Deforestation and subsequent land-use conversion has altered ecosystems and led to negative effects on biodiversity. To ameliorate these effects, nitrogen-fixing ( $N_2$ -fixing) trees are frequently used in the reforestation of degraded landscapes, especially in the tropics; however, their influence on ecosystem properties such as nitrogen (N) availability and carbon (C) stocks are understudied. Here, we use a 30-y old reforestation site of outplanted native  $N_2$ -fixing trees (*Acacia koa*) dominated by exotic grass understory, and a neighboring remnant forest dominated by *A. koa* canopy trees and native understory, to assess whether restoration is leading to similar N and C biogeochemical landscapes and soil and plant properties as a target remnant forest ecosystem. We measured nutrient contents and isotope values ( $\delta^{15}N$ ,  $\delta^{13}C$ ) in soils, *A. koa*, and non- $N_2$ -fixing understory plants (*Rubus* spp.) and generated  $\delta^{13}C$  and  $\delta^{15}N$  isoscapes of the two forests to test for (1) different levels of biological nitrogen fixation (BNF) and its contribution to non- $N_2$ -fixing understory plants, and (2) the influence of historic land conversion and more recent afforestation on plant and soil  $\delta^{13}C$ . In the plantation, *A. koa* densities were higher and foliar  $\delta^{15}N$  values for *A. koa* and *Rubus* spp. were lower than in the remnant forest. Foliar and soil isoscapes also showed a more homogeneous distribution of low  $\delta^{15}N$  values in the plantation and greater influence of *A. koa* on neighboring plants and soil, suggesting greater BNF. Foliar  $\delta^{13}C$  also indicated higher water use efficiency ( $WUE_i$ ) in the plantation, indicative of differences in plant-water relations or soil water status between the two forest types. Plantation soil  $\delta^{13}C$  was higher than the remnant forest, consistent with greater

contributions of exotic C<sub>4</sub>-pasture grasses to soil C pools, possibly due to facilitation of non-native grasses by the dense *A. koa* canopy. These findings are consequential for forest restoration, as they contribute to the mounting evidence that outplanting N<sub>2</sub>-fixing trees produces different biogeochemical landscapes than those observed in reference ecosystems, thereby influencing plant-soil interactions which can influence restoration outcomes.

25 **Abstract**

26 Deforestation and subsequent land-use conversion has altered ecosystems and led to negative  
27 effects on biodiversity. To ameliorate these effects, nitrogen-fixing ( $N_2$ -fixing) trees are  
28 frequently used in the reforestation of degraded landscapes, especially in the tropics; however,  
29 their influence on ecosystem properties such as nitrogen (N) availability and carbon (C) stocks  
30 are understudied. Here, we use a 30-y old reforestation site of outplanted native  $N_2$ -fixing trees  
31 (*Acacia koa*) dominated by exotic grass understory, and a neighboring remnant forest dominated  
32 by *A. koa* canopy trees and native understory, to assess whether restoration is leading to similar  
33 N and C biogeochemical landscapes and soil and plant properties as a target remnant forest  
34 ecosystem. We measured nutrient contents and isotope values ( $\delta^{15}N$ ,  $\delta^{13}C$ ) in soils, *A. koa*, and  
35 non- $N_2$ -fixing understory plants (*Rubus* spp.) and generated  $\delta^{13}C$  and  $\delta^{15}N$  isoscapes of the two  
36 forests to test for (1) different levels of biological nitrogen fixation (BNF) and its contribution to  
37 non- $N_2$ -fixing understory plants, and (2) the influence of historic land conversion and more  
38 recent afforestation on plant and soil  $\delta^{13}C$ . In the plantation, *A. koa* densities were higher and  
39 foliar  $\delta^{15}N$  values for *A. koa* and *Rubus* spp. were lower than in the remnant forest. Foliar and  
40 soil isoscapes also showed a more homogeneous distribution of low  $\delta^{15}N$  values in the plantation  
41 and greater influence of *A. koa* on neighboring plants and soil, suggesting greater BNF. Foliar  
42  $\delta^{13}C$  also indicated higher water use efficiency ( $WUE_i$ ) in the plantation, indicative of  
43 differences in plant-water relations or soil water status between the two forest types.  
44 Plantation soil  $\delta^{13}C$  was higher than the remnant forest, consistent with greater contributions of  
45 exotic  $C_4$ -pasture grasses to soil C pools, possibly due to facilitation of non-native grasses by the  
46 dense *A. koa* canopy. These findings are consequential for forest restoration, as they contribute to  
47 the mounting evidence that outplanting  $N_2$ -fixing trees produces different biogeochemical

48 landscapes than those observed in reference ecosystems, thereby influencing plant-soil  
49 interactions which can influence restoration outcomes.

## 50 Introduction

51 Forests provide essential ecosystem services including carbon storage and nutrient  
52 cycling. However, human-induced disturbances, deforestation, land conversion, and invasive  
53 species have led to devastating losses in biodiversity and potentially irreversible alterations to  
54 biogeochemical processes (Cramer et al., 2004; Asner et al., 2008; Handa et al., 2014; Veldkamp  
55 et al., 2020). While active forest restoration has been touted as a tool to spur secondary  
56 succession and regain desirable ecosystem states, it remains unclear if this practice will lead to  
57 the recuperation of the biogeochemical properties provided by primary forest reference  
58 ecosystems (Aerts & Honnay, 2011; Sullivan et al., 2019; Yelenik et al., 2021). As land  
59 management strategies focused on restoration are developed to reconcile losses of ecosystem  
60 services, there is a need to understand the spatial extent and long-term impacts of these  
61 restoration strategies on restoring biogeochemical properties and carbon and nutrient cycling.

62 Nitrogen (N) is a key component of biogeochemical cycles, and N is often one of the  
63 most limiting nutrients for plant growth and photosynthesis – especially in early successional or  
64 secondary tropical forests (Vitousek & Farrington, 1997). Furthermore, the conversion of  
65 tropical forests to pasture and other agricultural crops can lead to significant changes in soil  
66 properties such rates of N cycling and N availability, as well as carbon sequestration and storage  
67 (Veldkamp et al., 2020). Trees capable of atmospheric nitrogen (N<sub>2</sub>) fixation via symbiotic  
68 interactions with root nodule inhabiting bacteria (ex. *Rhizobia* spp.) can be integral to restoring  
69 forests by catalyzing ecological succession, reversing the effects of destructive land-use practices  
70 on soil N availability, and aiding global efforts to mitigate climate change through increasing C  
71 sequestration (Chazdon, 2003; Batterman et al., 2013; Chazdon et al., 2016; Levy-Varon et al.,  
72 2019; but see, Kou-Giesbrecht & Menge, 2019). Specifically, as the density of N<sub>2</sub>-fixing trees,

73 such as leguminous species in the genus *Acacia* (Resh, Binkley & Parrotta, 2002) increases, N in  
74 the soil and neighboring plants can also increase (Sitters, Edwards & Olde Venterink, 2013).  
75 Therefore, BNF has the capacity to positively influence the performance and N-budgets of both  
76 N<sub>2</sub>-fixing and non-N<sub>2</sub>-fixing plants.

77 In the tropics, N<sub>2</sub>-fixing trees are often used as ecosystem engineers for the restoration of  
78 degraded landscapes (Fisher, 1995; Scowcroft, Haraguchi & Hue, 2004). However, the outcomes  
79 of these efforts are mixed, with some restored areas stalled in apparent alternative stable states  
80 (Yelenik, 2017), while others progress toward ecosystem targets and restoration goals (Fisher,  
81 1995; Rhoades, Eckert & Coleman, 1998; Koutika et al., 2021). These differing effects of N<sub>2</sub>-  
82 fixing trees may be owed to heterogeneous N inputs across landscapes (Dixon et al., 2010;  
83 Sullivan et al., 2014), as well as ecosystem-specific biotic and abiotic factors (Pearson &  
84 Vitousek, 2002; Staddon, 2004; Wynn & Bird, 2007; Dixon et al., 2010; Barron, Purves &  
85 Hedin, 2011; Sitters, Edwards & Olde Venterink, 2013). For example, active restoration that  
86 relies on establishing forests of N<sub>2</sub>-fixing trees may have unintended consequences, such as  
87 promoting weedy or invasive species (Funk & Vitousek, 2007), thereby altering successional  
88 trajectories toward non-target states (Stinca et al., 2015). A better understanding of the  
89 spatiotemporal effects of N<sub>2</sub>-fixing trees on ecosystems is needed, especially in the context of  
90 forest restoration.

91 Stable isotopes are time-integrating markers that can provide insight into biogeochemical  
92 processes and shifts in ecosystem services occurring across multiple landscapes and  
93 spatiotemporal scales (Cheesman & Cernusak, 2016). Spatially explicit, geo-referenced isotope  
94 landscapes (termed ‘isoscapes’) allow for the measured isotope values of individual replicates  
95 (i.e., within or among species, or sample types) to be interpolated to landscape scales (Bowen,

96 2010). While only a few studies have used isoscapes in plant ecology (Hellmann et al., 2011;  
97 Rascher et al., 2012), their application may provide new and important insights into plant-  
98 microbe and plant-soil feedbacks, such as biological nitrogen fixation (BNF) by N<sub>2</sub>-fixing trees,  
99 which can vary at relatively smaller spatial scales.

100         BNF results in nitrogen stable isotope values ( $\delta^{15}\text{N}$ ) that are more similar to the  
101 atmosphere (~0‰) relative to nitrogen assimilated from soil nitrogen pools (Craine et al., 2015).  
102 Soil  $\delta^{15}\text{N}$  values represent an integration of nitrogen inputs and outputs in an ecosystem, and are  
103 influenced by processes that lead to isotope fractionation (i.e., nitrification, denitrification,  
104 ammonia volatilization), atmospheric deposition, leaching, as well as the pedogenic and  
105 environmental factors that shape these processes (Natelhoffer & Fry, 1988; Austin & Vitousek,  
106 1998; Martinelli et al., 1999; Burnett et al., 2022). Variability in soil  $\delta^{15}\text{N}$  can complicate the  
107 interpretation of leaf  $\delta^{15}\text{N}$  values, especially for non-N<sub>2</sub>-fixing plants (Robinson, 2001).  
108 However, the low  $\delta^{15}\text{N}$  values associated with BNF are distinct enough to be traced through soils  
109 and vegetation (Hellmann et al., 2011). For instance,  $\delta^{15}\text{N}$  isoscapes revealed the contribution of  
110 an invasive, non-native N<sub>2</sub>-fixing shrub (*Acacia longifolia*) to the nitrogen pools of surrounding  
111 plants and the corresponding modification of nutrient cycling and community function due to  
112 this invasive species (Rascher et al., 2012).

113         Along with standard comparisons of C to N concentrations, leaf and soil C stable isotope  
114 values ( $\delta^{13}\text{C}$ ) can provide additional evidence on the rates of nutrient cycling, the relative  
115 contribution of plant functional types (i.e., C<sub>3</sub> vs C<sub>4</sub> photosynthesis) to soil C pools, and the  
116 integrated plant water use efficiency (WUE<sub>i</sub>) of plants in an ecosystem (Cernusak et al., 2013;  
117 Driscoll et al., 2020). Combined,  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values sampled across a landscape can provide  
118 spatially explicit information on plant performance and ecosystem processes, which can be

119 compared among ecological community members or between communities (Hellmann et al.,  
120 2016). While it is clear that isoscapes provide new perspectives on the spatial relationships of  
121 biochemical processes and biological interactions fundamental to ecology (Cheesman &  
122 Cernusak, 2016; McCue et al., 2020), they have yet to be widely applied to understand plant-soil  
123 feedbacks in the context of restoration.

124 Native Hawaiian montane mesic and wet forests have significantly declined due to over a  
125 century of deforestation and extensive human- and livestock-mediated disturbance (Pau,  
126 Gillespie & Price, 2009; McDaniel et al., 2011; Yelenik, 2017). These forests provide are  
127 dominated by two foundational endemic tree species – N<sub>2</sub>-fixing *Acacia koa* (koa, Fabaceae) and  
128 the non-N<sub>2</sub>-fixing *Metrosideros polymorpha* (‘ōhi‘a lehua, Myrtaceae) – and provide critical  
129 ecosystem services, including habitat for many endangered bird species in Hawai‘i (Paxton et al.,  
130 2018). To restore montane mesic forest habitats on Hawai‘i Island, over 390,000 nursery-grown  
131 *A. koa* trees (i.e., outplants) have been planted in the Hakalau Forest National Wildlife Refuge  
132 since 1987 (hereafter, Hakalau; Fig. 1). This effort started in the greenhouse, where individual  
133 trees (one per pot) were grown in 15-cm-long cone-tainers, reaching a height of 30-cm in <6  
134 months. In the plantation, a bulldozer with a miniblade scoured the soil to remove grass  
135 competitors and make plots (1 × 1 m) every 3 m, with rows every 4 m a part. Individual  
136 greenhouse-grown koa were planted in holes created by an auger power planter (the same size as  
137 the root plug) with fertilizer added to the auger hole (see Jeffrey and Horiuchi, 2003).

138 *Acacia koa* outplants were introduced to 5,000 acres of fenced, abandoned pastureland  
139 (previously grazed by cattle, pigs, goats) in an effort to restore forested habitats and support the  
140 recovery of native plants and endangered bird populations (Jeffrey & Horiuchi, 2003; McDaniel  
141 & Ostertag, 2010). Forest patches are critical in supporting biodiversity (Wintle et al. 2019), and

142 patchiness and/or fragmentation can lead to dramatic differences in forest climate that support  
143 rates litter decomposition and nutrient cycling (Crockatt & Bebber, 2014). Therefore, the active  
144 outplanting of *A. koa* in discrete corridors was leveraged to facilitate the passive restoration and  
145 expansion of koa recruitments and root-suckers, with the goal of ultimately turning isolated  
146 patches into intact, contiguous forests habitat (Scowcroft and Yeh, 2013). However, after 30  
147 years the understory of *A. koa* plantations remain grass-dominated, native woody plant  
148 recruitment is low, and endangered birds are sparse (Yelenik, 2017; Paxton et al., 2018). The  
149 causes of this stalled forest recovery are uncertain, but they likely include the influence of *A. koa*  
150 BNF on soil chemistry, nutrient concentrations, and nutrient cycling (Scowcroft, Haraguchi &  
151 Hue, 2004). As a N<sub>2</sub>-fixing tree, *A. koa* produces abundant low C:N leaf litter (high N), which  
152 can lead to greater supply of N to the soil surface under *A. koa* relative to *M. polymorpha*, which  
153 has high litter C:N (Scowcroft, 1999; Yelenik, Rehm & D'Antonio, 2022). These differences in  
154 litter N can increase rates of decomposition and ultimately affect the return of nutrients to soil N  
155 pools (Baker, 2009; Zhou et al., 2018). Differences in canopy composition and associated litter  
156 decomposition can have important implications for forest nutrient cycling and the composition of  
157 forest understories. In the plantations, the ability for *A. koa* to increase soil nutrient, coupled with  
158 the high densities of this canopy tree in monoculture corridors, may be favoring the growth of  
159 exotic nitrophilous grasses from the historic pastures and inhibiting native seedling establishment  
160 (Yelenik, 2017).

161 To examine the interactions between BNF, soil and leaf N content as well as C inputs at  
162 the ecological community scale, we applied a spatially explicit sampling approach within a  
163 mixed *M. polymorpha/A. koa* native montane forest (hereafter, the “remnant forest”) and an *A.*  
164 *koa* plantation (hereafter, “koa plantations”). The remnant forest is largely dominated by native

165 understory plants, whereas the koa plantation understory is dominated by C<sub>4</sub> exotic grasses  
166 interspersed with a C<sub>3</sub> non-native shrub (*Rubus argutus*). While the land-use history and present-  
167 day plant communities of these two forest types differ, they occupy the same climate and parent  
168 soil types (<http://rainfall.geography.hawaii.edu>, <https://gis.ctahr.hawaii.edu/SoilAtlas>). We used  
169  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  values of soil and foliar samples to construct isoscapes and examine the degree of  
170 BNF between the two forest types and test the influence of BNF by *A. koa* on  $\delta^{15}\text{N}$  values in  
171 soils and neighboring plants (*Rubus* spp.). We hypothesized that the higher density and more  
172 even distribution of *A. koa* in the plantation compared to the remnant forest will result in lower  
173  $\delta^{15}\text{N}$  values in soil and plants from the plantations with greater and spatially more homogeneous  
174 BNF inputs than the remnant forests. In addition, we expected higher foliar  $\delta^{13}\text{C}$  values in the  
175 plantation as a result of greater water demand in the young, dense *A. koa* forests driving higher  
176 WUE<sub>i</sub> (Kagawa et al., 2009). Introduced C<sub>4</sub> grasses are abundant in the understory of the  
177 plantation but are uncommon in the remnant forest where there are no known native C<sub>4</sub> plants  
178 (Yelenik 2017). Therefore, we also predicted that soil  $\delta^{13}\text{C}$  would be higher in the plantation  
179 relative to the remnant forest, indicating greater contributions of C<sub>4</sub> grasses to soil C pools. The  
180 results of this study will clarify the effects of tropical N<sub>2</sub>-fixing monoculture plantations on the  
181 distribution of N and soil nutrient cycling and how these may differ from the target ecosystem  
182 for restoration.

183

## 184 **Materials and Methods**

### 185 *Site description and sample collection*

186 Two sections of remnant forest and koa plantation were identified within the Hakalau  
187 Forest National Wildlife Refuge on the Island of Hawai'i (19°49'12"N, 155°19'22"W) (Fig. 1).

188 Remnant forests are characterized by a mixed canopy of *Acacia koa* (koa) and *Metrosideros*  
189 *polymorpha* (‘ōhi‘a lehua) along with native understory woody plants *Cheirodendron trigynum*  
190 (‘ōlapa), *Coprosma rhynchoarpa* (pilo), *Leptecophylla tameiameia* (pukiawe), *Myrsine*  
191 *lessertiana* (kōlea), *Rubus hawaiiensis* (‘ākala), and *Vaccinium calycinum* (‘ōhelo). In contrast,  
192 the plantations are largely monoculture stands of *A. koa*, with non-native grass understories of  
193 *Cenchrus clandestinus* (kikuyu, a C<sub>4</sub> grass), along with *Ehrharta stipoides* (C<sub>3</sub>), with sporadic  
194 occurrences of the non-native shrub *Rubus argutus* and ferns.

195 Each sampling area – koa plantation (KP) or remnant forest (RK) – had similar montane  
196 forest climates, elevations (~1800 m), and soils from the same parent material (Scowcroft et al.,  
197 2007), and were selected due their proximity to transects used in previous studies (Paxton et al.,  
198 2017). Both the plantation and the remnant forest were dominated by *A. koa*, with koa  
199 representing 100% of the canopy tree species in the plantation. ‘Ōhi‘a was absent in the koa  
200 plantation, and only one mature ‘ōhi‘a was observed in the remnant forest area. Each 700 m<sup>2</sup>  
201 sampling area was representative of the vegetation found throughout the remnant and “restored”  
202 plantation forests of Hakalau. Samples were collected at a spatial resolution (0-5 m) relevant for  
203 detection of BNF and changes in C cycling at the landscape scale in soil, N<sub>2</sub>-fixing and non-N<sub>2</sub>-  
204 fixing foliage. Individual samples were also collected at a spatial resolution that balanced  
205 considerations of spatial autocorrelation and the ability to extrapolate via kriging (see methods  
206 section below) to the landscape scale (Hellmann et al., 2011; Rascher et al., 2012).

207 In each forest plot of 20 × 35 m (Fig. S1), we collected soil samples at 4 or 5-m intervals  
208 ( $n = 48$  soil samples per forest) using a sterilized (70% ethanol) soil borer that sampled the upper  
209 10 cm of the soil after surface leaf litter was removed. Soil samples were placed into paper  
210 envelopes for future processing. Within the remnant forest and the plantation, we collected foliar

211 samples from all mature *A. koa* canopy trees and understory *Rubus* spp. (detailed below).  
212 Juvenile *A. koa* have bipinnately-compound true leaves that develop into phyllodes during  
213 maturation. Hereafter, we will refer to all foliar samples (i.e., *A. koa* phyllodes, *Rubus* true  
214 leaves) as ‘leaves’. Grasses were not sampled due to grasses being rare in the remnant forest.  
215 Similar to other plant derived isoscapes (Hellmann et al., 2011; Rascher et al., 2012), this  
216 sampling scheme was designed to capture any signature of N<sub>2</sub>-fixation from *A. koa* on understory  
217 plants as well as the soil environment.

218         In both forests, all mature *A. koa* larger than 2 m tall were marked (plantation [ $n = 18$ ]  
219 and remnant [ $n = 10$ ], 257 and 142 trees per hectare, respectively) and their relative position  
220 mapped (Fig. 1, Fig. S1). Three leaves were collected and pooled from each individual *A. koa*  
221 tree in the mid-exterior forest canopy using pole pruners at a consistent height (ca. 6 m). The  
222 pooled leaf sample for each *A. koa* was placed into a paper envelope until further processing for  
223 isotope analyses (detailed below). Due to the distance between individual koa trees and their lack  
224 of clonal reproduction, each pooled leaf sample per tree is considered an independent replicate.  
225 Each tagged *A. koa* was measured for diameter at breast height (dbh) using a diameter tape,  
226 measured at 1.5 m from the ground. When multiple trunks were found on the same tree, dbh was  
227 represented as the square root of the sum of squared dbh measurements of individual trunks  
228 (Meeuwig et al., 1981). Canopy area (m<sup>2</sup>) was measured for each *A. koa* in the forest type using a  
229 laser to measure distance from the trunk to the canopy edge; measurements were taken at four  
230 bearings (0°, 90°, 180°, 270°). Individual *A. koa* canopy area (canopy m<sup>2</sup>) was determined using  
231 the formula for the area of an ellipse (area =  $\pi ab$ ), where  $a$  and  $b$  are the average distances at the  
232 major radii (0° and 180°) and minor radii (90° and 270°).

233 Two Rosaceae species (*Rubus* spp.) were present in the two sampling areas and were  
234 used as indicator plants for the influence of BNF on neighboring plants based on their  $\delta^{15}\text{N}$   
235 values: the native *Rubus hawaiiensis* in the understory of the remnant forest ( $n = 14$  plants [200  
236 plants hectare<sup>-1</sup>) and the invasive *Rubus argutus* in the plantation ( $n = 28$  plants [400 plants  
237 hectare<sup>-1</sup>]). Since the two *Rubus* species tended to separate by forest type, it was not possible to  
238 collect both species in the two forests. When a *Rubus* individual was present in a quadrat (20  
239 m<sup>2</sup>), three leaves were collected from the top of up-to three adult stems and pooled per individual  
240 plant and placed in a paper envelope. The spatial location of the *Rubus* samples was standardized  
241 to the centroid of the quadrat where they were collected (Fig. S1). Within 6 h of collection, soil  
242 and foliar samples were transported to the University of Hawai‘i-Hilo Hakalau Forest Biological  
243 Field Station and oven dried (60°C, ca. 5 h) in paper envelopes. The dried samples were  
244 transported to the BayCEER Laboratory of Isotope Biogeochemistry at the University of  
245 Bayreuth for processing.

246

#### 247 *Stable isotope analyses*

248 Prior to final analysis, foliar and soil samples were again oven dried (105°C) to a  
249 constant weight (Gebauer & Schulze, 1991) and homogenized to a powder using a ball mill  
250 (Retsch Schwingmühle MM2, Haan, Germany). While many studies use 60°C for foliar samples,  
251 extensive internal laboratory testing of drying procedures and temperatures (60°, 80°, 105°C)  
252 have shown negligible drying effects on foliar and soil isotope values (within  $\pm 0.2$  ‰  
253 measurement error), while drying at higher temperatures ensures complete sample desiccation.  
254 Where present, root material was removed from soil samples prior to homogenization. A subset  
255 of each sample was placed in a tin capsule and weighed (foliar [2.8 - 5.5 mg], soil [3.5 - 4.5

256 mg]). A standard material (acetanilide [0.4 - 1.5 mg]) with known C and N stable isotope  
257 abundance and concentration was also analyzed for quality control and calculation of C and N  
258 concentrations in our samples. Standard materials were run at least six times within each batch of  
259 50 samples following protocols previously described (Gebauer & Schulze, 1991). Molar  
260 concentrations of C and N and their ratio (C:N), as well as natural abundance isotope values  
261 ( $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ ), were measured using an elemental analyzer-isotope ratio mass spectrometer (EA-  
262 IRMS) coupling, combining an elemental analyzer (Carlo Erba Instruments 1108, Milano, Italy)  
263 with a continuous flow isotope ratio mass spectrometer (delta S, Finnigan MAT, Bremen,  
264 Germany) via a ConFlo III open-split interface (Thermo Fisher Scientific, Bremen, Germany).  
265 Natural abundance isotopic values were reported in delta values ( $\delta$ ) using permil (‰) notation  
266 relative to standard materials (Vienna-Peedee Belemnite [V-PDB] and atmospheric  $\text{N}_2$  standards  
267 [air] for C and N, respectively). Reproducibility of isotope abundance measurements was always  
268 within  $\pm 0.2\%$ . All standard gases (Riessner, Lichtenfels, Germany) were calibrated versus the  
269 international standards using reference substances provided by the International Atomic Energy  
270 Agency, Vienna, Austria (CH-3, CH-6 and NBS-18 for the carbon isotopes and N-1 and N-2 for  
271 the N isotopes).

272

### 273 *Isoscape kriging*

274       Spatially explicit sampling of soil, *A. koa*, and indicator plant taxa (*Rubus* spp.) allowed  
275 for the generation of maps of  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  values across the two forest types (i.e., isoscapes).  
276 The spatial coordinates for each sample were determined by its location within the sampling grid  
277 (i.e., quadrat corners [soil], centroid [*Rubus* spp.], or relative position [*A. koa*]), which was used  
278 to generate a spatial grid and points for interpolation using the functions *coordinates* and

279 *spsample* in the R package *sp* (Pebesma & Bivand, 2005; Bivand, Pebesma & Gómez-Rubio,  
280 2013). To visualize the stable isotope landscape, we used kriging: a common statistical method  
281 that uses variograms to calculate the spatial autocorrelation between points and distance and  
282 interpolate isotope values across a continuous surface (Bowen, 2010). We generated  $\delta^{15}\text{N}$  and  
283  $\delta^{13}\text{C}$  isoscapes for soil-only and foliar-only samples. A foliar  $\delta^{13}\text{C}$  isoscape was not generated  
284 since samples were limited to  $\text{C}_3$  plants of similar  $\delta^{13}\text{C}$  values. Data interpolation was performed  
285 using ordinary kriging to a continuous surface, with variogram models generated by the function  
286 *autoKrige* in the R package *automap* (Hiemstra et al., 2009). *AutoKrige* performs iterative model  
287 selection fitting variogram models to the collected data (the experimental variograms). Best-fit  
288 variogram models (i.e., those with lowest residual sum of squares) have four main model  
289 parameters: *the nugget effect*, the estimate of experimental error inherent in measurements,  
290 sampling design, and environmental variability; *the sill*, the spatial pattern intensity and the  
291 semivariance asymptote; *the spatial range*, the distance or lag of sample correlation where  
292 samples are influenced by same underlying process; and *the sserr* (sum of squares between  
293 experimental and fitted variogram model) (Fortin, Dale & Ver Hoef, 2012). These model  
294 parameters describe the autocorrelation between the semivariance (y-axis) and distance or lag  
295 parameter (x-axis). With distance between samples, semivariance increases and correlation  
296 decreases; therefore, model saturation (i.e., *sill*) indicates a point where semivariance no longer  
297 increases with increasing distance (i.e., *range*) and points no longer show autocorrelation. We  
298 used variogram models and their predicted values ( $\delta^{15}\text{N}_{\text{predicted}}$  and  $\delta^{13}\text{C}_{\text{predicted}}$ ) to generate  
299 isoscapes using the function *splot* in the R package *sp*. Where model variograms showed poor  
300 fit to experimental variogram data, we used *autoKrige* to run iterations of user-defined, fixed  
301 values for variogram parameters (*nugget*, *range*, *sill*). Predicted values from model variograms

302 were then compared between the two forest types over a continuous surface with statistical  
303 inferences made on the distributions of predicted values using non-parametric tests.

304

### 305 *Statistical analyses*

306 Data normality and heteroscedasticity were inferred from graphical inspection of  
307 residuals and quantile-quantile plots. Where data failed to meet assumptions of parametric  
308 models, non-parametric tests were used. Differences in *A. koa* dbh and canopy area between  
309 forest types (koa plantation or remnant forest) were analyzed using Mann-Whitney *U*-tests using  
310 the function *mwu* in the package *sjstats* (Lüdecke, 2021). Isotope data ( $\delta^{15}\text{N}$ ,  $\delta^{13}\text{C}$ ), total C and  
311 total N concentration (mmol g/dry weight [gdw]), and molar C:N were analyzed using a two-way  
312 linear model with sample type (*A. koa*, *Rubus* spp., soil) and forest type (remnant forest, koa  
313 plantation) as fixed effects. Analysis of variance tables were generated with Type-II sum of  
314 squares in the *car* package (Fox et al., 2019). Post-hoc slice-tests were used in *a priori* contrasts  
315 to test for significant differences among sample types within a forest (*A. koa* vs. *Rubus* spp.) and  
316 between forest types using the *emmeans* package (Lenth, 2022). Differences between the  $\delta^{15}\text{N}$   
317 and  $\delta^{13}\text{C}$  isoscapes in the remnant forest and koa plantation were assessed visually, through  
318 Mann-Whitney *U*-tests using density plots of interpolated/predicted isotope values ( $\delta^{15}\text{N}$  or  
319  $\delta^{13}\text{C}$ ), and the characteristics of the model variogram.

320 While we recognize our study is limited to two areas ( $20 \times 35$  m) each within a different  
321 forest type (plantation and remnant forest), the utility of an isoscape approach is that it allows for  
322 spatial interpolation so that biogeochemical patterns at community and ecosystem levels can be  
323 quantified. Experimental designs such as ours, where a single large area representative of the  
324 community types to be compared, are common and accepted approaches among isoscape studies

325 assuming that sampling is sufficient to capture natural variation in isotope values within the  
326 community of interest (Bowen, 2010; Hellmann et al., 2011; Rascher et al., 2012). Here, the unit  
327 of replication is individual sample points used to generate isoscape maps (plants [ $n = 24 - 36$ ],  
328 soil [ $n = 48$ ]), with statistical relationships determined using linear models. All data analyses  
329 were performed in R (version 4.2.1) (R Core Team, 2022). Archived data and code for analyses  
330 can be found at GitHub (<https://github.com/cbwall/Hakalau>) and are published at Zenodo (Wall  
331 et al., 2023).

332

## 333 **Results**

### 334 *Vegetation structure*

335 Differences between *A. koa* trees in the two forest types were observed, notably dbh was  
336 greater in the plantation ( $p=0.010$ ) (Fig. S2A), but the *A. koa* canopy area was not different  
337 between the two forests ( $p=0.666$ ) (Fig. S2B, Table S1). In the remnant forest, 80% of *A. koa*  
338 were single-stemmed, whereas in the plantation multi-stemmed *A. koa* dominated with only 20%  
339 of trees being single-stemmed. The total basal area of mature *A. koa* cover in the plantation and  
340 remnant forest (18 and 10 trees, respectively) was 283 and 258 m<sup>2</sup>, covering ~40% of the 700m<sup>2</sup>  
341 sampling areas in each forest.

342

### 343 *Soil and foliar isotope values*

344  $\delta^{15}\text{N}$  values differed according to sample type ( $p<0.001$ ) and forest ( $p<0.001$ ), with  
345 overall lower  $\delta^{15}\text{N}$  values in the plantation (Table S2).  $\delta^{15}\text{N}$  values of soils were not different  
346 among the forests ( $p = 0.085$ ). *Acacia koa* and *Rubus* spp.  $\delta^{15}\text{N}$  values were both significantly  
347 closer to zero (less <sup>15</sup>N-enriched by ~1‰) in the plantation compared to remnant forest samples

348 (post-hoc:  $p \leq 0.029$ ) (Fig. 2A). As expected,  $\delta^{15}\text{N}$  values of the  $\text{N}_2$ -fixing *A. koa* were  
349 significantly lower compared to *Rubus* spp. in both the plantation (post-hoc:  $p=0.020$ ) and  
350 remnant forest (post-hoc:  $p=0.029$ ). Overall, there was a greater range and standard deviation in  
351  $\delta^{15}\text{N}$  values in the remnant forest *A. koa* (range: 2.19‰, SD: 1.03‰) and *Rubus* spp. (range:  
352 3.54‰, SD: 0.89‰) compared to plantation *A. koa* (range: 0.85‰, SD: 0.65‰) and *Rubus* spp.  
353 (and 2.55‰, SD: 0.75‰). This larger range and variance in plant  $\delta^{15}\text{N}$  values is consistent with  
354 heterogeneous N sources in the remnant forest, which is being expressed in the leaves of canopy  
355  $\text{N}_2$ -fixing trees and understory plants. Soil  $\delta^{15}\text{N}$  values were  $\sim 3\%$  higher than those in foliar  
356 samples, but similar among the plantation and the remnant forest (post-hoc:  $p=0.085$ ) (Fig. 2A).  
357  $\delta^{13}\text{C}$  values were different among sample types ( $p < 0.001$ ) and between forests ( $p < 0.001$ ),  
358 with significantly lower  $\delta^{13}\text{C}$  values in all sample types from the remnant forest relative to those  
359 from the plantation (Fig. 2B; Table S2). However, when compared within the same forest, the  
360  $\delta^{13}\text{C}$  values of *A. koa* and *Rubus* spp. were not different from each other in the remnant forest  
361 (post-hoc:  $p=0.057$ ) or the plantation (post-hoc:  $p=0.281$ ).

362

### 363 *Isoscapes and model variograms*

364 Variograms provided insights into the spatial correlation within isoscapes and the  
365 semivariance-by-distance relationship.  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  isoscape variograms for both soil and  
366 leaves showed equivalent ranges in spatial autocorrelation in both forests ( $\sim 3\text{-}5$  m) (Table S3).  
367 These results indicate similar relationships between semivariance-by-distance decay (i.e., less  
368 autocorrelation with increasing distance) in the koa plantation and the remnant forest at the scale  
369 of our experimental sampling. However, these estimates should be interpreted with caution since  
370 (1) the minimum sampling distance between samples for soils was 4 m and (2) in several

371 modeled variograms the increased *nugget* values coupled with low *sill* values may indicate  
372 greater influence of random variation. Nevertheless, we found significantly different  
373 distributions of  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  isotope values between forest types for both soil and foliar  
374 isoscapes ( $p < 0.001$ ) (Figs. 3, 4 & 5; Table S1).

375 In both soil and foliar  $\delta^{15}\text{N}$  isoscapes, we observed lower  $\delta^{15}\text{N}_{\text{predicted}}$  values in the koa  
376 plantation ( $p < 0.001$ ) (Table S1), with mean  $\delta^{15}\text{N}$  values for all interpolated data points lower by  
377  $\sim 0.5\text{‰}$  (soil isoscape) and  $1.2\text{‰}$  (foliar isoscape) in the plantation relative to the remnant forest  
378 (Fig. 3A, C). Both forests showed hot spots of low  $\delta^{15}\text{N}$  values ( $< 4\text{‰}$  soil [Fig. 4A-B],  $< 2\text{‰}$   
379 foliar [Fig. 5A-B]) that tended to be in areas proximate to *A. koa* or sampling points representing  
380 *A. koa* leaves (and to a lesser extent *Rubus* spp.) (Figs. 4 & 5). However, low  $\delta^{15}\text{N}$  areas were  
381 most pronounced in the plantation, where *A. koa* density was greater than the remnant forest (18  
382 [KP] vs. 10 [RK] mature trees), particularly through the middle of the plantation where *A. koa*  
383 trees are numerous and planted in parallel rows. Similarly, in the  $\delta^{15}\text{N}$  soil-isoscape, the koa  
384 plantation had more uniform low  $\delta^{15}\text{N}$  areas within this central *A. koa* corridor (Fig. 4A). The  
385 influence of *A. koa* on soils in the remnant forest was more variable, with a localized region of  
386 low  $\delta^{15}\text{N}$  values in the southern portion of the forest plot (Fig. 4B).

387  $\delta^{13}\text{C}$  isoscapes of soil samples showed lower  $\delta^{13}\text{C}$  values throughout the remnant forest  
388 relative to the plantation (Fig. 4C-D), with the distribution of  $\delta^{13}\text{C}_{\text{predicted}}$  values for soil samples  
389 (Fig. 3B) being lower in the remnant forest ( $p < 0.001$ ) (Table S1). These differences represent  
390  $\sim 1.5\text{‰}$  lower mean  $\delta^{13}\text{C}$  values for interpolated values in the remnant forest compared to the  
391 plantation. Hotspots of low  $\delta^{13}\text{C}$  values in both  $\delta^{13}\text{C}$  soil isoscapes corresponded to areas within  
392 the *A. koa* corridor in the plantation and areas where juvenile *A. koa* were located (Fig. 4C-D &  
393 Fig. S1).

394

395 *Nitrogen and carbon concentration patterns*

396 N concentration (mmol/gdw) differed according to sample types ( $p < 0.001$ ) (Fig. 2C),  
397 being highest in *A. koa*, followed by *Rubus* spp., and lowest in soil samples ( $p < 0.001$ ) but did not  
398 differ between forests ( $p = 0.107$ ) (Table S2). Total C concentrations (mmol/gdw) differed among  
399 sample types ( $p < 0.001$ ) and were overall lower in the koa plantation ( $p = 0.003$ ), driven by small  
400 differences in C concentrations of soil and *Rubus* sp. ( $< 2\%$ ) (Fig. 2D). N and C concentrations  
401 were greater in *A. koa* compared to *Rubus* spp. in the plantation (post-hoc:  $p < 0.001$ ) and the  
402 remnant forest (post-hoc:  $p \leq 0.022$ ). Molar C:N values differed by sample types ( $p < 0.001$ ), but  
403 not forests ( $p = 0.621$ ), and were lowest in soil (16), followed by *A. koa* (19), and *Rubus* spp. (21)  
404 (pooled means  $\pm 0.3$  SE,  $n = 14-96$ ).

405

406 **Discussion**

407 Assessments of biogeochemical landscapes can provide insight into key ecosystem  
408 properties, plant-soil feedback, and plant-plant interactions. As the degree of BNF increases,  
409 there is a well-documented decrease in foliar  $\delta^{15}\text{N}$  in  $\text{N}_2$ -fixing plant species (Craine et al.,  
410 2015). Differences in BNF between ecological communities often have corresponding effects on  
411 other ecosystem properties such as soil and neighboring non- $\text{N}_2$ -fixing plant  $\delta^{15}\text{N}$  values and  
412 nutrient status, as well as rates of photosynthesis and nutrient cycling. In addition to  $\delta^{15}\text{N}$   
413 analyses,  $\delta^{13}\text{C}$  values coupled with information on C and N concentrations can aid in inferences  
414 about each of these ecosystem-level processes occurring at different spatial scales (Moyer-Henry  
415 et al., 2006; Rascher et al., 2012; Hoogmoed et al., 2014; Craine et al., 2015). The use of large  
416 “super-plots” in discrete habitats, which are sampled at small spatial scales and/or grids to

417 perform spatial interpolation, is common in isoscape experimental designs (Rasher et al., 2012;  
418 Hellmann et al., 2016). Earlier studies sampled *A. koa* across elevation and rainfall gradients on  
419 Hawai‘i Island, mapping  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  values to determine environmental impacts on plant  
420 performance and suitability of sites for forest restoration (Lawson & Pike 2017). We find that  
421 spatially-explicit sampling at smaller spatial scales is equally useful in identifying difference is  
422 plant-soil-microbe interactions and the influence of BNF. Here, using  $\delta^{15}\text{N}$  isoscapes to  
423 determine differences in BNF between two forest patches that differ in their land use histories  
424 and management, we found strong evidence for greater, and more homogeneous contribution of  
425 newly-fixed N in the soil and plants of the afforested koa plantation compared to the remnant  
426 native forest. While these forests plots represent but a subset of the plantation and remnant  
427 forests habitats, each plot covered a significant area (700 m<sup>2</sup>) and were specifically chosen  
428 because the vegetation is representative of each unique forest type, while the abiotic conditions  
429 are similar (climate, slope, aspect, soil parent material). Therefore, the results of our study should  
430 be considered representative of forest community-level dynamics. However, increasing plot-  
431 level replication in future studies may allow for greater biogeochemical heterogeneity to be  
432 quantified within and among forest types (plantations and remnant forests) and the influence of  
433 environmental factors (such as elevation, rainfall, volcanic organic gases) on BNF and forest  
434 restoration.

435         In the koa plantation,  $\delta^{15}\text{N}$  soil and foliar isoscapes revealed a more evenly distributed  
436 signature of low  $\delta^{15}\text{N}$  values in the plantation relative to the remnant forest, indicative of a  
437 greater contribution of BNF in the plantation that could be related to the demography and density  
438 of *A. koa* in the plantation (Figs. 4 & 5). The finding that both *A. koa* and understory *Rubus* spp.  
439 also had lower  $\delta^{15}\text{N}$  values in the plantation relative to the remnant forest (Fig. 2) further

440 suggests greater BNF by *A. koa* and a greater contribution of newly-fixed N to neighboring  
441 plants. While soil  $\delta^{15}\text{N}$  values did not statistically differ significantly between forest types, the  
442  $\delta^{15}\text{N}$  soil isoscape showed overall lower  $\delta^{15}\text{N}$  values in the plantation compared to the remnant  
443 forest (Fig. 4). The marginal differences in soil  $\delta^{15}\text{N}$  between the two forest types may be due in  
444 part to differences in water availability between forest types (Austin & Vitousek, 1998), but  
445 further efforts are needed to determine if the soil water status differs among these forests  
446 (Bothwell et al., 2014). In both forests, however, the high soil  $\delta^{15}\text{N}$  values indicate significant  
447 losses of N relative to the size of the nitrogen pool, possibly from rapid N turnover and  
448 fractionation or leaching (Natlhoffer & Fry, 1988; Austin & Vitousek, 1998; Burnett et al.,  
449 2022). Nevertheless, our suite of biogeochemical metrics ( $\delta^{15}\text{N}$ ,  $\delta^{13}\text{C}$ , N and C concentrations)  
450 provide new insights on plant-soil-water relations, nutrient and carbon cycling, and offer clues as  
451 to why the plantations continue to foster a non-native grass dominated state even after three  
452 decades post reforestation (Yelenik, 2017; Yelenik et al., 2021).

453         In addition to higher density of *A. koa* in the plantation, the demographics of *A. koa*  
454 outplants and saplings in the plantation (<30 y old) compared to the remnant forest may be  
455 influencing C and N cycling in this system. Nodule biomass and N fixation rates are life-stage  
456 dependent, with younger stands (6 y) exhibiting an order of magnitude higher nodule biomass  
457 and  $\text{N}_2$ -fixation rates than older stands (20 y) (Pearson & Vitousek, 2001). The growth rate of *A.*  
458 *koa* across the Hawaiian Islands is variable, with dbh-based growth rates of 10-15 mm/y in sunlit  
459 areas where the crown is exposed and 6-7 mm/y estimated across a range of sites in the Hawai'i  
460 Department of Forestry and Wildlife long-term forest plots (Baker, Scowcroft, & Ewel, 2009). In  
461 remnant forests of Hakalau, growth rates of 4 mm/y for *A. koa* have been observed (Hart 2010),  
462 but no dbh-age estimates exist for the koa plantation. If we assume *A. koa* in the sunlit plantation

463 have growth rates similar to other sunlit areas across Hawai'i (~ 12 mm/y) and *A. koa* in the  
464 remnant forest are 4 mm/y, we estimate mean ( $\pm$ SE) ages of trees from the plantation to be  
465 significantly younger ( $p=0.049$ , Table S1) than the remnant forest ( $30 \pm 2$  [KP] and  $55 \pm 12$   
466 years [RK]) (Fig. S3), with two trees from the remnant forest being  $> 110$  years old. These  
467 estimates agree with the known age of the planting of the plantation (~ 1990) and support the  
468 hypothesis that forest demographics may be important to affecting the degree of  $N_2$ -fixation in *A.*  
469 *koa* and its contribution to plants and soils of Hakalau.

470         In our study system, the high densities *A. koa* in the plantation, along with immature *A.*  
471 *koa* recruits in thickets adjacent to planted trees, may be contributing to the higher rates of  $N_2$ -  
472 fixation we detected based on lower  $\delta^{15}N$  values (Figs. 2A, 4 & 5). The high density of *A. koa*  
473 has the potential to contribute more leaf litter of lower C:N to the forest floor relative to the  
474 mixed-canopy remnant forest. The greater number of multi-stemmed *A. koa* in the plantation  
475 (80% in KP vs. 20% RK) – which may be due to the spacing of outplants and the lack of  
476 competition in the plantation – also emphasizes the differing growth patterns in the outplanted *A.*  
477 *koa* relative to naturally recruited trees in remnant forests. These conditions may shape litterfall  
478 to the forest floor, which can be dynamic in both abundance and nutrient concentrations and  
479 reflective of shifts in plant community composition (Lanuza et al., 2018). Taken together, we  
480 suggest the greater densities, faster growth rates, and younger demographics of *A. koa* in the  
481 plantation provide a context for low C:N litterfall (and greater N contributions) in the early  
482 stages of reforestation to lead to persistent changes in nutrient cycling.

483         Despite a strong signal of significantly higher BNF in the plantation (Figs. 2A, 4A &  
484 5A), we found no statistically significant differences in foliar or soil N concentrations (Fig. 2C-  
485 D). While this result is puzzling, one likely explanation is that the plantation may have relatively

486 more well drained soils, and plantation *A. koa* may have higher water demands compared to  
487 remnant forests (Meinzer, Fownes & Harrington, 1996; Brauman, Freyberg & Daily, 2015). We  
488 note *A. koa* foliar  $\delta^{15}\text{N}$  values reported here are high relative to other studies of *A. koa* (Burnett et  
489 al., 2022; Lawson and Pike, 2017); however, these values are in-line with  $\text{N}_2$ -fixing plants from  
490 dry-forests and grasslands (Heaton, 1986), suggesting water limitations may be influencing *A.*  
491 *koa*  $\delta^{15}\text{N}$  in these forests. Even though we did not measure water holding capacity of each soil  
492 type, the significantly higher foliar  $\delta^{13}\text{C}$  values in the plantation – coupled with the lack of  
493 differences in soil and foliar N despite evidence of higher BNF – is indicative of water being an  
494 important factor limiting *A. koa* productivity and affecting soil N properties (Ares & Fownes,  
495 1999; Burnett et al., 2022).

496         Assuming water is more limited in the plantation, higher  $\delta^{13}\text{C}$  foliar values among *A. koa*  
497 and *Rubus* sp. individuals in the plantation may indicate higher rates of photosynthesis (reduced  
498  $^{13}\text{CO}_2$  discrimination) and/or higher  $\text{WUE}_i$  relative to the remnant forest (Farquhar, Ehleringer &  
499 Hubick, 1989; Cernusak et al., 2013). Considering the similarity in soil and foliar N in the two  
500 forests, we expect the differences in  $\delta^{13}\text{C}$  values are more likely to relate to  $\text{WUE}_i$  and not  
501 increased rates of photosynthesis. In support of this, (Ares & Fownes, 1999) found *A. koa* foliar  
502  $\delta^{13}\text{C}$  values increased across a gradient of decreasing rainfall, and  $\text{WUE}_i$  increased in greenhouse  
503 grown seedlings experiencing drought-stress. Furthermore, it has been documented that remnant  
504 native Hawaiian forests conserve more water (Kagawa et al., 2009) and contribute more to  
505 aquifer recharge compared to plantation forests (Brauman, Freyberg & Daily, 2015). More stable  
506 water availability and less draw down of water resources in the remnant forest is consistent with  
507 patterns of greater stomatal conductance, higher  $c_i/c_a$ , and lower  $\text{WUE}_i$  (Farquhar *et al.* 1989).  
508 Therefore, lower foliar  $\delta^{13}\text{C}$  values in *A. koa* and *Rubus* sp. in the remnant forest may be an

509 effect of less water demand in native/remnant forests, better soil water holding capacity, or both  
510 (Fig. 2). This finding is important, as the greater abundance of C<sub>4</sub> grasses in the understory of the  
511 plantation (Yelenik, 2017) may relate to the greater competitive ability of these grasses for water  
512 resources compared to native understory plants.

513         Photosynthetic fractionation is less in C<sub>4</sub> than C<sub>3</sub> plants, resulting in <sup>13</sup>C-enrichment and  
514 higher leaf δ<sup>13</sup>C values ranging from -10‰ to -15‰ compared to C<sub>3</sub> plants (-21‰ to -30‰)  
515 (Farquhar, Ehleringer & Hubick, 1989; Ehleringer, Buchmann & Flanagan, 2000). In the  
516 plantation soils, a clear pattern emerges of higher soil δ<sup>13</sup>C values, consistent with a greater  
517 contribution of C<sub>4</sub>-derived C to soils (Staddon, 2004). This finding is also supported by the soil  
518 δ<sup>13</sup>C isoscape (Fig. 4), where we observed increasing soil δ<sup>13</sup>C values in areas where grasses  
519 were dominant. N availability also influences rates of decomposition and has a direct influence  
520 on soil C pools (Averill & Waring, 2018); therefore, greater BNF in the plantation could  
521 accelerate soil C turnover, which may result in soils enriched in <sup>13</sup>C (Choi et al., 2005).  
522 Accordingly, future studies should examine isotope values in understory grasses and how low  
523 C:N leaf litter such as *A. koa*, is assimilated into soil and understory plant biomass, especially in  
524 the nitrophilous kikuyu grass (*Cenchrus clandestinus*). Follow up studies are on-going to  
525 determine rates of soil nutrient cycling in Hakalau, especially in order to disentangle how soil C,  
526 N, and leaf litter C:N influence soil δ<sup>13</sup>C values.

527

## 528 **Conclusion**

529         Recuperating biogeochemical properties in secondary tropical forests is vital to  
530 supporting plant growth and post-disturbance recovery (Sullivan et al., 2019). In some cases N<sub>2</sub>-  
531 fixing plants may therefore be useful in facilitating nutrient and plant community recovery

532 (Chaer et al., 2011). However, our data suggest that monoculture plantations of a native N<sub>2</sub>-  
533 fixing tree can lead to an increase in BNF and a more homogeneous distribution of fixed N in  
534 plants and soils that is unlike the distribution of N in a primary forest – the target habitat for  
535 restoration (Figs. 4 & 5). If this “plantation-effect” promotes undesirable species such as the non-  
536 native grasses in our plantation site, then creating a homogeneous area of high BNF may hinder  
537 restoration goals. Therefore, restoration efforts should consider how the abundance and density  
538 of N<sub>2</sub>-fixing trees may influence plant-plant and plant-soil interactions and the potential for  
539 restoration to produce ecosystem states that differ from reference ecosystem counterparts. Our  
540 study represents a subset of the larger remnant forest and koa plantations in Hakalau and many  
541 more restoration areas and forest reserves exist across Hawai‘i Island (Lawson & Pike, 2017).  
542 Considering the wide application of N<sub>2</sub>-fixing trees in tropical forest restoration, both in Hawai‘i  
543 and abroad, there remains a need to better understand how BNF by canopy trees varies within-  
544 and-among forest areas, across environmental conditions and habitat types, and its role in  
545 affecting nutrient cycling and forest communities. Addressing this uncertainty will support  
546 effective restoration strategic planning (i.e., outplanting density, multiple species planting) and  
547 management goals (i.e., habitat restoration, seedling and avian recruitment). Based on our  
548 findings in Hakalau, we suggest future restoration efforts might include a greater diversity of N<sub>2</sub>-  
549 fixing and non-N<sub>2</sub>-fixing canopy tree species to generate greater variation in understory and soil  
550 conditions more typical of remnant or intact forests.

# Figure 1

The Hawaiian Archipelago and sampling sites.

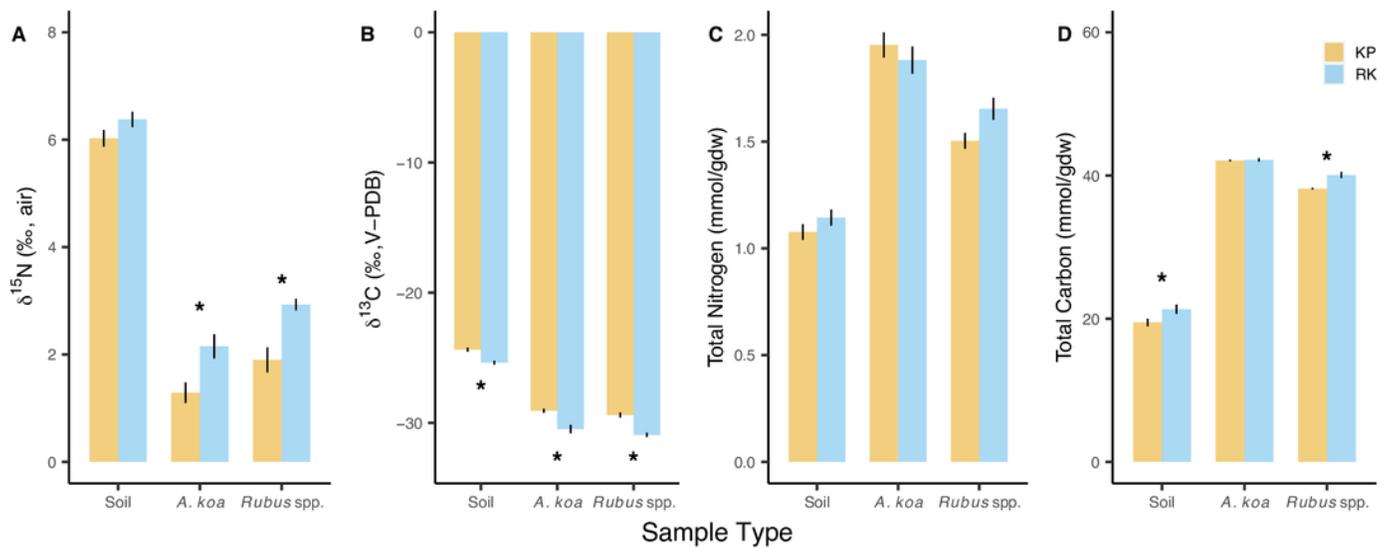

Site map of **(A)** the Hawaiian Archipelago highlighting the location of Hakalau Forest National Wildlife Refuge (red diamond) on the island of Hawai'i; **(B)** Koa plantation and remnant forest sampling areas (KP, RK); **(C, D)** layouts (20 × 35 m), with plot corners in red circles and *Acacia koa* trees in green triangles; **(E)** images of the koa plantation and **(F)** perimeter of the remnant forest. Image credit: (A-D) GoogleMaps from R package ggmap, (E-F) L. Kersting.

## Figure 2

Soil and foliar isotope values and elemental concentrations.

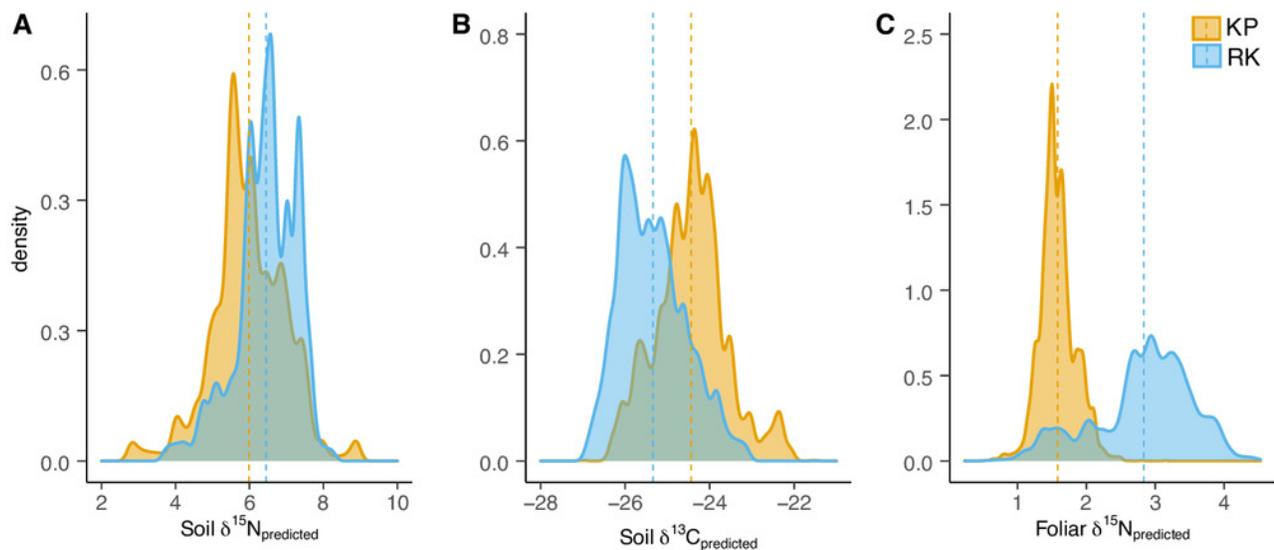

Soil and foliar (*Acacia koa*, *Rubus* spp.) (A)  $\delta^{15}\text{N}$ , (B)  $\delta^{13}\text{C}$ , (C) total nitrogen, and (D) total carbon in koa plantation (KP) and remnant (RK) Hakalau forests. Asterisks indicate significant differences between forests within a sample type ( $p < 0.05$ ). Values are mean  $\pm$  SE,  $n=48$  (soil), 18 and 10 [*Acacia koa*], 28 and 14 [*Rubus* spp.] in KP and RK forests, respectively.

## Figure 3

### Soil and foliar isoscape density plots

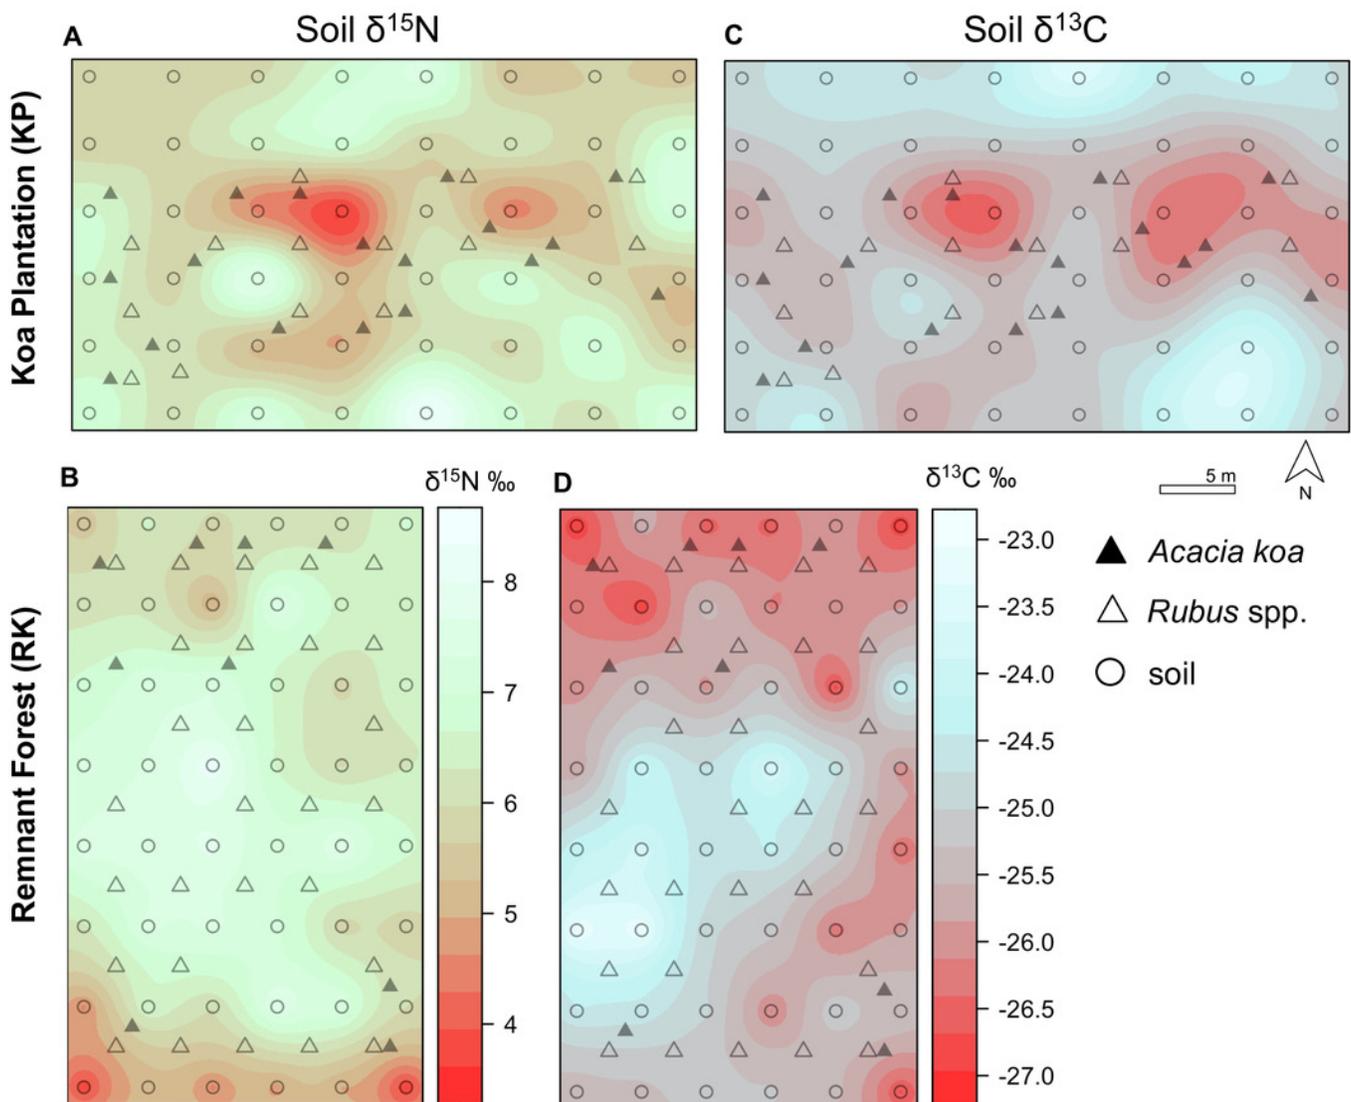

(A, B) Density plot of soil  $\delta^{15}\text{N}_{\text{predicted}}$  (left), soil  $\delta^{13}\text{C}_{\text{predicted}}$  (middle), and (C) foliar  $\delta^{15}\text{N}_{\text{predicted}}$  samples (*Acacia koa* and *Rubus* spp., right) from isoscapes in the koa plantation (KP) and remnant (RK) Hakalau forests. Dashed lines indicate mean values in each forest.

## Figure 4

Soil  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  isoscapes

(**A, B**) Soil  $\delta^{15}\text{N}$  and (**C, D**)  $\delta^{13}\text{C}$  isoscapes for Hakalau koa plantation (KP, *top*) and remnant forests (RK, *bottom*). Color bar represents  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  values. Symbols represent locations where soil (open circles), *Acacia koa* (filled triangles), and *Rubus* spp. (open triangles) samples were collected; only soil samples were used in spatial interpolation.

## Figure 5

Foliar  $\delta^{15}\text{N}$  isoscapes

(**A**) Foliar  $\delta^{15}\text{N}$  for Hakalau koa plantation (KP, *top*) and (**B**) remnant forests (RK, *bottom*).

Color bar represents  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  values. Symbols represent locations where soil (open circles), *Acacia koa* (filled triangles), and *Rubus* spp. (open triangles) samples were collected; only foliar samples were used in spatial interpolation.
