradation of damaged mitochondria (the main organelles producing reactive oxygen species (ROS)) to reduce ROS production during oxidative stress in *Arabidopsis thaliana*, which improves the survival rate of root cells in the early stages of waterlogging stress. Waterlogging stress activated ethylene-related genes, including *ACO2*, *ACS2*, *ERF72*, *ERF73*, and *EIN3*, and ethylene content of plants increased significantly within 24 h of continuous waterlogging. As stress duration increased, increased amounts of ROS accumulated in *Arabidopsis thaliana* roots, and the activity of antioxidant enzymes initially increased and then decreased. Concurrently, the level of ethylene-induced autophagy, which participates in antioxidant defense, is higher in wild-type plants than in the octuple *acs* mutant *cs16651* (*acs2-1/acs4-1/acs5-2/acs6-1/acs7-1/acs9-1/amiRacs8acs11*). Exogenous application of 1-aminocyclopropanecarboxylic acid (ACC), resulted in a more pronounced manifestation of autophagy in the stele of *Arabidopsis* roots. Compared with the waterlogging treatment group or the ACC treatment group, the waterlogging + ACC treatment can induce autophagy to occur earlier and expand the autophagic range to the epidermis of *Arabidopsis thaliana* roots. Overall, our results provide insight into the important role of ethylene-induced autophagy in enhancing the antioxidative capacity of *Arabidopsis thaliana* during the early stages of waterlogging stress. Furthermore, we suggest ethylene as a potential candidate for mitigating the deleterious effects caused by waterlogging in *Arabidopsis thaliana*.

## Introduction

During the growth process, plants face various abiotic stressors such as drought, salt, and flooding stress. These stressors can cause energy and carbohydrate crises in plants, limit plant growth and development, and lead to a decline in crop yield and quality (Zhu, 2016). Soil

flooding creates a hypoxic environment (Phukan, Mishra & Shukla, 2016). Plants undergo two important changes during waterlogging: an increase in ROS and the gaseous plant hormone ethylene. Waterlogging-tolerant plants use changes in O<sub>2</sub>, ROS, and ethylene as signals to induce adaptive processes (Voeselek & Sasidharan, 2013).

The ethylene content in *Arabidopsis* root tips increases rapidly after submergence (Perata, 2020). Ethylene insensitive protein 3 (EIN3) is an important transcription factor that mediates the ethylene response (Xie et al., 2015; Hartman et al., 2019). Multiple studies have shown that ethylene is critical in hypoxia and metabolic adaptation during plant flooding and can adapt to hypoxia by enhancing the stability of ethylene-responsive factor family VII (ERF-VIIs) (Chen et al., 2015a; Yao et al., 2017; Hartman, Sasidharan & Voeselek, 2021). ERFs are involved in hormones, development, metabolic adaptation, and abiotic stress responses. Ethylene response factor 74 (ERF74) can activate the expression of respiratory burst oxidase homolog D (RbohD) by binding to the promoter of RbohD to induce ROS production (Yao et al., 2017).

ROS homeostasis in plants modulates metabolic responses, contributes to morphological fitness, and increases the likelihood of plant survival under flooding stress (Yeung, Bailey-serres & Sasidharan, 2019). In maize, ethylene can upregulate the expression of ZmEREB180, which is closely related to waterlogging tolerance (Yu et al., 2019).

ROS, as metabolic byproducts and secondary messengers, play an important role in growth, development, and programmed cell death in response to the environment (Suzuki et al., 2011; Liu & He, 2016). In higher plants, ROS are produced in various subcellular structures during plant growth and development, including mitochondrial respiration, chloroplast photosynthesis, peroxisomes, and NADPH oxidase (respiratory burst oxidase homologues) located on the plasma membrane (Waszczak, Carmody & Kangasjärvi, 2018). During waterlogging, the formation of ROS is a common physiological process in plants (Mu et al., 2007; Iskandar & Mahmood, 2010; Parlanti et al., 2011). When plants are exposed to various environmental stressors, the content of ROS in plants increases, causing damage to lipids, proteins, and DNA (Gill & Tuteja, 2010; Wang et al., 2018a). Plants have evolved corresponding antioxidant systems to remove excess ROS and protect them from oxidative damage. For example, superoxide dismutase (SOD) converts superoxide anion radicals (O<sub>2</sub><sup>-</sup>) into H<sub>2</sub>O<sub>2</sub> and catalase (CAT) converts H<sub>2</sub>O<sub>2</sub> into H<sub>2</sub>O and O<sub>2</sub>. Ascorbate peroxidase (APX) relieves the toxic side effects of H<sub>2</sub>O<sub>2</sub>, and glutathione reductase (GR) participates in metabolic regulation and antioxidant processes (Morel & Barouki, 1999; Foyer & Noctor, 2003; Iskandar & Mahmood, 2010).

Autophagy is a conserved process that decomposes misfolded proteins or toxic substances and damaged organelles into biological macromolecules (such as amino acids and fatty acids) for recycling to maintain eukaryotic growth, development, and survival (Li & Vierstra, 2012; Wang, Mugume & Bassham, 2018). Normally, autophagy occurs at very low levels, but the process is activated under various environmental cues (Marshall & Vierstra, 2018). Studies have shown that to resist waterlogging stress, autophagy can balance energy and ensure basic metabolism in plants (Chen et al., 2015b). Mitophagy is an adaptive regulation that is critical for reducing ROS levels and preventing cell death when mammalian cells are chronically hypoxic (Zhang et al., 2008). Although mitophagy is less frequently reported in plants, it can recycle damaged mitochondria during abiotic stress (Ma et al., 2021; Nguyen & Lazarou, 2021). Studies have shown that autophagy plays an important role in ethylene-mediated drought tolerance. Autophagy induced by ROS levels, dependent on mitochondrial alternating oxidase (AOX), is critical for ethylene-mediated drought tolerance in tomato. ERF5 binds to the promoters of autophagy-related genes (ATGs) ATG8d and ATG18h and is critical for ethylene-induced autophagosome formation in tomato under drought conditions (Zhu et al., 2018). Another study showed that ethylene mediates the induction of GmATG8i in soybean plants under starvation stress (Okuda et al., 2011). Ethylene signaling is involved in autophagy in response to stress by inducing ATGs gene expression and altering ROS levels, but only in energy crises caused by insufficient carbohydrate reserves (Hartman, Sasidharan & Voesenek, 2021). Ethylene and ROS can enhance hypoxia resistance in wheat seedlings by controlling morphological adaptation and metabolic responses (Yamauchi et al., 2014). Under hypoxic conditions, root cortex cells induce RbohD translation to increase ROS production, which plays an important role in ethylene-induced stomatal formation in rice roots (Yamauchi et al., 2017). Some studies suggest that ethylene plays an important role in the induction of autophagy, thereby improving the survival rate under flooding and hypoxia stress (Hartman, Sasidharan & Voesenek, 2021). While we speculate that ethylene may be involved in hypoxia-mediated autophagy under waterlogging stress, we also propose that in plants, mitophagy can be activated by ethylene-dependent ROS production, which may have a negative regulatory effect on ROS production.

## Materials & Methods

### Experimental materials and growth conditions

The wild-type (WT) *Arabidopsis* used in this study was Columbia-0 (Col-0). *Rbohdf*, octet *acs* mutant (*CS16651*, *acs2-1/acs4-1/acs5-2/acs6-1/acs7-1/acs9-1/amiRacs8acs11*), *ein2-5*, *p35S::EIN3-GFP*, and *ein3/eil1-1* (Lv et al., 2018) were presented by Professor Ding Zhaojun of Shandong University. *ATG8epro::GUS* (Guan et al., 2019) was obtained from our laboratory. Before germination, the seed surface was sterilized with 5% sodium hypochlorite NaClO + 0.05% TWEEN-20 solution for 12 minutes, washed with sterile water 5 times, and vernalized at 4 °C for 3 days. Then, the seeds were sown on 1/2 MS medium and cultured in a growth room (16/8 h light/dark at 22 °C /19 °C and 70% relative humidity) for 7 days.

## Experimental design

Waterlogging Treatment (WL): According to the method (Wang et al., 2020), the waterlogging treatment was carried out with slight modification. Seven-day-old seedlings were transferred from 1/2 MS medium to a Petri dish filled with distilled water and placed in a growth chamber under controlled conditions so that the roots of *Arabidopsis* seedlings are completely immersed in distilled water. The leaves were kept 0.5 cm above the water surface.

ACC Treatment (ACC): Seven-day-old seedlings were transferred to 1/2 MS medium supplemented with 0.05 μM ACC (Sigma).

WL+ACC Treatment (WL+ACC) : After diluting the ACC stock solution to a concentration of 0.05 μM with distilled water, 7-day-old seedlings were transferred from 1/2 MS medium to 1/2 MS medium containing 0.05 μM ACC. The seedlings were placed in a growth chamber with their roots completely submerged in the 0.05 μM ACC solution, while their leaves were kept 0.5 cm above the water surface. All treatments were performed in three independent biological replicates.

## Ethylene measurements

The method (Sun et al., 2017) was slightly modified to determine the ethylene content, as described above. Seven-day-old seedlings were randomly selected, with 30 of them transferred to a 25 mL vial containing 3 mL of liquid MS medium. The vial was then sealed with a rubber stopper and left for 12 h at 22°C before measuring the ethylene content. A gas-tight syringe was used to draw 1 mL of the upper air sample from each bottle through the septum, which was immediately injected into a GDX-502 column (2 m \* 1/8 inch) and flame ionization detector (FID) gas chromatograph (Agilent 7890BGC, Agilent Technologies, USA). Nitrogen (N<sub>2</sub>) was used as the carrier gas and separation was performed at 90 °C. The ethylene peak area was

integrated with Agilent ChemStation, and the result was expressed as the average relative ethylene production (%) of each treatment.

## ROS assays

Nitro Blue Tetrazolium Chloride monohydrate (NBT) and 3,3'-diaminobenzidine (DAB) staining were performed according to the method (Kumar et al., 2014) with minor modifications. Seven-day-old seedlings were immersed in 2 mg/mL NBT solution (Sigma) for 15 min and then washed 3 times with distilled water. The seedlings were photographed with a differential interference microscopy (Nikon 80i Eclipse) and the staining intensity was analyzed using Image J software to detect  $O_2^-$  content. To detect  $H_2O_2$  content, the seedlings were immersed in a 1 mg/mL DAB solution (Sigma) for 2 h, washed 3 times with distilled water, and then photographed with a differential interference microscopy (Nikon 80i Eclipse) and the staining intensity was analyzed using Image J software to detect  $H_2O_2$  content. ROS level was detected by  $H_2DCF$ -DA staining. Seven-day-old seedlings were immersed in 10  $\mu$ M  $H_2DCF$ -DA solution for 30 minutes and then washed 3 times with distilled water. The seedlings were photographed with a laser scanning confocal microscopy (TCS SP8, Leica) using 488 nm excitation light and 525 nm emission light, and the fluorescence intensity was analyzed using Image J software.

## Observing autophagosomes in roots

To detect autophagy levels, seven-day-old seedlings were immersed in a 0.05 mM Monodansylcadaverine (MDC) solution (Sigma-Aldrich, 30432), gently shaken, and protected from light for 10 minutes. The seedlings were then washed twice with phosphate-buffered saline (PBS) for 5 min each. Finally, the seedlings were photographed using a laser scanning confocal microscope (TCS SP8, Leica) with an excitation wavelength of 345 nm and an emission wavelength of 455 nm.

For the GUS staining assay, seven-day-old ATG8<sup>pro::GUS</sup> seedlings were soaked in 10 mL of GUS staining solution (0.1 M PBS (pH 7.0), 5 mM potassium ferricyanide, 5 mM potassium ferrocyanide, 0.1% Triton X-100, 0.5 mg/mL X-Gluc) for 10 min in a vacuum system. The samples were then incubated in 75% ethanol for 1 h at 37°C in the dark. Finally, the seedlings were photographed using differential interference microscopy (Nikon 80i Eclipse).

## Antioxidant enzyme activity measurement

CAT enzyme activity was calculated by measuring the absorbance at 405 nm, and SOD enzyme activity was calculated by measuring the absorbance at 550 nm. The roots of seven-day-old seedlings were collected and weighed, and the enzymatic activity of CAT and SOD was

examined using a kit (Jiancheng Institute of Bioengineering, Nanjing) according to the manufacturer's instructions.

### RNA extraction and qRT-PCR

TRIzol reagent (Invitrogen, 15596026) was used to extract total RNA from the fresh roots of seven-day-old *Arabidopsis* seedlings. The cDNA template was synthesized using the PrimeScript RT kit (Takara, RR047A), and qRT-PCR was performed using the Hieff® qPCR SYBR Green Master Mix (Shanghai Yisheng Biotechnology Co., Ltd., China) according to the manufacturer's instructions. The qRT-PCR primer sequences are provided in Appendix S1. The AtACTIN2 gene was used as an internal control, and relative gene expression was calculated using the  $2^{-\Delta\Delta CT}$  method.

### Transmission Electron Microscopy

Prepare TEM samples with minor modifications according to the method (Guan et al., 2019). *Arabidopsis* root meristems were selected and immediately cut into 3 mm long small segments, then fixed with 2.5% glutaraldehyde in 0.1 M PBS (pH 7.0) at 4 °C for 12 h. The samples were then rinsed 3 times with 0.1 M PBS for 10 min each time. After being fixed with 1% osmium tetroxide for 3 h, the samples were again rinsed 3 times with 0.1 M PBS for 10 min each time. The samples were dehydrated in a graded acetone series of 30%, 50%, 70%, 80%, 90%, and 100% (three times each, for 15 min per step) and embedded in SPI-PON 812 resin. Ultrathin sections (70 nm) were prepared on an ultramicrotome (Leica EM UC7, Germany) with a diamond knife and collected on Formvar-coated grids. To enhance the image contrast, the sections were stained with 2% uranyl acetate and lead citrate. Finally, the cell ultrastructure was observed using a transmission electron microscopy (Hitachi H-7650, Japan).

### Cell viability test

Seven-day-old seedlings were soaked in 10 mL propidium iodide (PI) solution for 10 min and photographed with a laser scanning confocal microscopy (TCS SP8, Leica) using an excitation wavelength of 488 nm and an emission wavelength of 660 nm. Seven-day-old seedlings were soaked in 20 μM fluorescein diacetate (FDA) solution and treated at 37°C for 10 min. Subsequently, the seedling were photographed with a laser scanning confocal microscopy (TCS SP8, Leica) using an excitation wavelength of 480 nm and an emission wavelength of 530 nm.

### Statistical Analysis

All the experiments were performed in triplicate or more unless otherwise indicated, and the results reported in this study are presented as the mean ± SD. Data were analyzed by a two-tailed

Student's t-test using GraphPad Prism 7.0. The significance levels are \* $P < 0.05$ , \*\* $P < 0.01$ , and \*\*\* $P < 0.001$ .

# Results

## Ethylene responds to waterlogging stress

To investigate the physiological regulation of ethylene in plants under waterlogging conditions, an experiment was conducted to screen the ACC concentration, which revealed that 0.5  $\mu\text{M}$  ACC significantly inhibited the growth of *Arabidopsis* roots (Fig. 1A). Seven-day-old WT seedlings were then subjected to ACC, WL, and WL+ACC treatments. The root lengths of the treated groups were all significantly shorter compared to the control group (Fig. 1B), indicating that both WL and ACC treatments negatively affected root growth. To analyze the changes in ethylene content in plants after waterlogging, the relative ethylene content was measured at different time points in the WT (Fig. 1C). The ethylene content in the WL treatment group increased significantly at 24 h compared to the control group. The WL+ACC treatment group had the highest ethylene content at 8 h compared to the control group. The ethylene content in the ACC treatment group varied significantly at 4 h and reached its maximum at 12 h. These results demonstrate that the ethylene content in *Arabidopsis* can be increased under waterlogging stress. To investigate the molecular mechanism of plant ethylene response to waterlogging stress, the expression levels of genes *ACO2*, *ACS2*, *ERF72*, *ERF73*, and *EIN3*, which are closely related to ethylene signaling, were analyzed. The relative expression levels of these genes were significantly increased in the WL and WL+ACC treatment groups, indicating that waterlogging stress can enhance the expression of ethylene signaling (Fig. 1D). *ERF72* and *ERF73*, which are ethylene-responsive factors associated with hypoxic stress, were significantly upregulated in the WL and WL+ACC treatment groups. *ACO2* and *ACS2*, which are involved in the conversion of ACC to ethylene, were significantly upregulated in the early stages of the ACC treatment group. *EIN3* is an important gene downstream of the ethylene signaling pathway that is involved in ethylene-induced biological responses. The *p35S::EIN3-GFP* plants were observed using laser confocal microscopy under different experimental treatments. Compared to the control group, the fluorescence signals of the WL and ACC treatment groups were significantly enhanced. Interestingly, the fluorescence intensity of the WL+ACC group decreased at 12 h compared to the WL and ACC-treated groups (Fig. S1). Therefore, both WL and ACC treatments can induce *EIN3* protein synthesis and regulate related physiological changes.

## Ethylene induces partial ROS production and activates antioxidant enzyme system

Previous studies have shown that waterlogging stress can increase ROS accumulation in *Arabidopsis* roots (Guan et al., 2019). To determine whether there is a regulatory relationship between ethylene and ROS under waterlogging stress, we used  $\text{H}_2\text{DCFH-DA}$ , DAB, and NBT staining methods to detect the contents of ROS,  $\text{H}_2\text{O}_2$ , and  $\text{O}_2^{\cdot-}$  in WT roots after different treatments (Fig. 2A). Compared to 0 h, the ROS content in the WL treatment group was significantly increased at 24 h, and the ROS content in the ACC treatment group reached its maximum at 12 h (Fig. 2A-d). The contents of ROS,  $\text{H}_2\text{O}_2$ , and  $\text{O}_2^{\cdot-}$  in ACC and WL+ACC

treatment groups were significantly increased. Compared to the WL and ACC treatment groups, the WL+ACC treatment group showed an earlier and more significant increase in ROS and H<sub>2</sub>O<sub>2</sub> content (Fig. 2A-d and 2A-f). To further demonstrate the role of ethylene in inducing ROS, *cs16651* mutants were submerged, and the ethylene content was measured. The ethylene content produced by *cs16651* mutants under waterlogging stress for 12 hours showed no significant difference compared to 0 h (Fig. S2B). With an increase in waterlogging time, the H<sub>2</sub>O<sub>2</sub> content of the *cs16651* mutants continuously increased (Fig. S2A). The H<sub>2</sub>O<sub>2</sub> content was significantly lower than that of the WT in the same treatment group (Fig. S2a). The H<sub>2</sub>O<sub>2</sub> content in *ein3/eil1-1* plants was continuously increased (Fig. S2A). The H<sub>2</sub>O<sub>2</sub> content of *ein3/eil1-1* was significantly lower than that of the WL treatment group at the same time point in WT (Fig. S2a). RBOHD and RBOHF enzymes play important roles in ROS production. Under the waterlogging treatment, the ethylene content of *rbohdf* mutants was not significantly different from that of the WT at the same time point (Fig. S2B). In the 0-24 h waterlogging period, the H<sub>2</sub>O<sub>2</sub> content of the *rbohdf* mutants was lower than that of the WT in the same period but still produced a large amount of H<sub>2</sub>O<sub>2</sub> (Fig. S2A). These experiments further demonstrated that ethylene production in *Arabidopsis* promotes ROS generation under waterlogging stress. When plants are subjected to environmental stress, the balance of ROS is disrupted, affecting the normal metabolism and regulatory functions of plants. As the ROS content of the treatment group increased, the relative expression levels of the *CAT1* and *SOD1* genes were up-regulated (Fig. 2B). During the treatment period from 0 to 24 h, the activities of CAT1 and SOD1 in *Arabidopsis* were higher in the WL+ACC treatment group before 12 h (Fig. S3), indicating an earlier antioxidant role and ROS scavenging. The expression of the *GST1* gene was mainly up-regulated after 12 h of submersion, further exerting an antioxidant effect (Fig. 2B).

### Ethylene induces partial autophagy in stele under waterlogging stress

Autophagy is an important physiological process for plant energy reuse. ROS induce the production of autophagy when plants are waterlogged (Guan et al., 2019). *ATG8<sup>pro::GUS</sup>* seedlings were stained to observe the autophagy phenomenon in *Arabidopsis* roots under different treatments. In this study, autophagy appeared only in the stele in the ACC treatment group, and the number of autophagosomes gradually increased as the treatment was prolonged. In the WL treatment group, autophagy first occurred in the stele and then in the cortex. Autophagy appeared in the WL+ACC treatment group at 4 h in the stele and cortex, and the number of autophagosomes increased as the treatment time was extended (Fig. 3B). This experiment showed that autophagy in the root stele of *Arabidopsis* was induced by ethylene under waterlogging stress and that it occurred earlier than in the cortex. The MDC staining experiment showed that, compared to the control group, the number of autophagosomes in the three treatment groups of WT seedlings significantly increased after 24 h (Fig. 3D). Autophagy gene expression was significantly up-regulated in the ACC, WL, and WL+ACC treatment groups. However, during the period from 0 to 48 h, the relative expression levels of *ATG2*, *ATG5*, *ATG7*, *ATG8e*, and *ATG10* in the WL+ACC group appeared earlier than those in the WL group (Fig. 3A), further indicating that ethylene plays a role in inducing autophagy.

Ethylene-induced autophagy helps scavenge ROS produced by mitochondria

To further elucidate the relationship between ethylene and autophagy under waterlogging stress, autophagosomes were observed using MDC staining in *ein3/eil1-1*, *cs16651*, and *rbohdf* mutants after waterlogging (Fig. 4A). At 0 h, the number of autophagosomes in *ein3/eil1-1*, *cs16651* and *rbohdf* mutants was significantly lower than in the WT. However, the number of autophagosomes in *ein3/eil1-1* and *cs16651* mutants increased after 24 h of waterlogging and had no significant difference compared to the WT (Fig. 4A-a). To further explore the role of ethylene-induced autophagy in plant responses to waterlogging stress, WT seedlings were observed by transmission electron microscopy. In the control group, cell morphology was normal, and the cell wall, cell membrane, and mitochondrial morphology were intact. However, in the other treatment groups, with the increase in treatment time, most of the mitochondrial cristae were degraded, and some mitochondrial cristae had completely disappeared to form vacuolar structures, and the number of mitochondria gradually decreased (Fig. 4B). In the early stage of waterlogging (duration of continuous waterlogging less than 12 h), the WL+ACC treatment group produced more autophagosomes, and more damaged mitochondria were cleared earlier (Fig. 4A-b). After 24 h, vacuolated mitochondria in the cytoplasm were transported into vacuoles via the autophagy pathway (Fig. 4B). In addition, ethylene-related mutants *ACS2*, *ACS6*, *ein3/eil1-1*, and *cs16651* were waterlogged and then observed by electron microscopy (Fig. S4A), and the number of mitochondrial lesions in the mutants was higher when waterlogged for 4 h (Fig. S4a).

## Effects of waterlogging on root cell activity

To further explore the physiological changes of plants in response to waterlogging stress, WT seedlings were subjected to different treatments for PI staining and FDA staining to observe changes in root cell activity. PI staining showed that the root cells did not die significantly at 0-24 h (Fig. S5A), while FDA staining showed that the WL+ACC treatment group had higher cell viability than the WL treatment group in the early stage of waterlogging (Fig. S5B). However, long-term waterlogging stress leads to cell death and production of aerenchyma (Fig. S6).

## Discussion

### WL and ACC enhance ethylene signaling and negatively regulate *Arabidopsis* root growth

Climate disasters, such as waterlogging, drought and high temperature, often cause huge losses to agriculture. To resist waterlogging, plants have evolved complex mechanisms to adapt to

307 flooded environments. Studies have shown that ethylene not only rapidly accumulates in plant  
 308 tissues but also rapidly activates ethylene-induced physiological responses under flooding stress  
 309 conditions (Hartman, Sasidharan & Voesenek, 2021). Deep water induces the expression of  
 310 genes SNORKEL1 and SNORKEL2, which encode ethylene response factors involved in  
 311 ethylene signaling in rice and indirectly increase the length of rice internodes to enhance gas  
 312 exchange with water to adapt to flooding stress (Hattori et al., 2009). The interrelationship  
 313 between ethylene and ROS produced by plants under submerged conditions has been reported  
 314 less frequently in *Arabidopsis*. Compared to the control group, the ACC and WL-treated group  
 315 showed a significant increase in the number of damaged mitochondria in root cells (Fig. 4b),  
 316 which may have contributed to the relatively stunted growth observed in the treated seedlings  
 317 due to the crucial role of mitochondria in plant growth, suggesting negative regulation of root  
 318 growth by WL and ACC (Fig. 1B). It is speculated that the difference in root length between the  
 319 different treatment groups may be related to the ethylene content. To further explore the changes  
 320 in ethylene content after WL treatment, this study showed that the ethylene content of the WL  
 321 treatment group and ACC treatment group increased continuously with the treatment time.  
 322 Compared with the WL and ACC treatment groups, the ethylene content of the WL+ACC  
 323 treatment group did not increase significantly, but ethylene accumulated rapidly in the early  
 324 stage of treatment, reaching the maximum ethylene content at 8 h, and decreased after 12 h (Fig.  
 325 1C). Treatment with ACC in wheat seedlings can increase ethylene accumulation in the roots of  
 326 wheat seedlings and enhance the seedlings' tolerance to hypoxic conditions (Yamauchi et al.,  
 327 2014). It has also been reported that ethylene promotes root hair growth in *Arabidopsis* by  
 328 coordinating the activities of EIN3/EIL1 and RHD6/RSL1 (Feng et al., 2017). Salt and drought  
 329 stress can induce the expression of *MnEIL3*, which is a homologous gene of *ein3* in the roots and  
 330 shoots of mulberry, and *Arabidopsis* overexpressing *MnEIL3* showed enhanced tolerance to salt  
 331 and drought stress. Therefore, *MnEIL3* may play an important role in abiotic stress resistance  
 332 (Liu et al., 2019). Using different treatments in *Arabidopsis* EIN3-GFP plants, the expression of  
 333 the EIN3 protein in *Arabidopsis* was significantly up-regulated in the WL and ACC treatment  
 334 groups, but the EIN3 protein in the WL+ACC treatment group was not significantly up-regulated  
 335 at 24 h (Fig. S1). The qRT-PCR data of ethylene-related genes further demonstrated that WL  
 336 treatment and ACC treatment enhanced ethylene signaling (Fig. 1D). The above experimental  
 337 results indicate that ethylene may only accumulate and play a role in the early stage of  
 338 waterlogging stress, and that plants may undergo adaptive morphological changes in the later

stage of waterlogging to respond to stress. However, further studies are needed to determine which genes in the ethylene signaling pathway are involved in the regulation mechanism of plant waterlogging stress.

The relationship between ethylene, ROS and autophagy under waterlogging stress

Ethylene plays an important role in inducing autophagy and reducing ROS in organisms, thereby improving plant survival during flooding, hypoxia and reoxygenation stress (Hartman, Sasidharan & Voesenek, 2021). This study showed that ACC could rapidly induce ROS production in *Arabidopsis* under waterlogging stress (Fig. 2A). Additionally, studies have shown that the expressions of GmATG8i, GmATG4, GmACC synthase, GmERF, and GmEin3 are up-regulated in soybean seedlings under starvation stress, and starvation-induced autophagy may be partially mediated by ethylene signaling (Okuda et al., 2011). In this study, the expression of autophagy genes in *Arabidopsis* was up-regulated under waterlogging stress, and the phenomenon of autophagy first appeared in the vascular column. Over time, the phenomenon of autophagy was also found in the cortex of the root. Autophagy occurred only in the vascular column in the roots under ACC treatment. Compared with the WL and ACC-treated groups, the location and extent of autophagy in the WL+ACC treatment group were changed (Fig. 3B). Various abiotic stressors, such as high salt, high temperature, drought, low temperature, and hypoxia can induce autophagy, which plays an important role in balancing plant growth and enhancing stress tolerance (Qi, Xia & Xiao, 2021). Additionally, this study found that the number of autophagosomes in *ein3/eil1-1*, *cs16651*, and *rbohdf* mutants were significantly lower than that of the WT at 0 h (Fig. 4a). Therefore, we presumed that this explains the difference in the number of autophagosomes and ROS content between the mutants (Fig. S2A). Ethylene participates in the induction of ROS generation under waterlogging stress

Adventitious root formation is a response to plant adaptation to flooding stress, and ROS signaling is involved in ethylene- and auxin-induced adventitious root formation in flooded cucumber plants (Qi et al., 2020). However, the regulatory relationship between ethylene and ROS under waterlogging stress remains unclear. Previous studies in the laboratory have demonstrated that roots can produce ROS after waterlogging, and ROS is an important signal in response to plant programmed cell death (Guan et al., 2019). WL and ACC treatments induced ROS production in *Arabidopsis* (Fig. 2A). The ethylene content no longer increased after 12 h (Fig. 1C), and the ROS content began to decrease in the ACC treatment group. The ROS content is closely related to the ethylene content, and ACC treatment increased the  $O_2^-$  content in the

roots (Fig. 2A-c). *Arabidopsis* treated with AVG (2-aminoethoxyvinyl glycine (an inhibitor of ethylene synthesis)) had a reduced  $O_2^-$  content in the roots (Lv et al., 2018). After the WL+ACC treatment, the ethylene content and ethylene-related gene expression of WT plants decreased with the increase in treatment time (Fig. 1C and 1D), but the ROS content generally increased (Fig. 2A). The ethylene content of *cs16651* mutant plants did not change significantly under waterlogging (Fig. S2B) but still produced ROS (Fig. S2A). Therefore, under waterlogging conditions, ROS production has a certain dependence on ethylene, but the increase in ROS is not completely dependent on ethylene. The decrease in ethylene content may also be due to excessive ROS levels, which negatively regulates ethylene production. However, the relevant regulatory mechanisms need further study.

### Excessive accumulation of ROS activates the antioxidant system

Under normal circumstances, ROS in plants is maintained at a low level. When plants are subjected to external environmental stress, ROS content increases, affecting the normal metabolic microenvironment in plants (Wang et al., 2018b). Plants have evolved a relatively complete scavenging system to maintain ROS balance (Gill & Tuteja, 2010). The activities of SOD, CAT, APX, and GR of the submerged-tolerant varieties were higher than those of the non-submerged varieties after 8 days of flooding treatment on rice. Rice can enhance the tolerance of rice to flooding stress by improving its antioxidant system (Iskandar & Mahmood, 2010). In the present study, compared with the WL treatment group, the WL+ACC-treated group had relatively higher CAT1 and SOD1 enzymatic activities at the early stage of waterlogging (Fig. S3), and *CAT1* and *SOD1* expression also occurred earlier (Fig. 2B), suggesting that excessive ROS accumulation activates the antioxidant system. During the 24-48 h period, the plants were in a waterlogged state, and the antioxidant system was insufficient to remove excess ROS. The WL and WL+ACC treatment groups continued to accumulate ROS. However, further studies are needed to determine which genes are involved in the regulation of the antioxidant system and lead to the weakening of the activity of antioxidant enzymes.

### Conclusions

In summary, ethylene can promote ROS production in the early stages of waterlogging (duration of continuous waterlogging for less than 12 h), and plants remove excess ROS through the antioxidant system, resulting in a temporary decrease in ROS content. With prolonged waterlogging treatment time, the ROS content continued to rise (Fig. 2). When the antioxidant systems of CAT1 and SOD1 enzymes were insufficient to remove excess ROS in plants (Fig.

S3), ethylene induced partial autophagy production, accelerating mitochondrial degradation to reduce ROS production and alleviate oxidative damage in plants (Fig. 4B). The autophagy pathway accelerates the degradation of mitochondria, which is essential for plants to alleviate oxidative damage and increase survival in the early stage of waterlogging stress. However, long-term waterlogging exacerbates mitochondrial degradation, resulting in cell death and the production of aerenchyma (Fig. S6). The lack of adequate energy supply in plants leads to restricted growth and development, and the shortened root length is a response to waterlogging stress (Fig. 1B). The mechanism by which ethylene induces autophagy and accelerates mitochondrial degradation is not fully understood. It is unclear to what extent ROS accumulation induces autophagy to degrade mitochondria. Additionally, why does ethylene-induced autophagy first occur in the vascular column and then spread to the root cortex after waterlogging? These issues warrant further study and exploration.

## Acknowledgements

We thank Prof. Zhaojun Ding (Shandong University) for octet *acs* mutant (*CS16651*, *acs2-1/acs4-1/acs5-2/acs6-1/acs7-1/acs9-1/amiRacs8acs11*), *ein2-5*, *p35S::EIN3-GFP*, and *ein3/eil1-1* seeds. We would like to thank LetPub (www.letpub.com) for providing linguistic assistance during the preparation of this manuscript.
