

Rates and modes of body size evolution in early carnivores and herbivores: a case study from Captorhinidae

Neil Brocklehurst

Body size is an extremely important characteristic, impacting on a variety of ecological and life-history traits. It is therefore important to understand the factors which may affect its evolution, and diet has attracted much interest in this context. A recent study, examining the evolution of the earliest terrestrial herbivores in the Late Carboniferous and Early Permian, concluded that in the four herbivorous clades examined there was a trend towards increased body size, and that this increase was more substantial than that observed in closely related carnivorous clades. However, this hypothesis was not based on quantitative examination, and phylogenetic comparative methods provide a more robust means of testing such hypotheses. Here, the evolution of body size within different dietary regimes is examined in Captorhinidae, the most diverse and longest lived of these earliest high fibre herbivores. Evolutionary models were fit to their phylogeny to test for variation in rate and mode of evolution between the carnivorous and herbivorous members of this clade, and an analysis of rate variation throughout the tree was carried out. Estimates of ancestral body sizes were calculated in order to compare the rates and direction of evolution of lineages with different dietary regimes. Support for the idea that the high fibre herbivores within captorhinids are being drawn to a higher adaptive peak in body size than the carnivorous members of this clade is weak. A shift in rates of body size evolution is identified, but this does not coincide with the evolution of high-fibre herbivory, instead occurring earlier in time and at a more basal node. Herbivorous lineages which show an increase in size are not found to evolve at a faster rate than those which show a decrease; in fact it is those which experience a size decrease which evolve at higher rates. It is possible the shift in rates of evolution is related to the improved food processing ability of the more derived captorhinids rather than a shift in diet, but the evidence for this is circumstantial.

11 ABSTRACT

12

13 Body size is an extremely important characteristic, impacting on a variety of ecological and life-
14 history traits. It is therefore important to understand the factors which may affect its evolution,
15 and diet has attracted much interest in this context. A recent study, examining the evolution of
16 the earliest terrestrial herbivores in the Late Carboniferous and Early Permian, concluded that in
17 the four herbivorous clades examined there was a trend towards increased body size, and that this
18 increase was more substantial than that observed in closely related carnivorous clades. However,
19 this hypothesis was not based on quantitative examination, and phylogenetic comparative
20 methods provide a more robust means of testing such hypotheses. Here, the evolution of body
21 size within different dietary regimes is examined in Captorhinidae, the most diverse and longest
22 lived of these earliest high fibre herbivores. Evolutionary models were fit to their phylogeny to
23 test for variation in rate and mode of evolution between the carnivorous and herbivorous
24 members of this clade, and an analysis of rate variation throughout the tree was carried out.
25 Estimates of ancestral body sizes were calculated in order to compare the rates and direction of
26 evolution of lineages with different dietary regimes. Support for the idea that the high fibre
27 herbivores within captorhinids are being drawn to a higher adaptive peak in body size than the
28 carnivorous members of this clade is weak. A shift in rates of body size evolution is identified,
29 but this does not coincide with the evolution of high-fibre herbivory, instead occurring earlier in
30 time and at a more basal node. Herbivorous lineages which show an increase in size are not
31 found to evolve at a faster rate than those which show a decrease; in fact it is those which
32 experience a size decrease which evolve at higher rates. It is possible the shift in rates of

- 33 evolution is related to the improved food processing ability of the more derived captorhinids
- 34 rather than a shift in diet, but the evidence for this is circumstantial.

35 **Introduction**

36

37 Body size is among the most important traits of an organism (Bell 2014). It influences,
38 amongst other things, an organism's potential diet range (Sinclair et al. 2003), the habitats it may
39 occupy, its energy requirements (Oksanen et al 1982), its ability to defend against predation
40 (Roff 1992), its development (Gillooly et al. 2002) and viable reproductive strategy (Tuomi
41 1980). As such, a great deal of effort has been put into understanding the patterns and processes
42 in body size evolution and how this varies between clades, through time, and between different
43 ecological groups.

44 In a recent paper, Reisz & Fröbisch (2014) examined body-size evolution in the earliest
45 terrestrial herbivorous vertebrate. During the first establishment of terrestrial ecosystems in the
46 Carboniferous and Early Permian, high-fibre herbivory appeared independently in at least four
47 different lineages: Edaphosauridae and Caseidae from the synapsid (mammal-line) amniotes,
48 Captorhinidae from the sauropsid (reptile/bird-line) amniotes and Diadectidae from the stem-
49 amniote diadectomorph lineage. Reisz & Fröbisch (2014) noted that, in these four families, the
50 evolution of herbivory appeared to be consistently correlated with increased body size. The
51 earliest members of each of these four clades are considered to be small carnivores or
52 insectivores, and the herbivorous members of these clades appeared in each case to be noticeably
53 larger than their carnivorous ancestors. Moreover, they suggested that there was more
54 pronounced increase in body size in the herbivorous members of these clades than in closely
55 related carnivores.

56 An association between herbivory and large body size has been noticed in other clades
57 e.g. mammals (Gaulin 1979; Fleming 1991; Isbell 1998; Price & Hopkins 2015), birds (Morton

58 1978; Dudley & Vermeij 1992; Klasing 1998) and lizards (Pough 1973; Schluter 1984; Cooper
59 & Vitt 2002). Two possible explanations have been offered for the association. The first is based
60 on the Jarman-Bell Principle (Geist 1974), originally used to explain body size evolution in
61 ungulates but since applied to other clades (e.g. Gaulin 1979; Fleming 1991; Isbell 1998). This
62 principle posits that, since smaller animals have higher metabolic energy requirements relative to
63 their body size, smaller herbivores are limited to more easily digestible plant material such as
64 roots and fruits. Larger members of a herbivorous clade have lower energy requirements relative
65 to their body size, and so are able to subsist on less digestible plant material such as leaves.
66 Since less digestible plant material is more abundant, those able to subsist on it (the larger
67 herbivores) have a selective advantage over their smaller relatives

68 The second explanation for the association between large body size and herbivory,
69 dubbed the abundance-packet size hypothesis by Olsen (2015), is based on the absolute nutrient
70 requirements rather than nutrient requirements relative to body size. A lineage which increases in
71 mass will require larger amounts of food. Therefore, the lineage must either feed on larger prey
72 (macro-carnivory) or find a more abundant food source such as plant material. It should be noted
73 that the abundance-packet size hypothesis differs from the Jarman-Bell Principle in the proximal
74 cause for the association between herbivory and larger body size; the Jarman-Bell principle
75 posits that in a herbivorous lineage there will be a selective pressure towards larger body size,
76 while the abundance-packet size hypothesis posits that in a lineage with a large body size there
77 will be a selective pressure to a more herbivorous diet.

78 Reisz & Fröbisch (2014) did not quantitatively test their hypothesis that the earliest
79 herbivores showed a greater trend towards larger body size than the carnivores; rather it was
80 tentatively suggested based on a visual examination of plotting diet and body size over a

81 phylogeny. Such inferences do need to be rigorously tested, however; for example, a more
82 detailed examination of body-size evolution in Therizinosaurus showed that previous assumptions
83 of a trend towards large body size in these herbivorous theropods was unfounded (Zanno &
84 Makivicky 2012).

85 Of the four clades examined by Reisz & Fröbisch (2014), the captorhinids provide the
86 best case study for testing their theory. They are the longest lived of the clades, surviving from
87 the late Carboniferous until the end of the Permian. They are also the most speciose, with more
88 than 25 species currently described. Moreover, a recently published and comprehensive (19
89 captorhinid terminal taxa) phylogeny exists, well resolved and with reasonably high node
90 supports (Reisz et al. 2015), providing an excellent framework for an analysis of body-mass
91 evolution.

92 The captorhinids were the most diverse sauropsid clade in the Paleozoic. They first
93 appear in the fossil record in the Virgilian aged Hamilton Quarry of Kansas (Müller & Reisz
94 2005) before diversifying during the early Permian. By the Middle Permian they had achieved a
95 global distribution, being known from North America, Europe, Asia and Africa. The first
96 herbivorous members of this clade appeared during the Kungurian (Doddick & Modesto 1995).
97 Crucial to the evolution of herbivory in captorhinids were the multiple rows of maxillary and
98 dentary teeth. This feature first appeared in the insectivore/omnivore *Captorhinus* (Doddick &
99 Modesto 1995) but in the high-fibre herbivorous taxa up to 11 rows of bullet-shaped maxillary
100 teeth, combined with a propalinal motion of the lower jaw, form an effective grinding and
101 shredding surface for processing plant material (Modesto et al. 2007).

102 Here I examine changes in rate and mode of the evolution of size in captorhinids. In
103 particular the evolution of the carnivorous and herbivorous members is compared, in order to test

104 the hypothesis of Reisz & Frobisch. The applicability of the Jarman-Bell Principle and the
105 abundance-packet size hypothesis to captorhinid evolution is also examined.

106

107 **Materials and Methods**

108

109 Proxy for body size

110

111 The estimation of body mass in extinct organisms is unsurprisingly difficult, in the
112 absence of a complete skeleton and soft tissue. Some workers have attempted volumetric
113 reconstructions (e.g. Colbert 1962; Hurlbert 1999; Motani 2001), but these require relatively
114 complete skeletons and are not useful in examinations of body mass spanning entire clades. Most
115 other estimates have used a single measurement as a proxy for mass e.g. dorsal centrum cross
116 section (Romer & Price 1940), humerus and femur shaft circumference (Campione & Evans
117 2012). This of course requires those taxa not possessing the necessary elements to be ignored,
118 but in large analyses e.g. Benson et al. (2014) on dinosaurs, a small number of deletions should
119 not mask the overall pattern.

120 Since Captorhinidae are a small clade (18 taxa included in the most comprehensive
121 phylogenetic analysis) useful proxies for body size are limited by the available material. Due to
122 the fact that all terminal taxa analysed by Reisz et al. (2015) possess skull material, but only a
123 limited number have postcranial material preserved, it was decided to use the skull length as a
124 proxy for size. While cranial material is not often used in calculations of body mass, a precise
125 mass in grams is not necessary for the analyses herein; an estimate of relative difference in size
126 is the most important. It is obviously possible for skull size to vary relative to the rest of the

127 body, but comparison of skull measurements to postcranial measurements for those taxa which
128 preserve both indicate that, in captorhinids at least, this does not appear to be a serious concern
129 (see measurements provided by Reisz & Fröbisch 2014). Using skull material allows the study to
130 be as comprehensive as possible. Only two taxa are not represented by a skull complete enough
131 to measure the length (*Captorhinikos valensis* and *Gansurhinus quingtoushanensis*), and both of
132 these do preserve skull material, so an estimate of skull length could be obtained by comparing
133 the length of elements preserved in these taxa to the length of elements preserved in closely
134 related taxa.. The skull lengths were log transformed prior to analysis (see supplementary
135 materials for skull-length data).

136

137 Phylogeny and Time Calibration

138

139 The most recent and comprehensive phylogeny of captorhinids (Reisz et al. 2015) formed
140 the basis of the analyses presented herein. The phylogeny contains 19 captorhinid taxa, of which
141 6 are considered high-fibre herbivores (Figure 1). The phylogeny was time calibrated using the
142 method of Brusatte et al. (2008) in the R 3.03 (R Core Team 2014) package paleotree (Bapst
143 2012); zero-length branches resulting from inconsistencies between the order of branching and
144 the order of tip appearance in the fossil record were eliminated by sharing the zero-length
145 branches equally along the non-zero-length branch immediately ancestral to them. While other
146 time calibration methods are available for use on extinct datasets (for summary see Bapst 2014a;
147 b), the use of the Brusatte et al. method is less subjective than the addition of arbitrary amounts
148 of time to zero-length branches. Meanwhile, methods like the Cal3 method (Bapst 2013) are not

149 suitable for datasets with poor sample size and low resolution. After time calibration, the non-
150 captorhinid outgroups (*Paleothyris* and *Protorothyris*) were dropped.

151 To resolve the uncertainty surrounding the age ranges of taxa, 100 time calibrated trees
152 were generated using the method of Pol & Norrell (2006). For each tree, the ages of each taxon
153 were drawn at random from a uniform distribution of the full possible age range. A single age
154 was drawn for singletons, a first and last appearance for taxa represented by more than one
155 specimen. Subsequent analyses were performed on all 100 trees to assess the impact of uncertain
156 age ranges (see supplementary materials for trees in nexus format). Since the Reisz et al.
157 phylogenetic analysis found two most parsimonious trees (MPTs, differing in the position of
158 *Opisthodontosaurus*), 50 of these 100 trees were based on one MPT, 50 the other.

159

160 Models of Rate and Mode of Evolution

161

162 *Model fitting*

163 When examining the evolution of a continuous trait such as body size and comparing it in
164 different clades, ecological groups or time periods, one must consider both the rate and the mode
165 of evolution. Models such as Brownian motion (BM) assume evolution via a statistically random
166 walk with a constant normally distributed deviate from the observed morphology. In
167 macroevolutionary processes, this can result from randomly varying selection a lack of selective
168 pressure in any particular direction and a lack of variation in rate (Mooers et al 1999; Pagel
169 1997; Pagel 1999). As such, a clade evolving by simple Brownian motion will show no
170 directional trend in trait mean, but instead the trait variance will increase through time. More
171 complicated models can add parameters to provide a more detailed simulation of evolution. One

172 can, for example, incorporate a directional trend to the BM model; the trait variance will still
173 increase through time, but the mean will either increase or decrease. The Ornstein Uhlenbeck
174 (OU) model incorporates an adaptive optimum to which trait values are drawn; the further a
175 lineage strays from this optimum, the more strongly it is drawn back (Hansen 1997). Once the
176 trait has reached the adaptive optimum, it will show a constant variance and mean through time.
177 Rate variation has also been examined, such as in the early burst (EB) model (Harmon et al.
178 2010), where rate of change decreases exponentially from an initial maximum, causing the
179 increase in trait variance to be rapid in the early history of a clade, but to then slow. Further
180 models have been developed allowing shifts in either rate or mode of evolution between clades
181 (O’Meara et al. 2006; Thomas et al. 2009) or at specific points in time (Slater 2013).

182 Maximum likelihood was used to fit three sets of models to the observed size estimates,
183 with the Akaike weights used to deduce which model in each category fits best. The three
184 categories represent 1) models of the evolution of the continuous trait (body size) alone; 2)
185 models of the co-evolution of body size with a dietary regime; 3) models of the evolution of
186 body size subjected to external influences at specific times.

187 The models in the first category included Brownian motion, Brownian motion with trend,
188 Ornstein Uhlenbeck, the TM1 model and the SURFACE model. Under the TM1 model the trait
189 evolves by Brownian motion, but one or more heritable shifts in rate may occur at any node. If a
190 shift occurs at a node, an increase or decrease in rate is deduced for all lineages descended from
191 that node (Thomas et al. 2009). Under the SURFACE model, the trait evolves under an OU
192 process, but one or more shifts in adaptive peak may occur at any node; that is, the descendants
193 from the node at which the shift occurs will be drawn to a different trait value (Ingram & Mahler
194 2013). These five models represent models where captorhinid body size evolution is independent

195 of any specified factor; evolution is either consistent across captorhinids, or can shift but at
196 entirely unspecified points. The BM and BM with trend models were fit using the fitContinuous
197 function in the R package Geiger (Harmon et al. 2008); the OU model using the functions in the
198 package OUwie (Beaulieu et al. 2012); the TM1 model using the transformPhylo.ML function in
199 the package motmot (Thomas et al. 2009); the SURFACE model using the runSurface function
200 in the package surface (Ingram & Mahler 2013).

201 The models in the second category allow different rates or modes of evolution to occur
202 under different dietary regimes. Three such models are tested: BM-V OU-M and OU-MV. Under
203 the BM-V model, body size evolves by Brownian motion but with rates of evolution differing
204 between the carnivorous lineages and the herbivorous lineages. The OU-M model represents
205 body size evolution under an OU process, but with the different dietary regimes drawn to
206 different adaptive optima. The OU-MV model is similar to the OU-M model, but allows a
207 change in rate of evolution as well as adaptive optimum under different dietary regimes. All
208 three of these models were fit using the functions in the R package OUwie.

209 The third category of models tests for the possibility of extrinsic influences on the
210 evolution of body size in captorhinids; that is, changes in rate or mode are related to a change in
211 the organism's environment (both biotic and abiotic) rather than any evolutionary innovation
212 within the clade itself. Were this to be the case, one would expect a shift in rate or mode to occur
213 at a specific point in time, and affect all lineages after this point, rather than affecting all taxa
214 descended from a specific node. The captorhinids evolved at a time of great changes in
215 environment. Throughout the late Carboniferous and Permian, there was a trend towards a
216 warmer, dryer climate (Rees et al. 2002). At the end of the Carboniferous, there was a collapse in
217 the equatorial rainforest and a shift towards seasonally dry climates (DiMichelle et al. 2006;

218 2009). This coincided with, and possibly caused, a radiation in amniotes (Sahney et al. 2010). In
219 the Early Permian, during the Sakmarian stage, there was an abrupt shift towards higher
220 temperatures and accelerated deglaciation (Montanez et al. 2007), possibly coinciding with a
221 brief drop in amniote diversity (Brocklehurst et al. 2013). During the Kungurian and Roadian
222 there was transition from an early Permian fauna dominated by pelycosaurian-grade synapsids
223 and abundant amphibians to a Middle Permian fauna dominated by therapsids, possibly
224 accompanied by a mass extinction event (Sahney & Benton 2008; Benson & Upchurch 2013;
225 Brocklehurst et al. 2013; Brocklehurst et al. in press).

226 Slater (2013) described models to test the possibility of shifts in rate or mode coinciding
227 with a specific point in time. The Rate Shift (RS) model assumes evolution by Brownian motion,
228 but with a shift in rate at a specified point in time. The Ecological Release (ER) model allows a
229 shift in mode at the specified time from OU to BM. Both of these models were tested four times,
230 each with a different time specified for the shift to occur. The four times were the late Gzhelian
231 (coinciding with the rainforest collapse and amniote radiation), the end of the Sakmarian
232 (coinciding with the temperature spike), the early Kungurian and early Roadian (the time of the
233 tetrapod faunal turnover and Olson's extinction).

234 Having found the best fitting model in each of these three categories, these three models
235 were compared to find a single model which overall best fits the evolution of body size in
236 captorhinids.

237

238 *Rate variation*

239 When considering the evolution of a trait such as size, one cannot only consider shifts in
240 the rate. Increasing the rate of evolution under a BM model increases the rate of evolution in

241 both directions, towards larger and smaller. In order to examine whether there is indeed a greater
242 tendency towards larger body size in the herbivorous captorhinids, one must ascertain 1) whether
243 rates of increase in size of herbivores are greater than rates of increase in carnivores; 2) whether
244 rates of decrease in size of herbivores are less than rates of decrease in carnivores, and 3)
245 whether rates of increase in size of herbivores are greater than rates of decrease. Such an
246 examination requires a method which can assess rate variation along every branch in the
247 phylogeny. The method of Venditti et al. (2011) was used to assess rate variation across every
248 branch of the phylogeny. An MCMC analysis was carried out in BayesTraits V2.0 to calculate
249 the pattern of rate variation which best fits the body size data to the time calibrated phylogeny.
250 BayesTraits also scales the branch lengths of the phylogeny to represent rate variation. This
251 method has an advantage over similar methods (e.g. Mooers et al. 1999) in that it allows the
252 scaling of not only individual branches, but the equal scaling of all branches within an entire
253 clade, thus taking into account the possibility of rate heritability.

254 Along with the rate values calculated using the Venditti et al. method, each branch was
255 assigned an inferred diet based on likelihood ancestral state reconstruction, and a direction of
256 evolution (increase or decrease in size). The direction was deduced from ancestral state
257 reconstruction of size, assuming evolution by BM but rescaling the branch lengths to represent
258 the rate variation calculated in BayesTraits. The rates of both increase and decrease in body size
259 in carnivores and herbivores were compared using the Mann Whitney U test, calculated in R.

260

261 **Results**

262

263 The model from the first category (models of evolution independent of diet or extrinsic
264 events) which best fits the body size data and phylogeny of captorhinids is the TM1 model
265 representing a rate shift at a specific node in the tree (Figure 2a). This model has a median
266 Akaike weight score of 0.94. In all but three of the 100 time calibrated trees this model has a
267 higher Akaike weights score than all the others, and in 83 the Akaike weight score is above
268 0.8. The majority of analyses (91) suggest this rate shift was an increase occurring at the same
269 node: the clade containing *Captorhinus*, *Captorhinikos valensis*, *Labidosaurus* and the
270 Moradisaurinae (Figure 3), although there are a minority where the rate increase is found to have
271 occurred only in the genus *Captorhinus*. This indicates the uncertainty surrounding the ages of
272 taxa is influencing the results.

273 The best model from the second category (coevolution of body size and diet) which best
274 fits the body size data and phylogeny of captorhinids is, in all 100 of the time calibrated
275 phylogenies, the OU-M model (Figure 2b). In all 100, it is found that the herbivorous lineages
276 have are being drawn to a higher adaptive peak of body size than the carnivorous lineages. This
277 model receives an Akaike weight score of above 0.8 in 78 of the tested phylogenies, and has a
278 median Akaike wight score of 0.84.

279 The best model from the third category (coevolution of body size and diet) is the Rate
280 shift model, with a rate increase occurring at the end of the Sakmarian stage (Figure 2c). The
281 median Akaike weights score of this model is only 0.63, indicating greater uncertainty when
282 choosing between these models. There are 6 of the 100 time calibrated trees where a rate shift at
283 the end of the Sakmarian fits the body size data less well than an ecological release (a shift from
284 evolution under an OU process to a BM process) during the Kungurian or Roadian.

285 When the three best fitting models from each category are compared, it is the TM1 model
286 with a rate increase at the node indicated in figure 3 which is overall found to best fit the
287 captorhinid body size data, with a median Akaike weights score of 0.85 (Figure 2d). It should be
288 noted that this median Akaike weights score, while high, is not overwhelming. Only in 59 of the
289 100 time calibrated trees is the score over 0.8, and it is over 0.9 in only 37. The OU-M model
290 received the second highest median Akaike weight score of 0.14%, but receives a score of above
291 50% in 14 of the 100 time calibrated trees (see supplementary data). This indicates that the
292 uncertainty surrounding the ages of certain fossils is affecting the results. However, the majority
293 (86) of the trees best fit a BM model with a rate shift at the clade indicated rather than a higher
294 adaptive optimum for herbivores (see supplementary data). In none of the 100 time calibrated
295 phylogenies is the RS model with a rate shift at the end of the Sakmarian found to be a better fit
296 the either of the other two.

297 The variable rates analysis indicates that the mean rate of size increase in herbivores is
298 higher than that of carnivores, and the Mann Whitney U test suggests the difference is significant
299 (Table 1). However, there are also herbivorous lineages which show a decrease in size, and the
300 Mann Whitney U test suggests that the rate of decrease is also significantly faster in herbivores
301 than carnivores (Table 1). The rates of increase in size of herbivores was found to be lower than
302 rates of decrease (albeit not significantly), while in carnivores the reverse was found; rates of
303 increase in size are higher than rates of decrease, although again, not significantly (Table 1).

304

305 **Discussion**

306

307 Reisz & Frobisch (2014) put forward two theories about body size evolution in early
308 herbivores. First, they suggested that herbivorous clades showed a trend towards increased body
309 size. Second they suggested that this increase was more pronounced in herbivores than in closely
310 related carnivores. Support for these hypotheses depends on observing one or more of these three
311 possible results: 1) the Ornstein Uhlenbeck model with a variable trait optimum would be the
312 evolutionary model best fitting the size data, and the trait optimum would be higher in herbivores
313 than in carnivores; 2) the herbivorous branches which show an increase in size would have a
314 faster rate of change than the carnivorous branches showing an increase; 3) the herbivorous
315 branches which show a decrease in size should have a slower rate of change than the carnivorous
316 branches showing a decrease.

317 Support for a variable optimum OU model being the best fitting is equivocal due to the
318 uncertainty surrounding the age ranges. In most of the 100 sets of ages tested it is not the best
319 supported model. In fact the best supported model for size evolution is the TM1 model
320 incorporating a shift towards higher rates of size evolution, and this shift does not coincide with
321 the evolution of herbivory. Instead it occurred earlier, probably during the Sakmarian or
322 Artinskian. The node at which this shift is inferred to have occurred does contain the herbivorous
323 members of Captorhinidae, but also includes three species of *Captorhinus* and *Labidosaurus*
324 *meachami* (Figure 3), neither of which is considered to be a high-fibre herbivore (Dodick &
325 Modesto 1995; Modesto et al. 2007).

326 The results of the variable rates analysis in BayesTraits may be represented as a heat map
327 (Figure 4), in which high rates are represented by hot colours (purple and red). The results
328 indicate an increase in rates of size evolution at the same node identified by the model fitting
329 analysis. The greatest rate increase is identified in three tip branches: those leading to

330 *Captorhinus aguti*, *Captorhinus magnus* and *Captorhinikos valensis*. Ancestral size
331 reconstruction indicates that the size change on the branch leading to the herbivorous
332 *Captorhinikos valensis* was an extremely rapid decrease (Figure 5). Another herbivorous taxon
333 which shows high rates of body size evolution (albeit not so high as *Captorhinikos valensis*) is
334 *Gansurhinus*. Again, this herbivore is found to be experiencing a rapid decrease in body size.

335 Overall, the variable rates analysis also fails to support a tendency towards larger body
336 size in herbivores. The rates of evolution along the herbivorous branches of the Captorhinidae
337 are found to be, on average, higher than those of carnivores, but this increase in rate applies in
338 both directions: both towards larger and smaller sizes (Figure 6, Table 1). While this has resulted
339 in comparatively large sizes in herbivorous taxa such as *Moradisaurus*, *Rothianiscus* and
340 *Labidosaurikos*, all of which have skull lengths above 200mm, extremely rapid rates of
341 decreasing body size are also observed in herbivorous taxa such as *Captorhinikos valensis* and
342 *Gansurhinus* (Figure 5). Moreover, while herbivorous taxa do have a higher mean rate of skull
343 size evolution than the carnivorous taxa, both the variable rates analysis and the model fitting
344 analysis indicate that the shift in rate of evolution did not coincide with the evolution of high
345 fibre herbivory, but instead occurred earlier in time and at a node containing both carnivorous
346 and herbivorous taxa (Figure 2). The results support neither a general trend towards larger size in
347 herbivorous captorhinids nor an adaptive optimum of larger size; decreases in body size of high-
348 fibre herbivores occur no less rapidly than increases. In fact, the results directly oppose Reisz &
349 Frobisch's hypothesis that there was a more pronounced trend towards increased body size in
350 herbivores than in carnivores. The rate of size evolution in the high-fibre herbivores is found to
351 be higher in branches which decrease in body size than in those which increase (Figure 6),
352 although the difference is not significant, possibly due to the low sample size (Table 1).

353 Meanwhile the converse is found to be true in the carnivorous lineages; body size evolution is
354 faster in lineages which show an increase (although the difference is lowest of those tested and is
355 again not significant).

356 These results allow the rejection of the Jarman-Bell Principle as governing body size in
357 Captorhinidae. The Jarman-Bell Principle posits a selective pressure towards large body size
358 within an already herbivorous lineage. Therefore, were it applicable to captorhinids, one would
359 expect the OU-M model, with the herbivorous captorhinids being drawn to a higher body size
360 than carnivores, to best fit the captorhinid data, and one would expect the herbivorous
361 captorhinids to show higher rates of increase in body size than decrease. Neither of these
362 predictions is borne out by the data. The OU-M model cannot be completely rejected due to the
363 uncertainty surrounding the ages of taxa, but it is not the best fitting model in most cases.
364 Meanwhile, herbivorous captorhinids show some extremely rapid decreases in body size, while
365 most of the herbivorous lineages which increase in body size do so gradually (with the exception
366 of the lineage leading to *Labidosaurikos*).

367 Rejection of the abundance-packet size hypothesis is more difficult. This hypothesis
368 posits that lineages with a larger body size should experience a selective pressure towards a more
369 herbivorous diet, but does not preclude the possibility of herbivorous lineages returning to a
370 smaller body size. The transition to herbivory does appear to have occurred in lineages of above
371 average size, which would support this hypothesis. One should note, however, the uncertainty
372 surrounding how many transitions to herbivory there were and where they occurred (Figure 1). It
373 is unclear whether *Captorhinikos chozaenesis* represents a separate evolution of herbivory, or if
374 *Labidosaurus* represents a reversal to a more omnivorous diet.

375 Since the evolution of herbivory may be rejected as the cause of this shift in rate of body-
376 size evolution, an alternative explanation is necessary. Changes in rate and mode of evolution
377 can either be intrinsic, relating to the evolution of a “key” morphological, behavioural or
378 developmental innovation, or extrinsic, relating to a change in environment. An extrinsic cause
379 would be supported if a shift in rate or mode occurred at a specific time rather than in a specific
380 clade. This does not appear to be the case in the Captorhinidae; models involving a temporal
381 shift in rate and mode fit the captorhinid phylogeny worse than the TM1 model. Therefore an
382 intrinsic cause must be sought; one must consider the morphological variations within
383 captorhinids.

384 One feature which characterises the more derived captorhinids is the increased efficiency
385 of food processing. Multiple tooth rows have evolved at least twice; in *Captorhinus aguti* and in
386 the clade containing *Captorhinikos chozaensis* and the Moradisaurinae, although the lack of this
387 feature in *Labidosaurus* leads to uncertainty over the optimisation of this character (Figure 6).
388 The evolution of the propalinal motion of the lower jaw is another innovation which would
389 improve food processing in this clade. The ability to perform such a motion has been suggested
390 in *Captorhinus* (Heaton 1979), *Labidosaurus* (Modesto et al. 2007) *Captorhinikos valensis*
391 (Modesto et al. 2014) and the Moradisaurinae (Dodick & Modesto 1995), a distribution which
392 corresponds with the position of the inferred rate shift. One might reasonably suggest that the
393 improved food processing could have widened the range of ecological niches available to
394 captorhinids. Basal captorhinids were limited to a “grab and gulp” feeding habit, indicated by the
395 simple conical teeth and suitable only for capturing small, non-resisting prey such as
396 invertebrates (Hotton et al. 1997). The inferred evolution of propalinal jaw motion coincides
397 with the node at which the rate shift occurred, and the majority of taxa descended from this node

398 possess multiple tooth rows. The transition to a dentition and jaw morphology allowing
399 processing of food after capture widens the diet available for both carnivorous and herbivorous
400 forms; in carnivores it allows the capture of larger, more resistant prey and the detachment of
401 pieces for mechanical processing, while in herbivores it aids the digestion of tough fibrous plant
402 material whilst reducing the need for gut fermentation inferred for more bulky herbivores such as
403 caseids. One might therefore infer an “ecological release” as the increased food processing
404 ability permitted captorhinids to explore as-yet untried ecological niches, increasing the rate
405 body size evolution in both directions.

406 There are difficulties with conjecturing a causal relationship between the evolution of the
407 specialised jaw motion and the rate shift. One must remember this evidence is purely
408 circumstantial. Moreover the propalinal motion is in some cases difficult to infer; one can
409 deduce its presence from wear patterns on the teeth (Heaton 1979; de Riqles & Taquet 1982), but
410 such data is not always available and morphological correlates must be found. Dodick &
411 Modesto (1995) suggested the increased length of the articulation between the lower jaw and the
412 quadrate could be such an indicator, as could the vaulting of the skull roof which allows the
413 required angle of adductor musculature. However, these lines of evidence conflict in the case of
414 *Captorhinus*; the tooth-wear patterns suggest the ability to perform the jaw motion (Heaton
415 1979), but *Captorhinus* lacks the supposed morphological correlates (Dodick & Modesto 1995).

416 Despite these uncertainties a causal relationship between the evolution of improved oral
417 processing equipment and increased rate of body size evolution is an extremely tempting one.
418 Further confirmation could be provided by examination of other taxa with multiple rows of teeth
419 and the specialised jaw motion. *Baeotherates fortsillensis*, for example, was not included in the
420 analysis of Modesto et al. (2014), on which that of Reisz et al. (2015) is based, due to the lack of

421 material, but the single dentary preserved shows tooth morphology similar to *Captorhinus aguti*
422 (May & Cifelli 1998), and so could provide further information on the evolution of multiple
423 tooth rows in non-herbivorous taxa. Meanwhile, taxa such as *Gecatogomphius kavejevi*,
424 *Kahneria seltini* and *Captorhinikos parvus* would deliver further data on body size evolution in
425 the herbivorous taxa. Modesto et al. (2014) suggested further preparation of these taxa would be
426 required before attempting to fit them in a phylogenetic analysis.

427 It is necessary to conclude with an acknowledgement that, while this study does cast
428 doubt on the general hypothesis of Reisz & Frobisch (2014) that the earliest herbivores showed a
429 pronounced trend towards larger body size, one should be careful about expanding the inferences
430 presented here to other clades. Multiple clades evolved herbivory independently, and they all
431 show great variation in size, tooth morphology and environmental preference. Nevertheless this
432 study strongly highlights the need for quantitative examinations of evolution. It is difficult to
433 make inferences about evolutionary patterns and processes with visual examinations of trait data
434 divided into coarse categories. In clades where a comprehensive, well supported phylogeny
435 exists, a great variety of tools are available to test such hypotheses and provide robust
436 confirmation.

437

1

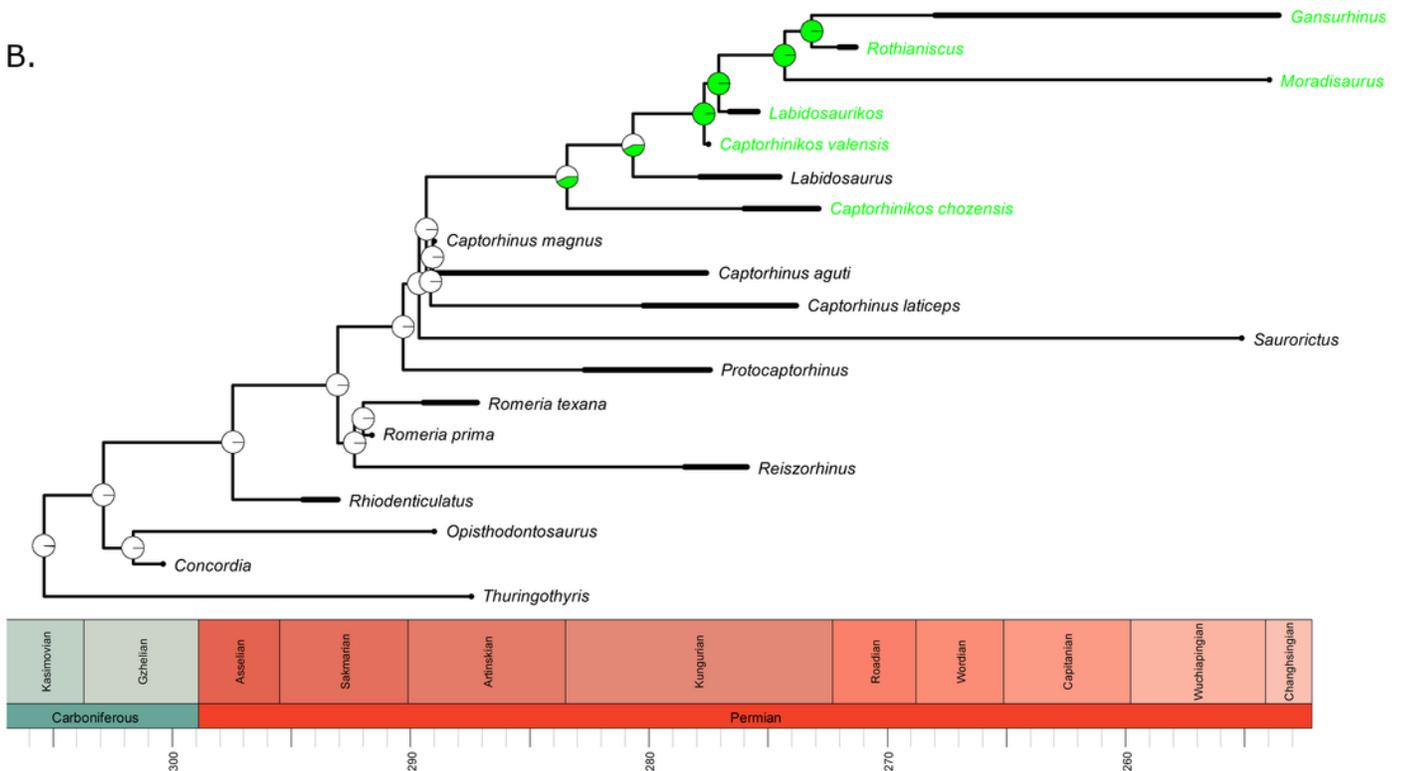

The phylogeny of Captorhinidae, illustrating the evolution of high-fibre herbivory.

Two of the 100 time calibrated phylogenies used in this analysis. The thick branches indicate the observed range for non-singleton taxa. The tip labels in green indicate those taxa inferred to have a high-fibre herbivorous diet. The pie charts represent the probability of each dietary regime inferred for each node, deduced by maximum likelihood ancestral state reconstruction using the ace function in the R package ape. A) MPT 1: *Opisthodontosaurus* is the sister to the clade containing *Rhiodenticulatus* and all captorhinids more derived. B) MPT 2: *Opisthodontosaurus* is the sister to *Concordia* .

2

The fit of models of body size evolution to the phylogeny of Captorhinidae

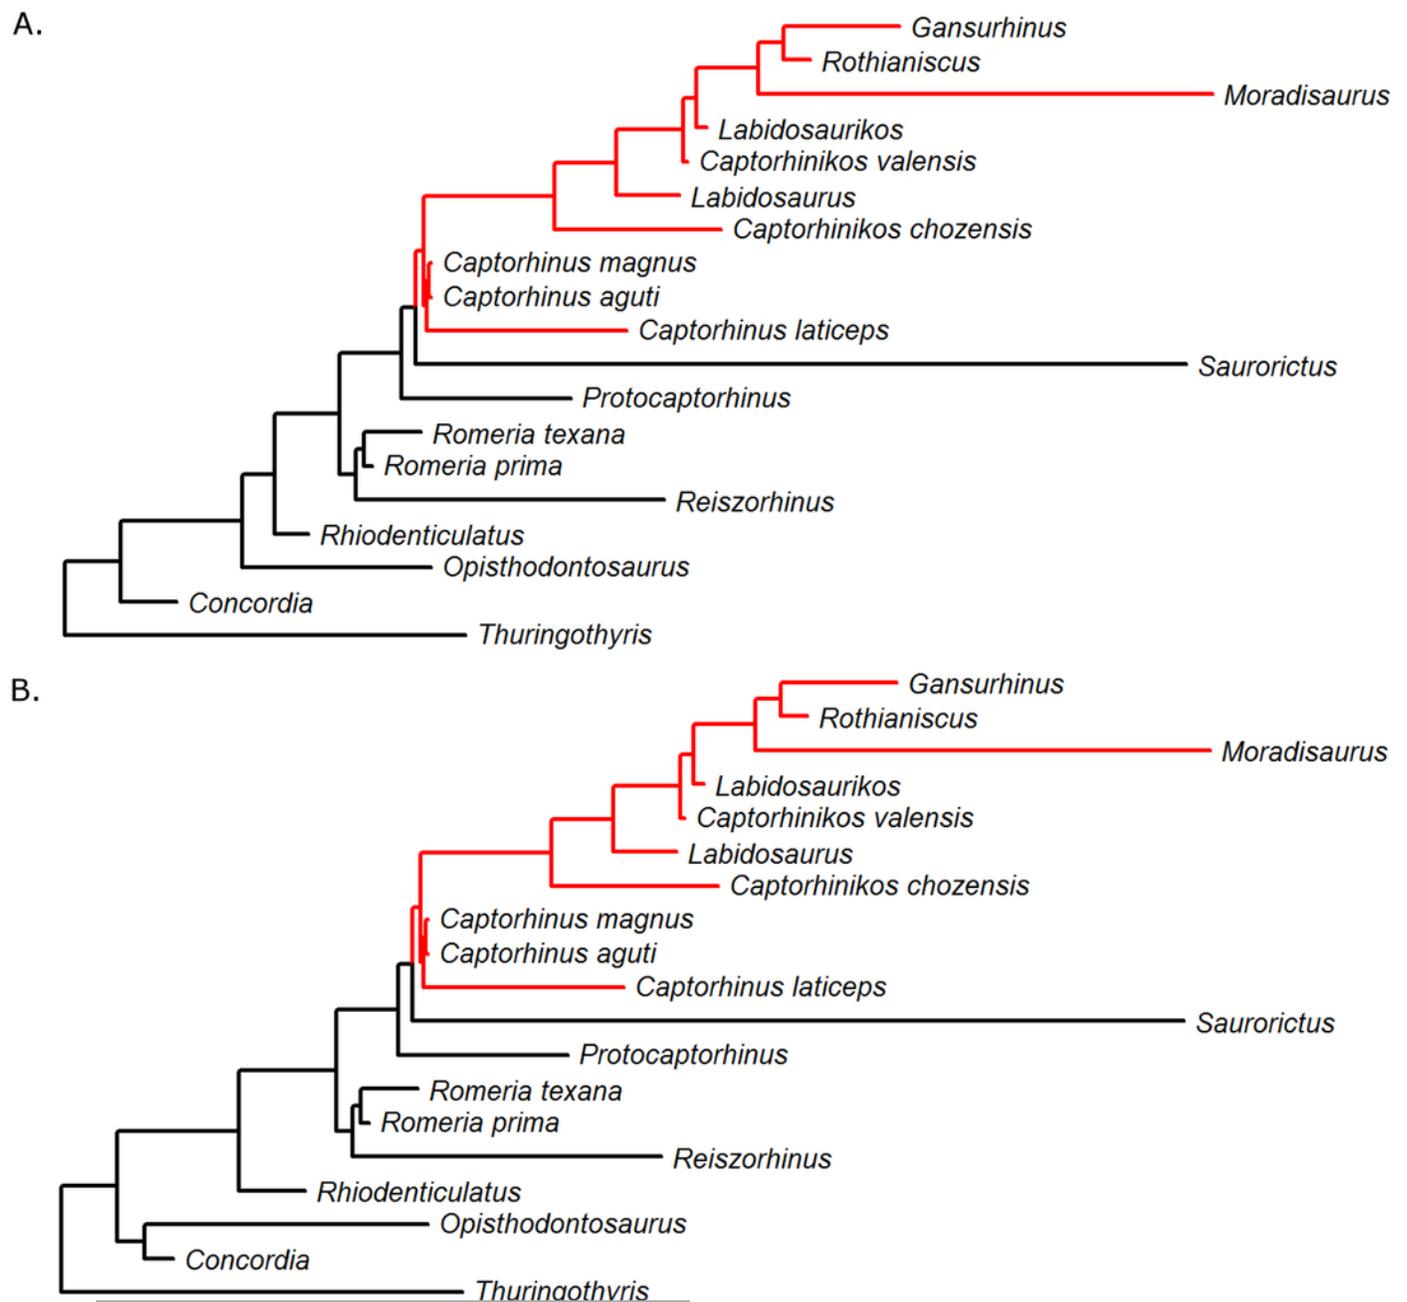

Boxplots showing the distribution of 100 Akaike weight values calculated for each model representing the fit of each model of body size evolution to the 100 time calibrated phylogenies. A) Category 1 models (Evolution of body size alone). B) Category 2 models (coevolution of body size with herbivory. C) Category 3 models (evolution of body size with shifts in rate or mode at specified points in time). D) Comparison of the best fitting models from each of the three categories. The abbreviation Gzh, Sak, Kun and Roa represent the time at which the shift in rate/ mode occurred in the RS and EC models. Gzh - end of the Gzhelian; Sak - end of the Sakmarian; Kung - beginning of the Kungurian; Road - beginning of the Roadian. Other abbreviations as in the main text.

3

The shift in rate of body size evolution, identified by fitting the TM1 model to the phylogeny of Captorhinidae

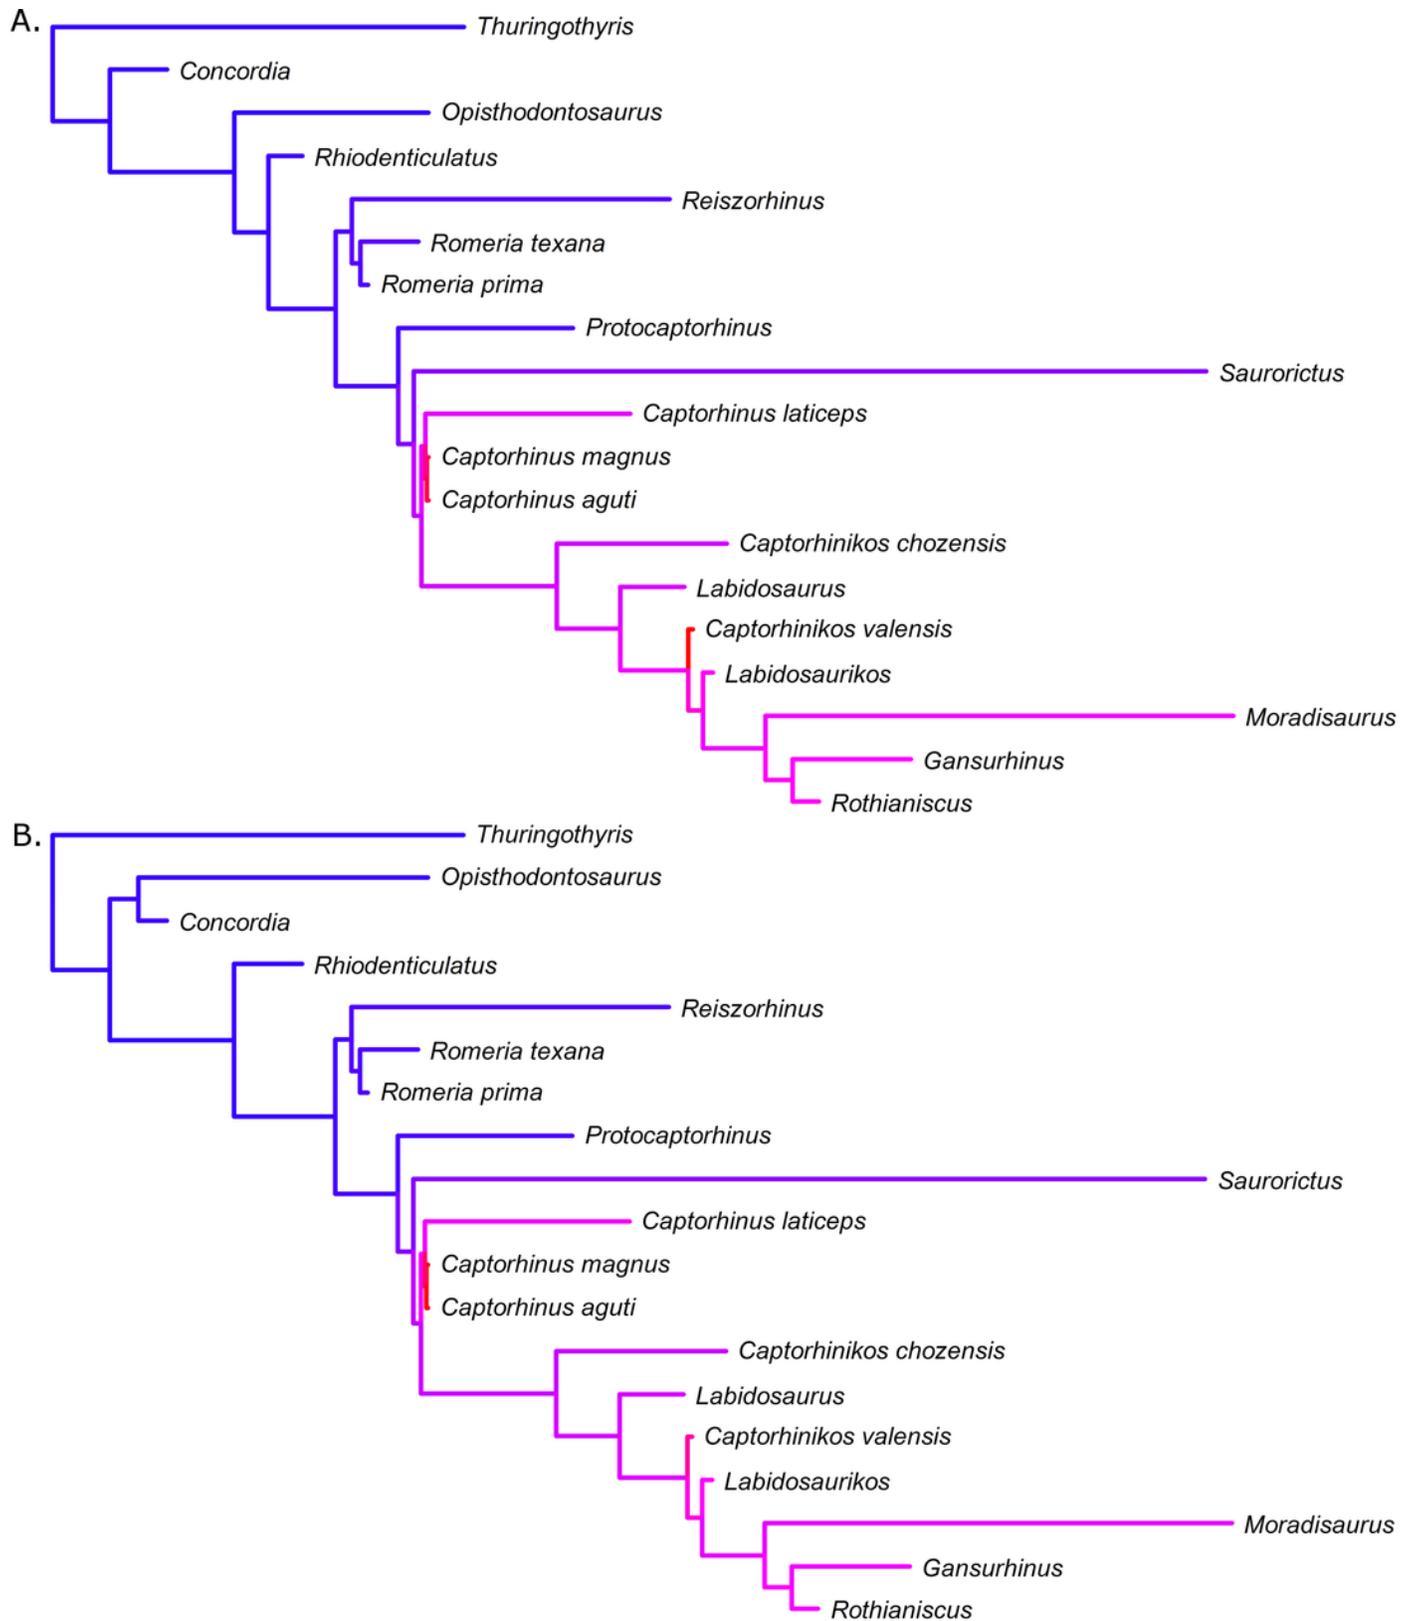

Two of the 100 time calibrated phylogenies of Captorhinidae, with the location of the rate increase indicated by the red branches. The branch lengths here represent the time until the first appearance of the taxa. A) MPT 1. B) MPT 2

4

Variation in rates of body size evolution within Captorhinidae, illustrated as a heat map.

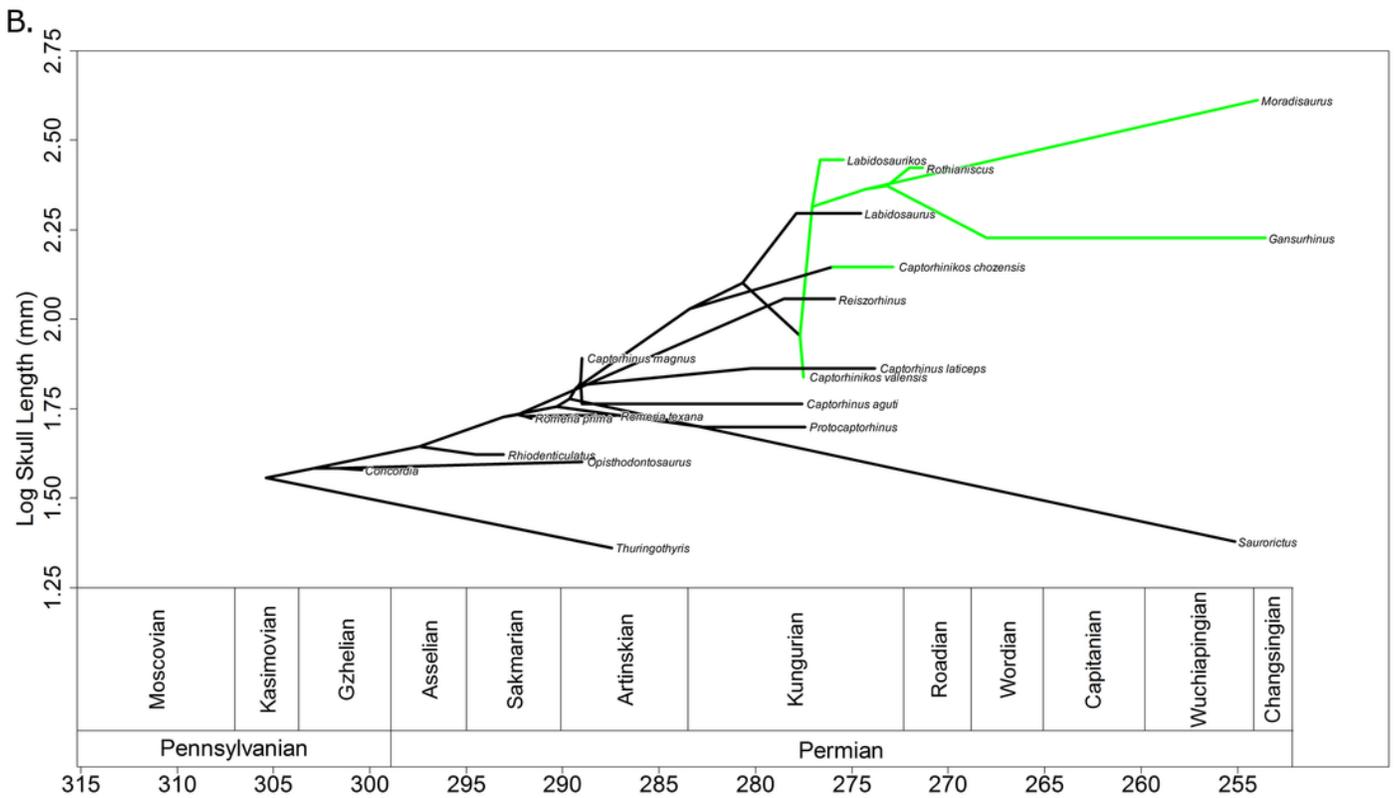

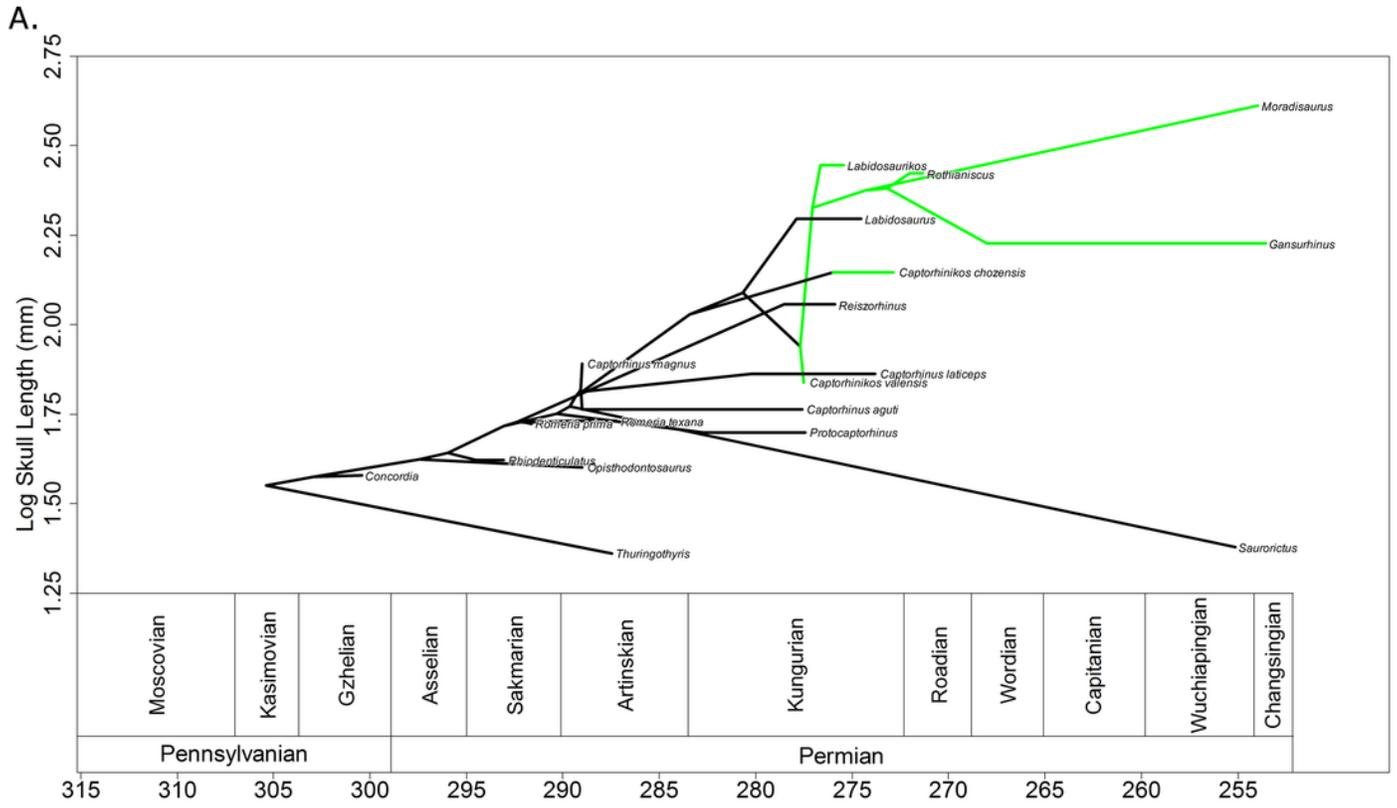

Two of the 100 time calibrated phylogenies of Captorhinidae, illustrating variation in rates of body size evolution identified using the method of Venditti et al. (2011). The branch lengths here represent the time until the first appearance of the taxa. A) MPT 1. B) MPT 2.

5

The evolution of body size through time of the Captorhinidae

Two of the 100 time calibrated phylogenies, illustrating both the age and inferred body size of each node. Ancestral body sizes are reconstructed using likelihood, assuming evolution by Brownian motion but scaling the branches to represent rate variation. Herbivorous lineages are coloured green. As the analyses do not take into account changes occurring within the observed ranges of the species, the observed ranges are here shown to experience no changes in body size. A) MPT 1. B) MPT 2.

6

The evolution of multiple toothrows in the Captorhinidae.

Two of the 100 time calibrated phylogenies used in this analysis. The tip labels in red indicate those taxa with multiple tooth rows. The pie charts represent the probability of an ancestral morphology including multiple tooth rows, deduced by maximum likelihood ancestral state reconstruction using the ace function in the R package ape. A) MPT 1. B) MPT 2.

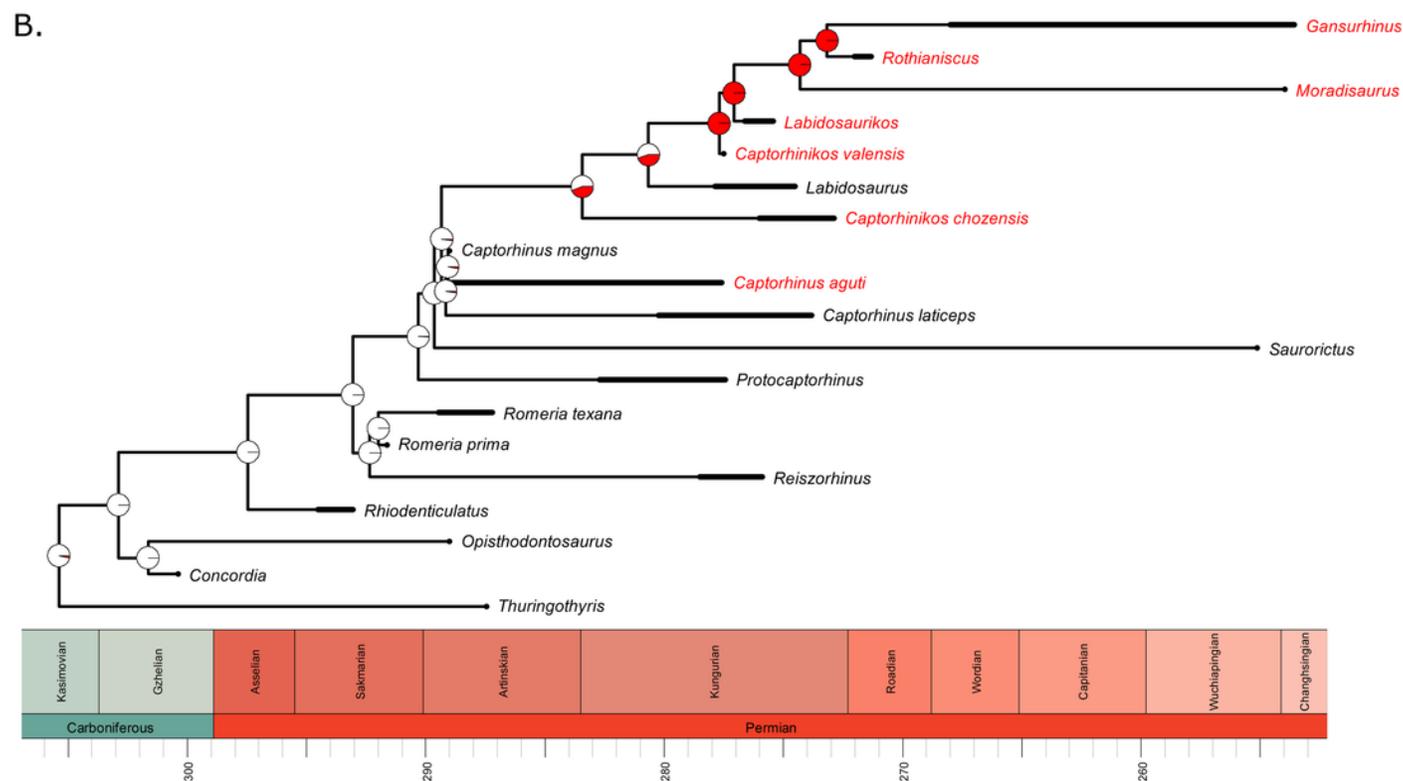

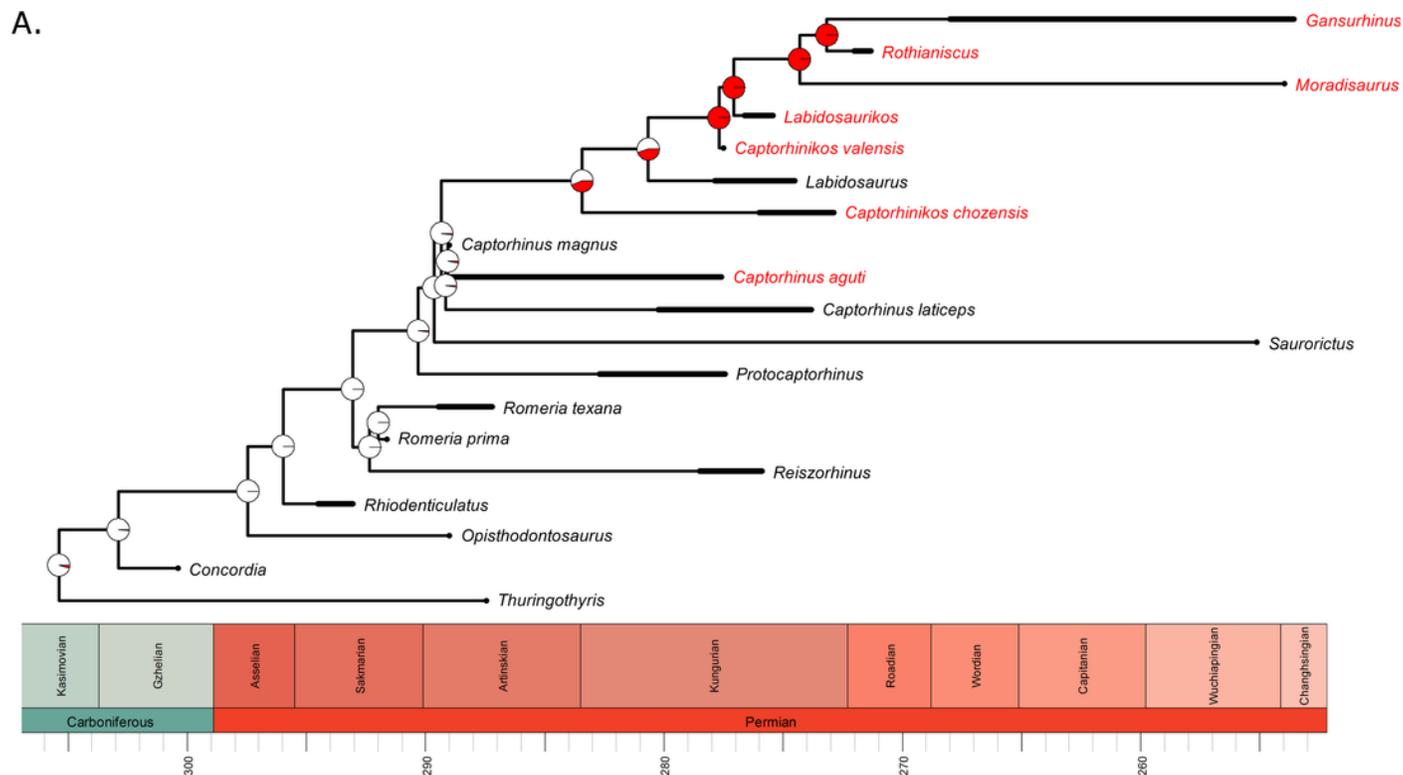

Table 1 (on next page)

Results of Mann Whitney U tests

Values of W and p -values resulting from the Mann Whitney U test comparing rates of lineages evolving in different directions and under different dietary regimes

| Comparison of rates | Sample size | Median of rates | W | P-value |
|--|---------------|----------------------|-----|---------|
| Herbivorous branches decreasing in size vs Carnivorous branches decreasing in size | 3 vs 9 | 4.144 vs 1.234 | 25 | 0.036 |
| Herbivorous branches increasing in size vs Carnivorous branches increasing in size | 9 vs 15 | 3.674 vs 1.308 | 104 | 0.029 |
| Herbivorous branches increasing in size vs Herbivorous branches decreasing in size | 9 vs 3 | 3.674 vs 4.144 | 22 | 0.146 |
| Carnivorous branches increasing in size vs Carnivorous branches decreasing in size | 9 vs 15 | 1.308 vs 1.234 | 52 | 0.379 |
