ABSTRACT

Wild soybean (*Glycine soja*), the ancestor of cultivated soybean, has evolved into many ecotypes with different adaptations to adversity under the action of divergent evolution. Barren-tolerant wild soybean has developed adaptation to most nutrient-stress environments, especially with respect to low nitrogen (LN) conditions. This study describes the differences in physiological and metabolomic changes between common wild soybean (GS1) and barren-tolerant wild soybean (GS2) under LN stress. Compared with plants grown under the unstressed control (CK) conditions, the young leaves of barren-tolerant wild soybean under LN conditions maintained relatively stable chlorophyll, concentration and rates of photosynthesis and transpiration, as well as increased carotenoid content, whereas the net photosynthetic rate (P_N) of GS1 decreased significantly 0.64-fold ($p < 0.05$) in the young leaves of GS1. The ratio of internal to atmospheric CO_2 concentrations increased significantly 0.07-fold ($p < 0.05$), 0.09-fold ($p < 0.05$) in the young leaves of GS1 and GS2, respectively, and increased significantly 0.05-fold ($p < 0.05$) and 0.07-fold ($p < 0.05$) in the old leaves of GS1 and GS2, respectively, relative to the CK. The concentration of chlorophylls *a* and *b* decreased significantly 0.45-fold ($p < 0.05$), 0.13-fold ($p > 0.05$) in the young leaves of GS1 and GS2, respectively, and decreased significantly 0.74-fold ($p < 0.01$) and 0.60-fold ($p < 0.01$) in the old leaves of GS1 and GS2, respectively. Under LN stress, nitrate concentration in the young leaves of GS1 and GS2 decreased significantly 0.69- and 0.50-fold ($p < 0.01$), respectively, relative to CK, and decreased significantly 2.10-fold and 1.77-fold ($p < 0.01$) in the old leaves of GS1 and GS2, respectively. Barren-tolerant wild soybean increased the concentration of beneficial ion pairs. Under LN stress, Zn^{2+} significantly increased by 1.06- and 1.35-fold ($p < 0.01$) in the young and old leaves of GS2 ($p < 0.01$), but there was no significant change in GS1. The metabolism of amino acids and organic acids was high in GS2 young and old leaves, and the metabolites related to the TCA cycle were significantly increased. The 4-aminobutyric acid (GABA) concentration decreased significantly 0.70-fold ($p < 0.05$) in the young leaves of GS1 but increased 0.21-fold ($p < 0.05$) significantly in GS2. The relative concentration of proline increased significantly 1.21-fold ($p < 0.01$) and 2.85-fold ($p < 0.01$) in the young and old leaves of GS2. Under LN stress, GS2 could maintain photosynthesis rate and enhance the reabsorption of nitrate and magnesium in young leaves, compared to GS1. More importantly, GS2 exhibited increased amino acid and TCA cycle metabolism in

INTRODUCTION

The identification and evaluation of germplasm resources is a basic and vital challenge for industrial crop improvement ([Abdurakhmonov & Abdusattor, 2008](#)). Wild soybean (*Glycine soja*) is considered the progenitor of cultivated soybean (*Glycine max*) and has been challenged by the natural environment for thousands of years to withstand various biotic and abiotic stresses ([Zhang et al., 2017](#)). Wild soybean maintains a much higher level of genetic diversity than cultivated soybean and represents a treasured genetic resource ([Xie et al., 2019](#)). Wild soybean has evolved many eco types under the action of divergent evolution, such as tolerances to salt alkali, drought, barren soil (such as phosphorus or nitrogen deficiency), and so on ([Sun et al., 2021](#)). To provide an important theoretical basis for the evaluation of plant resources, it is necessary to explore the mechanism of these exceptional traits in wild soybean ([Chen et al., 2019](#)).

Nitrogen (N) is the most important factor limiting plant growth and development, especially at the seedling stage ([Luca et al., 2019](#)). The symbiotic nitrogen fixation system of leguminous plants, such as soybean, is not fully established at the seedling stage, and the seedlings cannot or rarely use the nitrogen supplied by the symbiotic nitrogen fixation of rhizobia ([Mourtzinis et al., 2018](#)). Cultivating low nitrogen (LN) tolerant crop varieties can solve the problem of environmental pollution caused by the application of excessive nitrogen fertilizer in global agricultural production ([Arun et al., 2016](#); [Mourtzinis et al., 2018](#)). Wild soybean has high levels of stress tolerance and is an important germplasm resource for improving the stress tolerance of cultivated soybean. It has been reported that, under low-nitrogen stress in the leaves of wild soybean seedlings, the concentration of carotenoids, which can be used as a photo-protective substance to inhibit the increase of reactive oxygen species (ROS) ([Zhao et al., 2019](#)). Wild soybean could maintain the balance of carbon and nitrogen metabolism by regulating the activities of nitrogen metabolism-related enzymes to improve the ability to tolerate low-nitrogen stress ([Wang et al., 2019](#)). Therefore, it is necessary to improve the LN tolerance of soybean by using appropriate wild germplasm resources.

In recent years, metabolomics and its correlation with ion concentrations had been widely used to determine responses to various abiotic stresses, including salinity, drought, and nutritional deficits ([Li et al., 2017](#); [Jiao et al., 2018](#)). Metabolomics provides insights into the deep relationship between metabolites and changes in plant physiological conditions by combining a range of different analytical technologies and calculation methods ([Yi et al., 2016](#)). Under nutrient deficiencies, plant autophagic systems and

vacuolar proteinases can degrade nitrogen-based macromolecular substances into amino acids, peptides, and urea, and then transport them to nitrogen-demanding organs (Galloway *et al.*, 2004). Metabolomics analysis showed that wild soybean could improve its ability to tolerate nitrogen stress by increasing rates of secondary metabolism, carbohydrate metabolism and amino acid metabolism in the roots (Sun *et al.*, 2021). During senescence of plant leaves, the catabolic processes of macromolecular compounds increase, whereas anabolic processes decrease, and the mobilization and recycling of nutrients occur from old leaves to sinks, such as young leaves, especially under conditions of nutrient deficiency, similar findings have been reported in *Arabidopsis thaliana* (Mei & Thimann, 1984).

The transfer of some nutrients from senescent tissues to other, more demanding tissues in plants is called nutrient reabsorption (Kichey *et al.*, 2007; Elger *et al.*, 2009). This process can improve the utilization efficiency of nutrients by plants and reduce the dependence on soil nutrients (Taylor *et al.*, 2010; Wei *et al.*, 2018). Nutrient reabsorption is an important mechanism for plants to improve their ability to survive under adversity. Amino acids are important metabolites and carriers of organic nitrogen between plant organs (Häusler, Ludewig & Krueger, 2014). Under stress, amino acids are subsequently recycled and allocated for the synthesis of specific proteins required under nutrient limitation (Araújo *et al.*, 2011). Whereas during carbon or nitrogen starvation, proteins are degraded, and the complete oxidation of their amino acids produces the energy required to fuel the particular needs of stressed leaves. Furthermore, nitrogen uptake rates by roots of intact soybean plants are stimulated by malate, which moves down the phloem and accumulates in the root (López-Bucio *et al.*, 2000). Understanding the relationship between organic acid metabolism and nitrate uptake and utilization could be an important avenue to understand the survival strategies of barren-tolerant wild soybean. The combined analysis of physiological and metabolite profiles has provided a new perspective with which to reveal the reuse of nitrogen between young and old leaves of legumes under LN conditions (Tegeder & Masclaux-Daubresse, 2018).

In the current study, to analyze the tolerance strategies used by wild soybean ecotypes adapted to LN stress, common wild soybean (GS1) and barren-tolerant wild soybean (GS2) were used as the study materials. LN stress was simulated using Hoagland's nutrient solution containing one-quarter of the non-limiting nitrogen concentration. The photosynthetic rate, ion concentration changes, and the types, quantities, and pathways of small molecular organic metabolites in young and old leaves of the two accessions were determined and analyzed under LN stress. By comparing the differences in leaf nutrient reabsorption between the two ecotypes of wild soybean under LN stress, the mechanism of LN tolerance employed by wild soybean which evolved under divergent adaptation conditions are discussed from the perspective of nutrient reabsorption. The present study provides a quantitative standard by which to select, evaluate and utilize wild soybean germplasm accessions and provides an important scientific basis for research on plant divergent evolution.

MATERIALS AND METHODS

Plant materials and growth conditions

The experimental materials were common wild soybean ('Huinan 06116', GS1) and barren-tolerant wild soybean ('Tongyu 06311', GS2). GS1 is from Huinan County, Tonghua City, Southeast Jilin Province. The soil here is fertile and nutrient rich. The humus layer is deep, and the organic matter content of the soil surface is high, which contains rich nitrogen, phosphorus, sulfur and other nutrients. GS2 was collected in Tongyu County, Baicheng City, western Jilin Province, where the soil is poor and associated by salinization. Three seeds were uniformly sown in each 14-cm diameter plastic pot, with each pot containing 2.5 kg of washed sand and the seeds were covered with clean sand. The pots were irrigation with water. The experimental materials were cultivated in an outdoor experimental field at Northeast Normal University, Changchun, Jilin. The pots were placed outdoors but were sheltered from the rain. The average temperatures were 18.5 ± 1.5 °C and 26 ± 2 °C during the night and day, respectively, and the relative humidity was $60 \pm 5\%$.

Treatments

One seedling per pot was selected based on its growth, and the other two were removed. When the seedlings had produced their third (compound) leaves, GS1 and GS2 were both randomly divided into two groups of eight pots each: control (CK) and low nitrogen (LN)-treated. CK plants of GS1 and GS2 accessions were cultivated under normal conditions, with seedlings irrigated with Seeds and seedlings were irrigated with $1 \times$ Hoagland's nutrient solution (Table S1). The concentrations of $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ and KNO_3 in $1 \times$ Hoagland's nutrient solution were 3.45 and 5.01 mmol L⁻¹, respectively. In the LN-treated group, GS1 and GS2 seeds were placed in 1/4-strength Hoagland's nutrient solution, where the concentrations of $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ and KNO_3 were 0.87 and 1.25 mmol L⁻¹, respectively. The deficiency of calcium and potassium ions in the LN stress group were corrected by supplying seedlings with equivalent concentrations of $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ and KCl of 2.61 and 3.75 mmol L⁻¹, respectively. After 2 weeks, four replicate pots of each of the four treatments (LN/CK \times GS1/GS2) were randomly used for measuring physiological parameters, ion content and the remaining four pots were used for metabolomics analyses.

Measurements of physiological parameters

After the soybean plants were harvested, shoot height, root length, shoot dry weight (DW) and root shoot dry weight (DW) were measured for the four replicates of each treatment (Shi et al., 2015). A subsample (1 mg) of crushed dry tissue was used to measure the total nitrogen content (TN) (%) and total carbon content (TC) (%) by stable isotope mass spectroscopy (Iso Prime Elemental Analyzer, Isoprime Ltd., Tokyo, Japan), with three technical replicates measured for each replicate (Liu et al., 2020).

The leaves attached to the first and second nodes from the top of the plant were regarded as the young leaves, and the leaves attached to the first and second nodes from the bottom of the plant were regarded as old leaves for parameter determination. The gas-exchange parameters, namely net photosynthetic rate (P_N), transpiration rate (E), stomatal

conductance (g_s), and substomatal CO_2 concentration/atmospheric CO_2 concentrations (C_i/C_a) of young leaves and old leaves were measured at a photosynthetic irradiation of $1,200 \pm 50 \mu\text{mol C}^{-2} \text{ s}^{-1}$ using LI-6400 portable photosynthesis apparatus (LI-COR, Lincoln, NE, USA) with an open system. Approximately 500 mg of fresh leaves were used to measure the concentrations of chlorophyll a (*Chl a*), chlorophyll b (*Chl b*) and carotenoid (*Car*). *Chl a*, *Chl b* and *Car* were extracted with acetone and were measured using spectrophotometer at 645, 663 and 440 nm, respectively (Holm, 1954; Gao et al., 2022) (Spec trUV-754; Shanghai Accurate Scientific Instrument Co., Shanghai, China). All measurements were performed three times for each biological replicate.

Measurements of ion concentrations

Briefly, 0.05 g dry tissue samples were treated with 4 mL of deionized water at 100°C for 40 min and then centrifuged at $3,000 \times g$ for 15 min. The supernatant was collected, and the process was repeated on the residue twice more until the pooled supernatants totaled 15 mL and were used to determine anion concentrations of Cl^- , NO_3^- , H_2PO_4^- , SO_4^{2-} and oxalate ($\text{C}_2\text{O}_4^{2-}$) by ion chromatography (DX-300 ion chromatographic system, AS4A-SC chromatographic column, CDM-II electrical conductivity detector; mobile phase: $\text{Na}_2\text{CO}_3/\text{NaHCO}_3 = 1.7/1.8 \text{ mM}$, Dionex, Sunnyvale, CA, USA). The concentrations of cations Mn^{2+} , B^{3+} , Fe^{2+} , Zn^{2+} , Na^+ , Mg^{2+} , Ca^{2+} and K^+ were determined using an atomic absorption spectrophotometer (Super 990F; Beijing Purkinje General Instrument Co. Ltd., Beijing, China).

Metabolite profiling analysis

For metabolomics, metabolites were independently extracted from $100 \pm 5 \text{ mg}$ samples of the young and old leaves of accessions GS1 and GS2, and a gas chromatography–mass spectrometry (GC–MS) analysis was performed using a one-dimensional Agilent 7890 gas chromatography system coupled with a Pegasus HT time-of-flight mass spectrometer. The data was acquired and pre-processed using the manufacturer’s ChromaTOF software (versions 2.12, 2.22, 3.34; LECO, St. Joseph, MI, USA). Data analysis was performed using the SIMCA-P 13.0 software package (Umetrics, Umea, Sweden). Finally, to analyse the significance of changes in metabolite concentration compared with the corresponding control, Student’s *t*-test ($p < 0.05$), VIP > 1, and similarity value >700 were used to screen differential metabolites. Then, the Kyoto Encyclopedia of Genes and Genomes (KEGG) database was used to analyze metabolites and construct metabolic pathways, and the MetaboAnalyst website (<https://www.metaboanalyst.ca/>) was used to analyze the pathways (Xia et al., 2012).

Data analysis

All measurements were repeated three times, and the data organized in Microsoft Excel 2007. The data values are presented as mean \pm standard error (SE). The data were analyzed statistically by two-way analysis of variance (ANOVA) in SPSS (v.13.0; IBM, Armonk, NY, USA) and significant differences among treatment means were detected at $p < 0.05$ by pairwise multiple comparisons, using Duncan’s multiple range test. Sigma Plot 10.0. was

RESULTS

Morphological characteristic

Compared with the CK, shoot height decreased significantly 0.12-fold ($p < 0.05$) in GS1, but there was no significant change in GS2 under LN. Root length increased significantly 0.05-fold ($p < 0.05$) and 0.15-fold ($p < 0.05$) in GS1 and GS2, respectively under LN. Under LN, the shoot height of GS1 decreased more and the root length increased less than that of GS2. Shoot DW decreased significantly 0.92- ($p < 0.01$) and 0.51-fold ($p < 0.05$) in the GS1 and GS2, respectively. Root DW decreased significantly 0.36-fold ($p < 0.01$) and 0.27-fold ($p < 0.05$) in GS1 and GS2, respectively. The shoot DW and root DW decreased in both ecotypes under LN compared with CK, declined particularly in GS1 (Table S2). No significant changes in TN (%) and TC (%) in young leaves occurred in GS1 and GS2 ($p > 0.05$), whereas, in old leaves, TN (%) decreased significantly 0.35-fold and 0.13-fold ($p < 0.05$) in GS1 and GS2, respectively. Compared with CK, the TC/TN ratio increased significantly by 0.25-fold ($p < 0.05$) in GS1 and 0.17-fold ($p < 0.01$) in GS2 in old leaves under LN (Table 1). The number and weights of nodules in the seedlings of two wild soybean ecotypes did not vary significantly between CK and LN conditions. Overall, the results showed that the tolerant ecotype GS2 was less affected than GS1 under low-nitrogen stress.

Metabolomics response in young leaves

In PCA, PC1 explained 84% of the variance, in metabolite concentrations changes between the young leaves of GS1 and GS2 (Fig. 3). The main metabolites contributing to PC1 were alanine, 3-aminoisobutyric acid, lactulose, and threitol. The CK and LN-stressed young leaves in GS1 and GS2 were clearly distinguished by PC2, which represented 7.1% of the total variation, with the main factors contributing to PC2 were 3-hydroxypropionic acid, 2-hydroxypyridine, oxalic acid, and maleic acid (Fig. 3A, Table 3 and Table S4). PC3

Table 2 Ion contents in young and old leaves of two wild soybean ecotypes under LN stress values were presented as the mean \pm standard error of four biological replicates.

explained 4.1% of the variance and the main contributors were glucoheptonic acid, threitol, maleic acid, and palmitic acid (Fig. 3A, Table 3 and Table S4). The levels of 63 metabolites changed significantly under LN stress relative to CK in the young leaves of both ecotypes (Table 3).

Compared with CK, the relative concentrations of the amino acid metabolites L-proline, sarcosine, L-homoserine, and L-aspartic acid increased significantly 2.85-fold ($p < 0.01$), 1.88-fold ($p < 0.05$), 1.22-fold ($p < 0.01$), and 2.28-fold ($p < 0.05$), respectively in the old leaves of GS2, but the trend in old leaves of GS1 under LN conditions was decreased relative to CK (Table 4). It is noteworthy that the relative concentrations of GABA increased significantly 0.92-fold ($p < 0.05$) in GS2 old leaves. The relative concentrations of

Note:

Values were presented as the mean ± standard error of four biological replicates. GS1, common soybean; GS2, barren tolerant wild soybean; CK, control treatment; LN, low2N stress. * and ** indicate significant ($p < 0.05$) and highly significant ($p < 0.01$) differences, respectively.

isoleucine increased significantly 1.79-fold ($p < 0.01$) in GS2 under LN, but no significant changes were found in the old leaves of GS1 (Table 4).

Under LN stress, the relative concentrations of organic acid metabolites related to glycolysis and the TCA pathway, including pyruvic acid, L-malic acid, and succinic acid, increased significantly 0.94-, 0.45-fold and 1.07-fold ($p < 0.05$), respectively, in GS1, and increased significantly 1.31-, 0.64-fold, and 0.67-fold ($p < 0.05$), respectively, in GS2

Table 4 Changes of LN stress on metabolite content in old leaves of two wild soybean ecotypes.

Note:

The changes in gas exchange of the two soybean ecotypes young and old leaves. P, net photosynthetic rate; g, stomatal conductance; E, transpiration rate; C/C_a, ratio of sub-stomatal to atmospheric CO concentrations; GS1, common soybean; GS2, barren tolerant wild soybean. CK, control treatment; LN, low-nitrogen stress; one asterisk (*) indicates significance (< 0.05), two asterisks (**) indicate significance (p < 0.01).

compared with CK. Fructose 6-phosphate decreased 0.72-fold ($p < 0.05$) in GS1, but increased significantly 1.25-fold ($p < 0.01$) in GS2. The relative concentrations of organic acids including glycolic acid, galactaric acid, benzoic acid, and glyceric acid increased significantly 1.25-fold, 1.26-fold, 3.37-fold, and 4.19-fold ($p < 0.05$) in GS1, whereas lactic acid, maleic acid, galactaric acid, and glyceric acid increased significantly 0.44-fold, 2.41-fold, 0.44-fold, and 0.67-fold ($p < 0.05$) in GS2. The relative content of shikimic acid increased in the old leaves of GS2 but no significant changes were observed in the old leaves of GS1 under LN stress. The relative concentrations of palmitic acid, stearic acid, pelargonic acid, and linoleic acid decreased significantly 1.20-fold ($p < 0.05$), 0.33-fold ($p < 0.01$), 0.22-fold ($p < 0.01$), and 0.15-fold ($p < 0.01$), respectively, in GS1 but increased significantly 1.59-fold ($p < 0.05$), 0.87-fold ($p < 0.05$), 0.27-fold ($p < 0.05$), and 1.41-fold ($p < 0.01$), respectively, in old leaves of GS2 under LN stress. The relative salicylic acid and prunin content increased significantly 1.76-fold ($p < 0.01$) and 1.22-fold ($p < 0.05$), respectively, in GS2 under LN (Fig. 4).

DISCUSSION

In the process of adapting to a stressful environment, wild soybean has evolved a large number of ecotypes exhibiting valuable characteristics (Lu et al., 2020). Leaves of different ages respond positively in plants that are tolerating adverse environments (Liu et al., 2019). In the current study, the mechanism of LN tolerance in a wild soybean ecotype was analyzed from the perspective of leaf nutrient reabsorption and we assessed the plants for

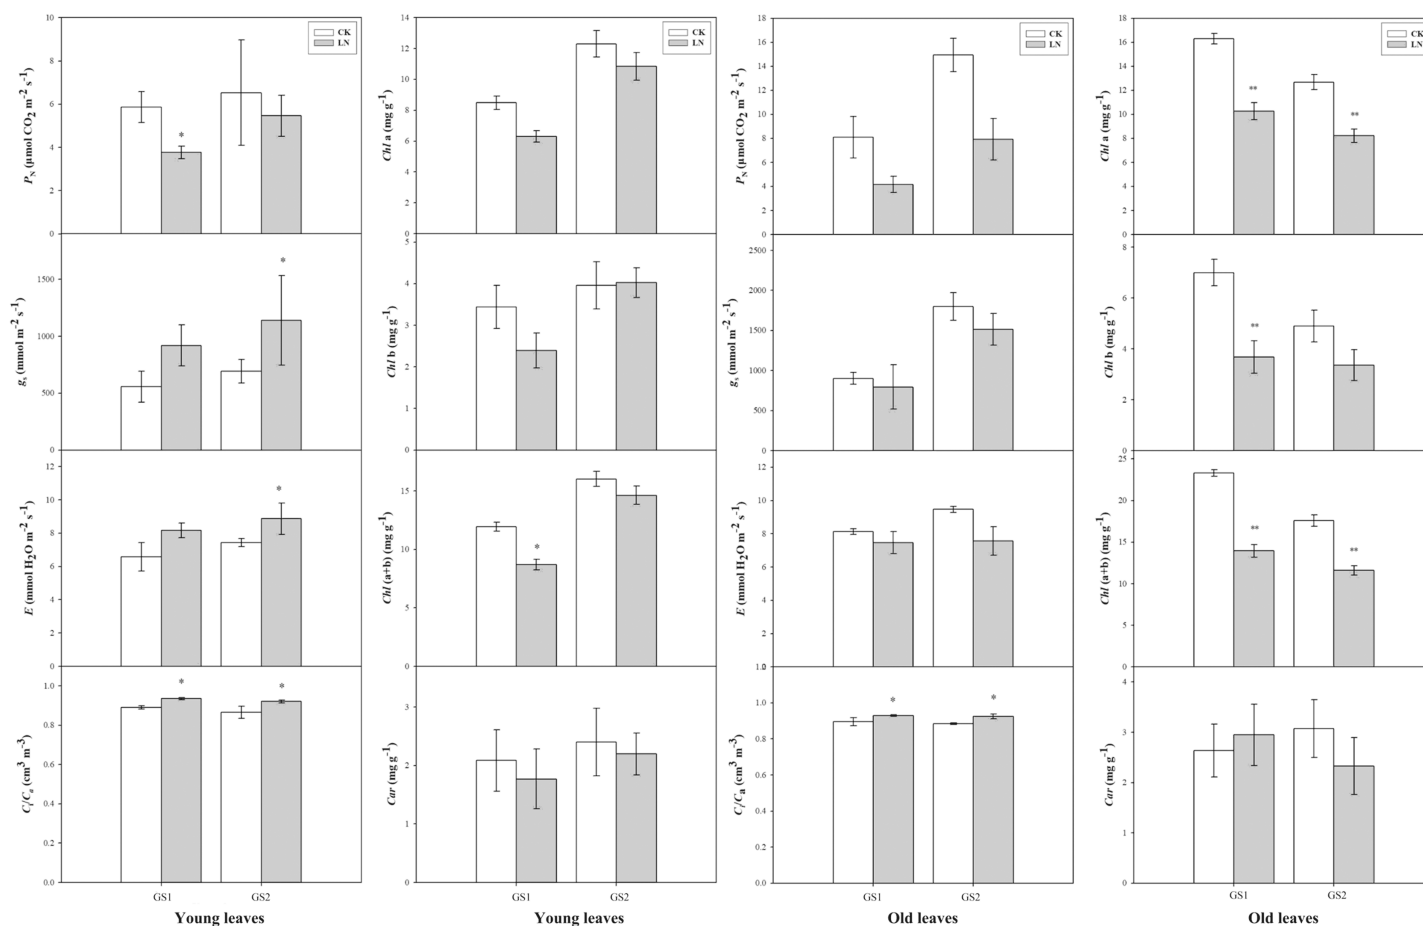

Figure 1 The changes in gas exchange of the two soybean ecotypes young and old leaves. P_n , net photosynthetic rate; g_s , stomatal conductance; E , transpiration rate; C_i/C_a , ratio of sub-stomatal to atmospheric CO₂ concentrations; GS1, common soybean; GS2, barren tolerant wild soybean. CK, control treatment; LN, low-nitrogen stress; one asterisk (*) indicates significance ($p < 0.05$), two asterisks (**) indicate significance ($p < 0.01$).

morphometry and rhizobium formation under LN conditions. N deficiency inhibited the growth of the seedlings of both wild soybean ecotypes according to their different adaptation to LN stress. The biomass of the tolerant GS2 seedlings decreased less than the GS1 seedlings under LN conditions and physiological and metabolite regulation in GS2 may play an important role in the process of tolerating low-nitrogen stress.

In the present study, plant phenotypes and biomass accumulation further confirmed that LN stress could delay plant development, with GS2 exhibiting a greater LN tolerance. TC and TN data display a worse N deficiency in the young leaves of GS1 than in GS2. N deficiency will destroy the chloroplast membrane and reduce chlorophyll content (Ohwaki & Sugahara, 1997). Under LN stress, photosynthetic pigment concentrations declined less in the young and old leaves of LN-tolerant GS2 than in GS1, compared with the CK. This helped GS2 to maintain relatively stable photosynthesis rates in both young and old leaves (Chen et al., 2019). The gas-exchange coefficient increased in both ecotypes, with the difference being more significant in the young leaves of GS2 than in GS1, compared with CK. The wild soybean younger leaves have higher P_n and g_s than old leaves, indicating that

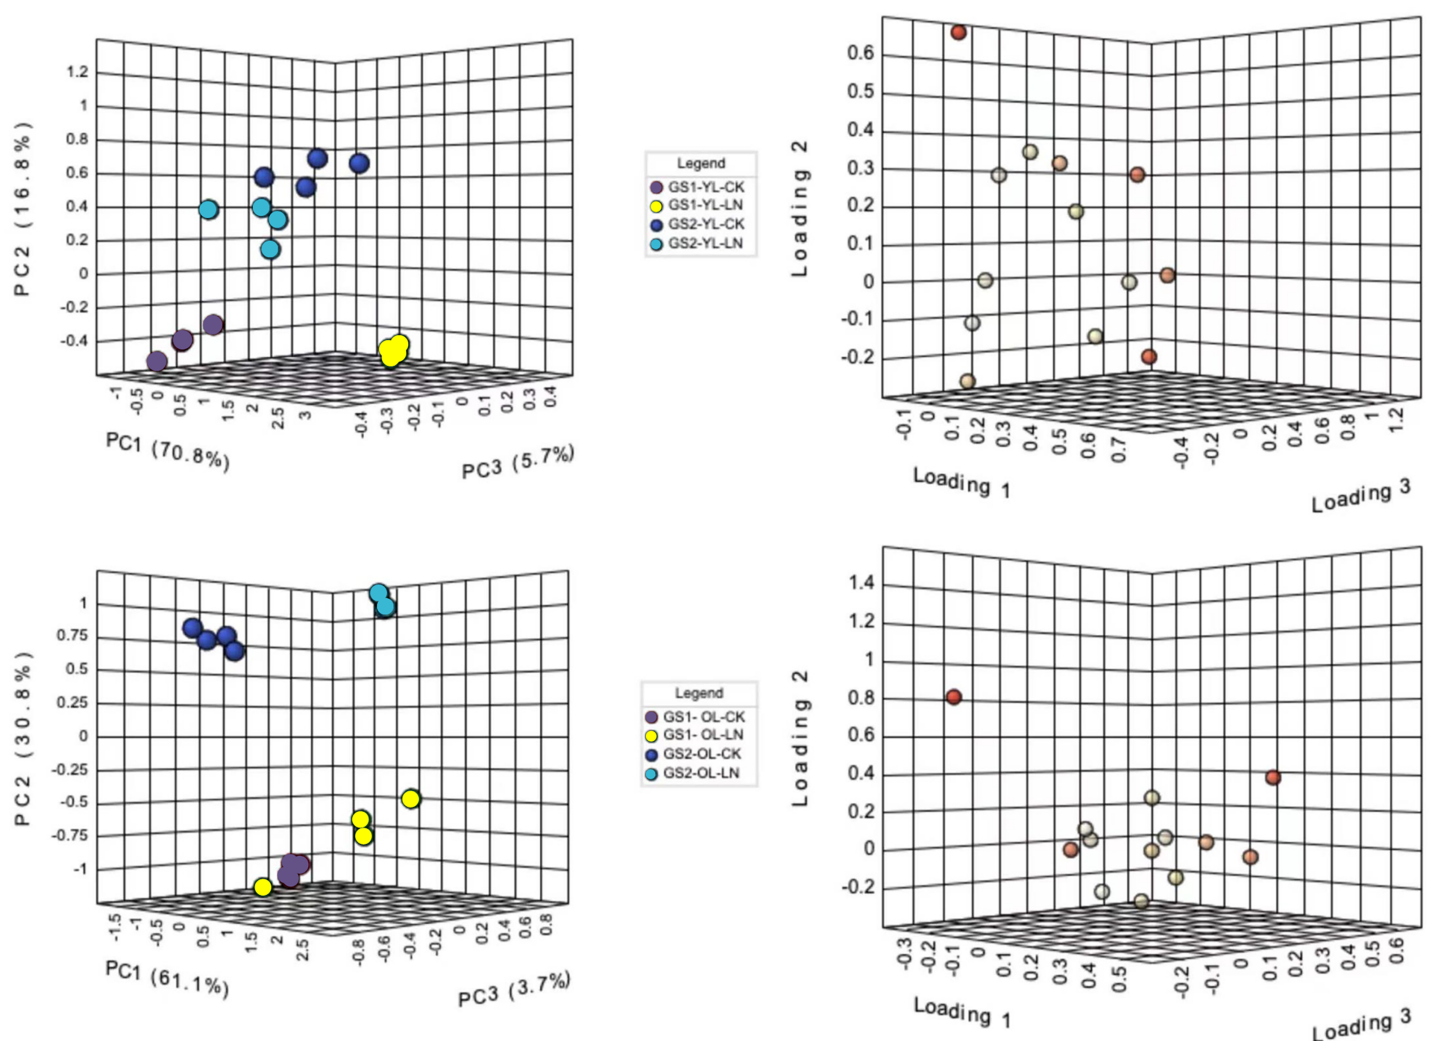

Figure 2 PCA of ionic profiles and loading plots of ionomics in young and old leaves. (A) PCA of young leaves; (B) loading plot of young leaves; (C) PCA of old leaves; (D) loading plot of old leaves; GS1, common soybean; GS2, barren tolerant wild soybean; CK, control treatment; LN, low-nitrogen stress. [Full-size DOI: 10.7717/peerj.15486/fig-2](https://doi.org/10.7717/peerj.15486/fig-2)

under low nitrogen stress, the carbon metabolism ability in the new leaves of wild soybean is stronger than that of the old leaves, which is a manifestation of its active resistance to low nitrogen stress. Indicating that GS2 slows down the photosynthetic rate in old leaves to reduce energy and material consumption to maintain relatively stable photosynthetic characteristics and resist LN stress. However, cultivated soybean younger leaves have lower P_N and g_s than old leaves, indicating an imbalance in their photosynthetic characteristics under low nitrogen stress.

It could be seen from the results that NO_3^- deficiency in GS1 leaves was more severe than in GS2 leaves which indicated that the barren-tolerant GS2 ecotype was more efficient in the process of absorption and storage of N under LN. The SO_4^{2-} concentrations decreased significantly in the old leaves of GS2 but increased in those of GS1. SO_4^{2-} concentrations decreased more sharply in the young leaves of GS1 than in those of GS2. Sulfur is essential

element in the active center of enzymatic reactions (Gao, Zhang & Ma, 2009) and it also plays a certain role in the process of plant growth regulation, detoxification, defense, and stress tolerance (Bollig et al., 2019). Organic sulfur can be converted into inorganic sulfur (mainly sulfate, SO_4^{2-}) by protein hydrolysis, sulfate can be converted into organic sulfur by metabolism, and can be transferred to young tissues for reuse (Liu et al., 2020). The results indicate that GS2 transferred most of the sulfate from senescent older leaves to young tender tissues to alleviate the obstruction by ion imbalance of plant growth. Mineral elements have a marked effect on the improvement of nitrogenase activity in the processes

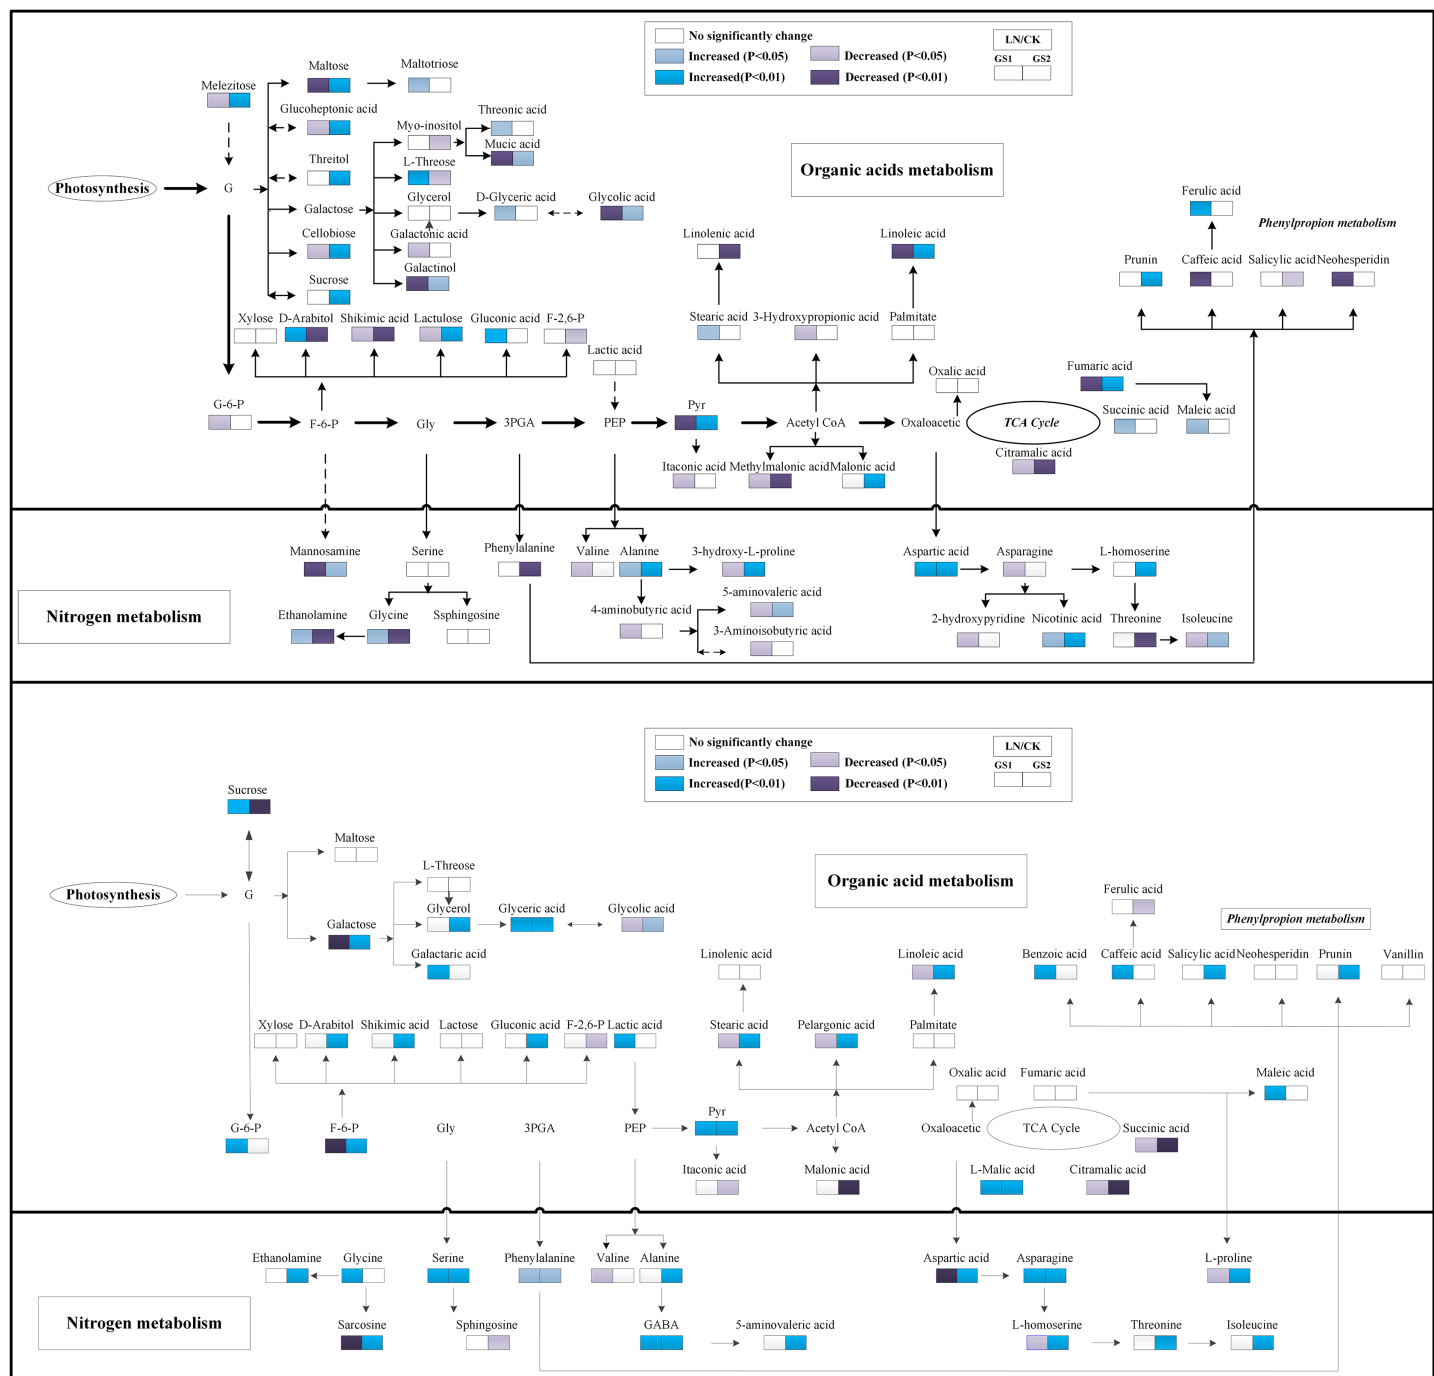

Figure 4 Changes in the metabolic pathways of young and old leaves in the two soybean ecotypes. Suggested changes in the metabolic network in soybean seedlings under LN-stress conditions based on a partial least square-discriminant analysis (PLS-DA). (A) Pathway of young leaves; (B) pathway of old leaves. GS1, common soybean; GS2, barren tolerant wild soybean; CK, control treatment; LN, low-nitrogen stress.

of nitrogen reduction and fixation (*Lecourt et al., 2015*). Previous studies have suggested that changes in the availability of one element could exert an effect on the uptake and accumulation of other elements in plants (*Xue et al., 2012*). In GS2 the concentrations of

Mn^{2+} and Zn^{2+} in the young leaves, and Cl^- , H_2PO_4^- , Mn^{2+} , B^{3+} , Fe^{2+} , and Zn^{2+} in the old leaves were particularly significant increased. Indicating beneficial mineral ions were enriched in the old leaves of GS2, which could help GS2 to avoid ion imbalance under LN stress (Zerche et al., 2016).

According to the results of the present study, the relative GABA concentrations decreased significantly in young leaves of GS1, although it increased in both the young and old leaves of GS2. GABA acts as an endogenous signaling molecule in plant growth and development and rapidly accumulates in plant tissue in response to several abiotic and biotic stresses (Nayyar et al., 2014; Priya et al., 2019). Firstly, under LN stress, hydroxyls produced by nitrate reduction decreased and the frequency of electron carriers in the electron transport chain decreased, resulting in a significant increase in ROS (Ramesh et al., 2015). GABA plays a crucial role in the scavenging of ROS generated rapidly due to disruption of the intracellular redox equilibrium and hence significantly mitigates oxidative stress-induced damages in plants (Streeter, Lohnes & Fioritto, 2001). Secondly, GABA has long been considered an important link in C and N metabolism since the GABA shunt pathway competes with the respiratory chain for SSADH (Shelp, Bown & McLean, 1999; Kinnersley & Turano, 2000). Glutamic acid, the precursor of GABA, is considered to be the main form of nitrogen accumulated in the roots of plants. Under an adverse environment, plants can make the nitrogen of glutamic acid flow into GABA and proline to regulate the metabolism of nitrogen, which is a key factor in the rapid response of plants to external stimuli (Nam et al., 2015; Shelp et al., 2012). Under salt stress, the accumulation of GABA in Arabidopsis leads to an increase in amino acids and the activity of glutamate dehydrogenase (GAD), increasing the expression of GAD instantaneously, and thus increasing the flux of the GABA shunt and other related pathways to regulate TC/TN balance (Renault et al., 2010). Under stress, the GABA shunt may perform a cataplerotic role by providing carbon to the cycle through the catabolism of GABA to succinic acid (Barbosa et al., 2010). Moreover, GABA is also a temporary N storage compound. The glutamate to GABA conversion is increased under conditions that inhibit glutamine synthesis, reduce protein synthesis, or enhance degradation (Sita & Kumar, 2020). Evidence also indicates that glutamine and GABA are produced during protein storage and mobilization as a means of recycling Arg-derived N and C (Shelp, Bown & McLean, 1999). Thus, the GABA shunt may be of considerable importance in the N economy of plants. Because, in the current study, the accumulation of GABA in the young and old leaves of GS2 was highly consistent, it can be inferred that GS2 can regulate TC/TN balance, antioxidants concentration, and N storage by enriching GABA content to alleviate stress (Kinnersley & Turano, 2016).

Asparagine has a higher N/C ratio than glutamine and can be used as a long-range transport and storage compound, especially in legumes (Masclaux-Daubresse et al., 2010; Lu et al., 2013). Under abiotic stress, the energy supply is insufficient, GS and Fd-GOGAT are inhibited, whereas AS is activated, and N assimilation proceeded toward asparagine metabolism. In the present study, the relative concentrations of asparagine increased in the old leaves of both GS1 and GS2 and decreased significantly in young leaves of only GS1, which indicates that N was transported and reused in GS2 but does not change

significantly in young leaves of GS2. Earlier study had confirmed that increases in asparagine concentrations suggest that it will be easier to render available N for remobilization from senescing leaves ([Tegeder & Masclaux-Daubresse, 2018](#)). In the current study, the relative concentrations of L-homoserine and isoleucine increased significantly in young and old leaves of GS2. The effective transport and utilization of these key amino acids between young and old leaves provide a relatively stable material basis for protein synthesis in the vigorous young growth parts of GS2.

Organic acid metabolism is of fundamental importance at the cellular level for several biochemical processes including energy production, formation of precursors for amino-acid biosynthesis, and, at the whole plant level, modulation of adaptation to the environment ([López-Bucio et al., 2000](#)). Organic acids exuded by roots originate from the downward transport of organic acids in leaves ([Hildebrandt et al., 2015](#)). The present results showed that most differential organic acids (e.g., L-lactic acid, maleic acid, caffeic acid, galactaric acid, benzoic acid, and glyceric acid) increased significantly in the old leaves of GS2 but no significant change was found in the corresponding leaves of GS1. Organic acid metabolism not only provides carbon skeletons during N assimilation but also plays potential roles in osmotic regulation, cation balance, nutrient deficiency-related coping mechanisms, and plant–microbe interactions at the root–soil interface ([Gregersen et al., 2013](#)). Organic acids have also been found to stimulate nitrate uptake. Nitrate uptake rates by roots of intact soybean plants are stimulated by malate, which moves down the phloem and accumulates in the root ([Touraine, Muller & Grignon, 1992](#)). Some plants have specialized roots that exude large amounts of organic acids (corresponding to up to 23% of net photosynthesis), which acidify the soil and chelate metal ions around the roots, resulting in the mobilization of micronutrients ([Schachtman & Shin, 2007](#)).

[Fritz et al. \(2006\)](#) found that the levels of 2-oxoglutarate and other TCA cycle intermediates, including citrate, isocitrate, succinate, fumarate, and malate, which are key regulators of carbon–nitrogen interaction, were lower under LN conditions. In the present study, the results showed that, under LN conditions, most differential metabolites related to glycolysis and the TCA pathway did not change significantly in the young leaves of GS2 under LN stress. However, compared with CK, the differences in concentrations of metabolites associated with the energy consumption stage of glycolysis (fructose-6-phosphate) increased significantly in the young leaves of GS1, under LN stress. In the second stage of glycolysis (energy generation), the relative concentrations of organic metabolites of pyruvic acid decreased significantly in the young leaves of GS1 ([Geigenberger et al., 1993](#)). In the old leaves of GS2, in particular, the relative concentrations of glycolysis-related metabolites of fructose-6-phosphate and pyruvic acid increased significantly, indicating that the old leaves of GS2 strengthen and generate energy ([Avila-Ospina, Clément & Masclaux-Daubresse, 2017](#)). The increase of L-malic acid and succinic acid concentrations enhanced the TCA cycle in old leaves of GS2. Compared with GS1, the strategies of glycolysis and TCA in the young leaves of GS2 could conserve energy from old leaves and maintain a relatively stable state under LN stress ([Huang et al., 2008](#)).

CONCLUSIONS

Improved carbon assimilation capacity and maintenance of adequate reabsorption of mineral and organic nutrients is an important survival strategy for barren-tolerant wild soybeans under low nitrogen stress. Compared with the common wild soybean, the barren-tolerant wild soybean has a relatively stable ability to maintain photosynthetic assimilation by young leaves and the supply of inorganic nutrients under low-nitrogen stress. In addition, the enrichment of specific nitrogen-containing compounds in old leaves of GS2, such as GABA and asparagine, can play a substantial role in N storage, TC/TN balance and antioxidant defense and can act as signaling molecules to help barren-tolerant soybean tolerate LN stress. The increase in the relative organic acid concentration in the old leaves of GS2 could improve the utilization rate of N in the soil. The rate of fatty acid catabolism and the TCA cycle in the old leaves of GS2 maintained a relatively high level of energy supply, provided an energy basis for nutrient transport and reuse, and improved the ability to tolerate low-nitrogen stress. Our study provides a quantitative standard by which to select, evaluate and utilize wild soybean germplasm accessions and provides an important scientific basis for research on plant divergent evolution.
