A detailed morphological description and comparative study were conducted on numerous large-sized hamster remains collected from the late Middle Pleistocene Locality 2 of Shanyangzhai (Syz 2), Hebei Province, China. The comparisons reveal that these fossils are highly similar to the extant *Tscherskia triton* in size and morphology, including the small degree of alternating between the main opposite cusps on M1-3, the presence of axioloph on M3, and mesolophids on m1-2 that are present but seldom reach the lingual margin of the teeth, among other features. However, minor differences between the two still exist. Consequently, all these fossils are designated as a chronosubspecies of the extant species, *T. triton varians* comb. nov. The skull and molar morphologies of *Cricetinus varians* and *T. triton* were meticulously compared to resolve the long-standing debate regarding the validity of *Cricetinus* Zdansky, 1928, and *C. varians* Zdansky, 1928. The findings indicate that the differences between the two are slight; as a result, *C. varians* can only be considered a chronosubspecies of *T. triton*, i.e., *T. triton varians* comb. nov., and *Cricetinus* should be recognized as a junior synonym of *Tscherskia*. We tentatively propose that, among the seven species once referred to *Cricetinus* in Eurasia, *C. europaeus*, *C. gritzai*, *C. janossyi*, and *C. koufosi* should be reassigned to *Tscherskia*, while *C. beremendensis* should be transferred to *Allocricetus*, and *C. mesolophidos* to *Neocricetodon*. Excluding *Tscherskia* sp. from the Late Pliocene Youhe fauna, there are no reliable *Tscherskia* fossils in China earlier than the Middle Pleistocene. Based on the current evidence, *Tscherskia* may have originated from *Neocricetodon* during the Early Pliocene in Europe and subsequently spread to Asia. *T. triton* is its sole surviving representative, which now exclusively inhabits East Asia.

## 17 **Abstract**

18 A detailed morphological description and comparative study were conducted on numerous large-  
19 sized hamster remains collected from the late Middle Pleistocene Locality 2 of Shanyangzhai  
20 (Syz 2), Hebei Province, China. The comparisons reveal that these fossils are highly similar to  
21 the extant *Tscherskia triton* in size and morphology, including the small degree of alternating  
22 between the main opposite cusps on M1-3, the presence of axioloph on M3, and mesolophids on  
23 m1-2 that are present but seldom reach the lingual margin of the teeth, among other features.  
24 However, minor differences between the two still exist. Consequently, all these fossils are  
25 designated as a chronosubspecies of the extant species, *T. triton varians* comb. nov. The skull  
26 and molar morphologies of *Cricetinus varians* and *T. triton* were meticulously compared to  
27 resolve the long-standing debate regarding the validity of *Cricetinus* Zdansky, 1928, and *C.*  
28 *variens* Zdansky, 1928. The findings indicate that the differences between the two are slight; as a  
29 result, *C. varians* can only be considered a chronosubspecies of *T. triton*, i.e., *T. triton varians*  
30 comb. nov., and *Cricetinus* should be recognized as a junior synonym of *Tscherskia*. We  
31 tentatively propose that, among the seven species once referred to *Cricetinus* in Eurasia, *C.*  
32 *europaeus*, *C. gritzai*, *C. janossyi*, and *C. koufosi* should be reassigned to *Tscherskia*, while *C.*  
33 *beremendensis* should be transferred to *Allocricetus*, and *C. mesolophidos* to *Neocricetodon*.  
34 Excluding *Tscherskia* sp. from the Late Pliocene Youhe fauna, there are no reliable *Tscherskia*  
35 fossils in China earlier than the Middle Pleistocene. Based on the current evidence, *Tscherskia*  
36 may have originated from *Neocricetodon* during the Early Pliocene in Europe and subsequently  
37 spread to Asia. *T. triton* is its sole surviving representative, which now exclusively inhabits East  
38 Asia.

## 39 Introduction

40 The late Middle Pleistocene Locality 2 of Shanyangzhai (village) has yielded abundant  
41 vertebrate fossils and one of the most common among them are the remains of hamsters—so  
42 far more than 50 skulls, 2500 jaws, and very numerous isolated teeth have been discovered.  
43 These materials can be readily divided into two groups based on size. Xie and Li (2016) have  
44 described the small-sized group, recognizing two hamster species, *Cricetulus longicaudatus* and  
45 *C. barabensis*. The present paper focuses on the remains of the large-sized group, providing a  
46 detailed morphological description and comparative study of these specimens.

47 The genus *Cricetinus* and its type species *C. varians* were erected by Zdansky (1928) on the  
48 basis of fossils from the renowned Middle Pleistocene Locality 1 of Zhoukoudian (i.e., the  
49 Peking Man Site), Beijing. Since then, hamster remains from several other Pleistocene mammal  
50 fossil sites have been continuously referred to *C. varians*, making it one of the most common  
51 micromammal species of Pleistocene faunas in northern China (refer to the synonymy of  
52 *Tscherskia triton varians* below). Kretzoi (1959) founded the second species of *Cricetinus*, *C.*  
53 *europaeus*, based on material from the Pliocene fauna of Csarnóta 2 in the Villány Mountains,  
54 southern Hungary. Following Kretzoi, five other hamster species have been successively  
55 allocated to *Cricetinus* (e.g., Hir, 1994; Wu & Flynn, 2017), rendering *Cricetinus* a widely  
56 distributed genus, both spatially and temporally. However, the validity of *Cricetinus* and *C.*  
57 *varians* has long been questioned by many researchers since the 1930s (e.g., Pei, 1936; Teilhard  
58 de Chardin & Pei, 1941; Teilhard de Chardin & Leroy, 1942; Gu, 1978; McKenna & Bell, 1997).  
59 The crux of this debate revolves around whether *Cricetinus* and *C. varians* are junior synonyms  
60 of *Tscherskia* and *T. triton*, respectively. In the present study, we examine the long-disputed  
61 issue of the validity of *Cricetinus* and *C. varians* based on a detailed description of large-sized  
62 hamster material from Locality 2 of Shanyangzhai, in order to enhance our understanding of the  
63 origin and evolution of extant Cricetinae taxa.

64 It is worth pointing out that, since Argyropulo (1933)'s work, *Tscherskia* has long been  
65 considered a subgenus of *Cricetulus*, with a few researchers maintaining this view until recently  
66 (e.g., Chen & Gao, 2000; Wang, Wu & Qiu, 2020). However, several molecular phylogenetic  
67 studies in recent years have demonstrated that *Cricetulus* in the traditional sense (usually  
68 including *C. barabensis*, *C. longicaudatus*, *C. migratorius*, *C. kamensis*, *C. triton*) is  
69 polyphyletic. As a result, the subgenera *Tscherskia* and *Urocrinetus* (the Tibetan hamster) should  
70 be treated as two independent genera (e.g., Neumann et al., 2006; Stepan & Schenk, 2017;  
71 Lebedev et al., 2018; Ding et al., 2020; Romanenko et al., 2021). Furthermore, *C. migratorius*  
72 (the grey hamster) should also be recognized as an independent genus, and Lebedev et al. (2018)  
73 have proposed a new genus name, *Nothocricetulus*, for it. According to these studies, *Cricetulus*  
74 is generally more closely related to *Nothocricetulus*, *Cricetus*, and *Allocricetulus* when compared  
75 to *Tscherskia*. In addition to molecular phylogenetic evidence, morphological differences  
76 between *T. triton* and members of *Cricetulus* (in the traditional sense) are also apparent (Musser  
77 & Carleton, 2005) (Figures S1 to S3). For instance, *T. triton* has a considerably larger body size  
78 than the latter: the average body length of the former is approximately 157 mm, while the same

79 measurement for the later ranges approximately from 90-100 mm (based on data provided by  
80 Chen & Gao, 2000). Moreover, we find that the M3 of *T. triton* bears an axiolph (*sensu*  
81 Freudenthal & Daams, 1988) (see “Discussion” for details), a feature that is, to the best of our  
82 knowledge, unique among all living Cricetinae species. The presence of the axiolph  
83 undoubtedly highlights the uniqueness of *Tscherskia* within Cricetinae, although its taxonomic  
84 significance warrants further investigation. For above reasons, we follow the prevailing opinion  
85 of researchers over the last two decades and no longer consider *Tscherskia* as a subgenus of  
86 *Cricetulus*, but rather as a distinct genus.

## 87 **Geologic setting**

88 Shanyangzhai Village (119°32'14.00"E, 40°5'17.82"N) is situated in the central part of  
89 Haigang District, Hebei Province, China, approximately 20 kilometers from Bohai Bay. The  
90 Ordovician limestone of the Majiagou Formation south of the village reveals numerous fossil-  
91 bearing fissures or cave deposits due to quarrying activities. To date, four primary fossiliferous  
92 localities have been discovered, numbered Localities 1, 2, 3, and 4 of Shanyangzhai (abbreviated  
93 as Syz 1-4) in order from south to north (Fig.1). Based on their mammalian components, these  
94 localities may have different ages. The fossils from Syz 1 and Syz 3 primarily consist of  
95 macromammals, whereas Syz 2 and Syz 4 have yielded an abundance of micromammal fossils  
96 (Niu, Zhang & Fa, 2003; Kong, 2009; Wang et al., 2010; Zhang et al., 2010; Li & Zhang, 2011,  
97 2013; Li, Zhang & Ao, 2013; Li, Zhang & Li, 2013; Li, Zhang & Zheng, 2013; Zhang & Li,  
98 2015; Li, Li & Zhang, 2016; Xie & Li, 2016; Chen et al., 2021). Although the majority of the  
99 original strata of Syz 2 site have been disrupted by quarrying activities, the Syz 2, from which  
100 the hamster fossils studied in this paper were obtained, is generally considered to date back to the  
101 late Middle Pleistocene (Zhang et al., 2010). This estimation mainly results from the overall  
102 faunal resemblance between Syz 2 and the Middle Pleistocene fauna of Zhoukoudian Locality 1  
103 (where the age of the primary fossiliferous deposits, i.e., layers 1-11, is generally considered to  
104 be ca. 0.6-0.2 Ma, Hu, 1985; Zhang, 2004; Chen & Zhou, 2009; Liu et al., 2014) and Jinniushan  
105 (ca. 0.31-0.2 Ma, Liu et al., 2014). We obtained a silty clay sample (field number 09SS1,  
106 laboratory number 11695) from about 2 meters below the fossil-bearing horizon at Syz 2 and  
107 determined its absolute age using the electron spin resonance (ESR) technique at the State Key  
108 Laboratory of Earthquake Dynamics, Institute of Geology of China Earthquake Administration.  
109 The test result demonstrates an age of  $300 \pm 30$  ka for the sample, implying that the fossil  
110 deposits located above the sampling site should be somewhat younger than this age. Kong (2009)  
111 dated the fauna between  $(1.8 \pm 0.2) \times 10^5$  years and  $(2.0 \pm 0.2) \times 10^5$  years ago using the thermo-  
112 luminescence (TL) technique, but the precise sampling layers in Kong (2009) require further  
113 verification. Based on the aforementioned absolute age dating results and faunal comparisons,  
114 we tentatively date Syz 2 to the late Middle Pleistocene, approximately 0.2 Ma.

## 115 **Material, methods, and abbreviation**

### 116 **Material**

117 The hamster fossils from Syz 2 examined in this study are housed in the Department of  
118 Geology, Northwest University (Xi'an, Shaanxi Province, China). For comparative purposes, we

119 observed about 50 skull specimens (including mandibles) of extant *Tscherskia triton* (the greater  
120 long-tailed hamster) stored in the College of Life Sciences, Northwest University. All of these  
121 specimens were collected from Shaanxi Province. Based on the collection sites indicated on the  
122 labels of these specimens, they might belong to the subspecies *T. triton incanus* and *T. triton*  
123 *collinus* (and possibly *T. triton triton* and *T. triton fuscipes*), following the subspecies  
124 classification and geographical distribution of *T. triton* summarized by Chen & Gao (2000).

## 125 **Methods**

126 The skull morphological terminology primarily follows Wang & Qiu (2018) and Voss (1988).  
127 For the description of molar occlusal morphology, we mainly follow Freudenthal & Daams  
128 (1988), Freudenthal, Hugueney & Moissenet (1994), and Li et al. (2018). Anatomical  
129 abbreviations for upper molars are M1, M2, and M3, while lower molars are represented by m1,  
130 m2, and m3. Measurements of the skull and mandible mainly follow the methodology described  
131 by Yang et al. (2005) and Xia et al. (2006). For molar measurements, L and W denote the  
132 maximum length and width, respectively. All measurements were obtained using a ZEISS  
133 Smartzoom5 automated digital microscope. Some images were reversed for ease of comparison  
134 and are indicated by an underlined label. Annotations of the synonymy list are in accordance  
135 with Matthews (1973). This work and the nomenclatural act it contains have been registered in  
136 ZooBank ([https://zoobank.org/urn:lsid:zoobank.org:act:833CA9EC-1051-4C8E-A032-](https://zoobank.org/urn:lsid:zoobank.org:act:833CA9EC-1051-4C8E-A032-04DF2AC46994)  
137 [04DF2AC46994](https://zoobank.org/urn:lsid:zoobank.org:act:833CA9EC-1051-4C8E-A032-04DF2AC46994)).

## 138 **Abbreviation**

140 Paleoanthropology, Beijing; Syz 1-4, Locality 1, 2, 3, 4 of Shanyangzhai; ZKD, Zhoukoudian (=   
141 Choukoutien); JNS, Jinniushan; RZD, Renzidong.

## 142 **Results**

### 143 **Systematic palaeontology**

144 Mammalia Linnaeus, 1758  
145 Rodentia Bowdich, 1821  
146 Cricetidae Rochebrune, 1883  
147 Cricetinae Fisher, 1817  
148 *Tscherskia* Ognev, 1914  
149 1928 *Cansumys*, Allen  
150 1928 *Cricetinus*, Zdansky  
151 1929 *Asiocricetus*, Kishida

152 **Type species** *Tscherskia albipes* Ognev, 1914 (= *Cricetus (Cricetulus) triton* de Winton, 1899).

153 **Referred species** *T. europaeus* (Kretzoi, 1959); *T. rusa* (Storch, 1974) ?; *T. gritzai* (Topachevski  
154 et Skorik, 1992); *T. janossyi* (Hír, 1996); *T. koufosi* (Koliadimou, 1996).

155 **Geographic distribution and geologic age** Southeastern Europe, Early Pliocene (MN 15, ca. 5-  
156 3.5 Ma) to early Middle Pleistocene (ca. 0.7 Ma); Southwestern Asia, Holocene ?; northern  
157 China, transitional region between northern and southern China, except *T. sp.* from Youhe fauna

158 with an age of Late Pliocene (ca. 3.15-2.59 Ma) (Yue & Xue, 1996; Xie, Zhang & Li, 2021), all  
159 other credible material of *Tscherskia* with an age not earlier than Middle Pleistocene.

160 **Diagnosis** Medium-sized cricetids typically between *Cricetulus* and *Cricetus*; molars  
161 brachyodont; mesolophes of M1-3 usually present, either free or connected to the metacone, but  
162 rarely reaching the buccal tooth edge; M3 with an anteroposteriorly directed axioloph rather than  
163 an anterolaterally extended protolophule II; anteroconids of m1 either divided or undivided;  
164 mesolophids on m3 almost always present and well-developed; mesolophids also often present  
165 on m1 and m2 but rarely reaching the lingual tooth edge (modified from Xie, Zhang & Li, 2021).

166 **Remarks** Hír (1996a, 1997) once proposed the diagnosis of *Cricetinus* (i.e., *Tscherskia*) as  
167 follows: “the undivided anteroconid on the m1 molars with a smooth and convex oral surface;  
168 the mesolophids missing or short on the m1-m2 molars; M1-M2 crowns characterized by the  
169 missing or weakly developed mesolophes; the posterior metalophule rare on M2.” Our  
170 observation demonstrates that the diagnosis proposed by Hír is not comprehensive and warrants  
171 further revision. Therefore, the diagnosis of *Tscherskia* is redefined here as stated above.

172

200 2004 *Cricetinus varians* Zdansky — Jin et al., p.284

201 2004 *Cricetulus triton* (de Winton) — Tong et al., p.855

202 ?2009 *Cricetinus varians* Zdansky — Jin et al., p.177

203 2010 *Cricetinus varians* Zdansky — Zhang et al., p.73

204 2015 *Tscherskia triton* (de Winton) — Liu et al., p.610

205 2017 *Tscherskia triton* (de Winton) — Chen et al., p.847

206 2018 *Cricetulus varians* (Zdansky) — Tong et al., p.287

207 2018 *Cricetinus varians* Zdansky — Wu et al., p.1396

208 2020 *Cricetulus varians* (Zdansky) — Wang, Wu & Qiu, p.104

209 2021 *Cricetulus varians* (Zdansky) — Huang et al., p.269

210 2021 *Cricetulus triton* (de Winton) — Huang et al., p.269

211 **Lectotype** As previously mentioned, Zdansky (1928) established *Cricetinus* and *Cricetinus*  
212 *variens* based on large-sized hamster material from Locality 1 of Zhoukoudian, which included 8  
213 maxillary fragments, 9 larger and some smaller mandibular fragments, 1 isolated M1, and 3  
214 isolated m1s. However, Zdansky did not designate a holotype for the new genus and its type  
215 species, so all these specimens should be considered the syntypes. Wang, Wu & Qiu (2020,  
216 pp.104-105) selected IVPP RV 340020 (original catalogue number C/C. 1049), an anterior  
217 portion of the skull with right M1-3 and left M1-2 figured by Young (1934, Text-fig. 19, 1, 1a,  
218 1b; Pl. 5, fig. 9) and Zheng (1984a, Fig.1, C), as the lectotype of *C. varians*. However, this  
219 designation should be considered invalid according to ICZN (1999, Art. 74.2), because IVPP RV  
220 340020 does not belong to the syntypes, although it was also collected from Locality 1, possibly  
221 even from the same layer as the syntypes (Young, 1934, p.63). Therefore, the fragmentary right  
222 upper jaw with M1-3 figured by Zdansky (1928, Taf. 5, Fig. 4) is here designated as the  
223 lectotype for *Tscherskia triton varians* (Lagrelus Collection housed in the Museum of  
224 Evolution, Uppsala University, Sweden), and other specimens in the type series should be  
225 considered the paralectotypes. The paralectotypes listed by Wang, Wu & Qiu (2020, p.104) are  
226 also invalid for the same reason discussed for the lectotype and should only be viewed as  
227 referred specimens.

228 **Type locality and geologic age** Locality 1 of Zhoukoudian, Beijing. The deposits of Locality 1,  
229 also known as Zhoukoudian Formation, are about 40 meters in thickness and traditionally  
230 divided into 1 to 13 layers from top to bottom, representing a period from approximately 0.78  
231 Ma to 0.2 Ma. This division scheme was published by Jia (1959), who adopted a similar scheme  
232 first proposed by Teilhard de Chardin & Young (1929), and has been widely followed since.  
233 Zdansky (1923, p.86) also published two profiles of deposits of Locality 1 (called Loc. 53 by  
234 Zdansky) from which the type specimens of *C. varians* and other fossils studied by Zdansky  
235 (1928) were collected. Teilhard de Chardin & Young (1929, p.179, footnote) considered that the  
236 sections given by Zdansky (1923, p.86) correspond probably to some part of their layers 5 and 6,  
237 although they also stated that a precise correlation with Zdansky's 1923 profile was rather

238 difficult to establish. If Teilhard de Chardin and Young are correct, according to Xu et al. (1997,  
239 p.219, Table 1), their layers 5 and 6 should essentially correspond to layers 4 to 6 of Jia (1959)'s  
240 scheme, which cover a period of approximately 0.3 - 0.4 Ma in the Middle Pleistocene (Chen &  
241 Zhou, 2009, Table 1).

242 **Geographic distribution and geologic age** Northern China, transitional region between  
243 northern and southern China, late Early Pleistocene to Late Pleistocene.

244 **Referred specimens from Syz 2** 21 incomplete skulls (NWUV 1489.a1-21); 10 maxillae with  
245 bilateral tooththrows (NWUV 1489.b1-10); 73 left maxillae (NWUV 1489.c1-73); 74 right  
246 maxillae (NWUV 1489.d1-74); 185 left mandibles (NWUV 1489.e1-185); 215 right mandibles  
247 (NWUV 1489.f1-215); 3 mandibles with bilateral branches (NWUV 1489.g1-3); 55 left M1s  
248 (NWUV 1489.h1-55); 54 right M1s (NWUV 1489.i1-54); 46 left M2s (NWUV 1489.j1-46); 35  
249 right M2s (NWUV 1489.k1-35); 2 left M3s (NWUV 1489.l1-2); 8 right M3s (NWUV  
250 1489.m1-8); 16 left m1s (NWUV 1489.n1-16); 22 right m1s (NWUV 1489.o1-22); 15 left m2s  
251 (NWUV 1489.p1-15); 19 right m2s (NWUV 1489.q1-19); 7 left m3s (NWUV 1489.r1-7); 8 right  
252 m3s (NWUV 1489.s1-8).

253 **Measurements** Refer to Tables 1-2 and Supplementary datasets 1, 3, 5, 7.

254 **Diagnosis** *Tscherskia triton varians* is highly similar to extant *T. triton* in size and most of the  
255 molar characters (see "Discussion"). However, the former exhibits slightly higher frequencies of  
256 mesolophids on m1 and m2 (refer to Table 7). In the majority of skull and mandible  
257 measurements, the mean values for *T. t. varians* may be slightly larger than those of extant *T.*  
258 *triton*.

259 **Remarks** The minor differences between *T. triton varians* and extant *T. triton* can only be  
260 observed when a statistically significant number of specimens are available. The reason for  
261 referring all items listed in the synonymy, most of which have limited material, to *T. triton*  
262 *variens* is solely based on their geologic age. Thus, this should be considered a temporary  
263 expedient.

## 264 **Description**

### 265 **(1) Skull**

266 The skull description primarily relies on the relatively well-preserved specimen NWUV  
267 1489.a8, with reference to other specimens (Fig. 2).

268 **Dorsal view** The nasal exhibits a narrow posterior and a wide anterior aspect. At its junction  
269 with the frontal, it is narrowest, then gradually widening anteriorly, and slightly narrowing again  
270 at the anterior border. The anterior-most point of the orbit is slightly anterior to the transverse  
271 level of the posterior end of the nasal. NWUV 1489.a7 has a larger skull width than normal due  
272 to post-mortem deformation, but it retains the complete interparietal, which is approximately  
273 pentagonal in shape, resembling that of extant *T. triton*. The frontal crest is more pronounced in  
274 adults, particularly in elderly individuals, extending posteriorly from the upper edge of the orbit,  
275 beyond the parietal bone, and reaching at least the anterior border of the interparietal bone.

276 **Lateral view** The upper contour of the skull presents a gentle arc, but this shape is often lost  
277 due to post-mortem deformation. The alveolus of the upper incisor creates a well-defined

278 semicircular crest on the lateral surfaces of the premaxilla and maxilla. The upper portion of the  
279 infraorbital foramen is fan-shaped, while its lower portion is slit-like. The outer wall of the  
280 zygomatic plate is slightly concave. Both the anterior and posterior edges of the zygomatic plate  
281 exhibit a gentle arc shape; the former is slightly convex anterodorsally, and the latter is slightly  
282 concave anterodorsally, with the two edges nearly parallel. The anterior root of the zygomatic  
283 arch is weak, measuring about 2-3 times narrower the width of the zygomatic plate. The small  
284 supraorbital foramen is situated posterior to the interorbital constriction and just below the  
285 supraorbital margin.

286 **Ventral view** The incisive foramen is elongated and narrow, with an obvious distance  
287 separating its posterior edge from the anterior edge of M1. The premaxillary-maxillary suture  
288 traverses the incisive foramen at about the anterior 2/5 of the foramen. The anterior-most point of  
289 the zygomatic plate approximately aligns with the center of the incisive foramen in the  
290 mediolateral direction. The masseteric tubercle is positioned at the base of the zygomatic plate,  
291 exhibiting a rough surface. Two posterior palatine foramina are almost situated on the connecting  
292 line of the posterior roots of the two M2s. The posterior border of the hard palate extends slightly  
293 beyond the posterior edge of M3 or is flush with it. The two molar series are not completely  
294 parallel, but slightly divergent anteriorly.

## 295 (2) Mandible

296 The lower edge of the mandible (Fig. 3) extends anteriorly in an arc from the base of the  
297 angular process. The mental foramen is small and round, located anteroventral to the anterior  
298 root of m1. The masseteric ridge is thin yet clearly evident, ending beneath m1 and posterodorsal  
299 to the mental foramen. The coronoid process is slender and hook-shaped, extending  
300 posterodorsally. A noticeable bulge formed by the posterior end of the lower incisor is present at  
301 the base of the condylar process, situated anteroventral to the mandibular notch on the buccal  
302 side of the mandible. The angular process extends in a posteroventral direction. The mandibular  
303 notch extends slightly further anteriorly than the notch between the condylar process and the  
304 angular process, with the latter slightly wider than the former. The mandibular foramen is oval  
305 and located at the base of the condylar process. The groove between the alveolus of molars and  
306 the base of the coronoid process slopes gently in the posterior direction, not as steep as that of  
307 murines; a small foramen of unclear function is situated in the middle of the groove. On the inner  
308 side of the mandible, numerous small nutrient foramina are typically found in the area beneath  
309 the molar series.

310 Measurements of skulls and mandibles are provided in Table 1 and Supplementary datasets 1,  
311 3.

## 312 (3) Teeth

313 **I2** The anterior end of the upper incisor (I2) points ventrally, and its posterior end terminates  
314 in an anteroventral position relative to the infraorbital foramen. The enamel layer covers the  
315 entire labial surface of I2, which is smooth and devoid of ridges, and also extends to cover a  
316 small portion of the lateral surface.

317 **M1** The occlusal morphologies of upper molars are illustrated in Fig. 4. The M1 is kidney-  
318 shaped, with an obtuse anterior edge, a comparatively straight buccal edge (but with a noticeable  
319 outward protrusion at the metacone), and an arc-shaped lingual edge. The degree of alternating  
320 of the opposite main cusps on M1 is small, as is the case for M2 and M3. The anterocone is  
321 broad and always splits posteriorly into two equal-sized cusps. In some specimens, the  
322 anterocone also exhibits a certain degree of separation from the mesial surface, and in a few  
323 cases, this separation is even pronounced. The lingual anterolophule is invariably present, while  
324 the buccal anterolophule is observed in 89.1% (41/46) of specimens. A small number of  
325 specimens (3.9%, 6/154) exhibit the spur of the anterolophule, which is thin and weak, with five  
326 instances extending to the buccal margin of the tooth (Fig. 4B). The presence of the protolophule  
327 I is detected in 57.4% (27/47) of specimens. The protolophule II is relatively weak, and even  
328 absent in a few specimens. The loph connecting the anterior arm of the hypocone and the  
329 metacone, in our opinion, should be viewed as the mesoloph, as in most specimens, there is an  
330 obvious contact trace between the loph and the metacone, implying that the loph does not  
331 originate from the metacone. In a few specimens, however, this loph can be completely fused  
332 with the metacone without any trace, making it difficult to determine whether the metalophule I  
333 contributes to the formation of the loph in these cases. No specimens exhibit a mesoloph with a  
334 free end. The metalophule II is present but weakly developed in most specimens. The  
335 posterosinus is small and shallow, with only a vestige observable in specimens exhibiting severe  
336 abrasion. The tooth has four roots.

337 **M2** The M2 is approximately square in shape. The buccal anteroloph is more developed than  
338 its lingual counterpart, with the latter occasionally nearly absent. The position of the buccal  
339 anteroloph is also elevated compared to the lingual one. The protolophule is double. The  
340 mesoloph resembles that of M1 but is relatively thicker. It may either merge with the metacone  
341 or display an evident contact trace between them, yet it never has a free end. In some specimens,  
342 the mesoloph extends to the tooth edge by adhering to the anterior wall of the metacone (Fig. 4  
343 B, F). The metalophule II is consistently present, albeit comparatively weak. The posterosinus is  
344 also small. The tooth is four-rooted.

345 **M3** The posterior portion of M3 is notably reduced, with both the hypocone and metacone  
346 significantly smaller than those of M1 and M2. This results in the occlusal outline of M3  
347 resembling a relatively obtuse equilateral triangle. The buccal anteroloph is more developed and  
348 positioned higher than the lingual counterpart, which is either absent or extremely weak. The  
349 protolophule I is consistently present. The most notable character of M3 is the presence of the  
350 axioloph, which originates from the junction of the protolophule I and the anterior arm of the  
351 protocone, and extends posteriorly. A small groove forms between the axioloph and paracone.  
352 Occasionally, the central part of the groove closes due to the proximity or fusion of the axioloph  
353 and paracone, leading to the formation of a small pit in the upper portion of the groove (Fig. 4 D,  
354 F). The morphology of the mesoloph is similar to that of M1 and M2. The metalophule II and  
355 posterosinus are absent. In some specimens, the mid-segment of the posteroloph (or the posterior

356 arm of the hypocone) inflates into a small cusp, situated between the hypocone and metacone  
357 (Fig. 4C, G). The tooth possesses three roots.

358 In a very small number of specimens, the upper molars exhibit morphological variation in  
359 certain structures. For example, the protolophule II on M2 occasionally assumes a form similar  
360 to that on M3, and vice versa.

361 **i2** The anterior part of the lower incisor (i2) extends anterodorsally, and the posterior end of it  
362 terminates at the base of the condylar process, forming a prominent bulge on the buccal side of  
363 the mandible. The enamel layer covers the whole labial surface, which is smooth and devoid of  
364 ridges, as well as about half of the lateral surface.

365 **m1** The occlusal morphologies of lower molars are shown in Fig. 5. The occlusal outline of  
366 m1 is comparatively elongated and gradually narrows from posterior to anterior. The anteroconid  
367 is bisected into two approximately equal-sized cusps in most specimens (93.0%, 80/86). In these  
368 specimens, the vast majority of anteroconids are slightly bifid posteriorly, although specimens  
369 with a more pronounced degree of posterior separation are occasionally observed. From an  
370 anterior perspective, the anteroconid is either weakly divided (in young individuals) or undivided  
371 (in middle-aged and elderly individuals). A small proportion of specimens (7.0%, 6/86) possess  
372 anteroconids split into three small cusps (Fig. 5E). Undivided anteroconids are observed only in  
373 heavily worn specimens. In the vast majority of specimens (97.6%, 82/84), the anterolophulid is  
374 single and connects either to the buccal anteroconulid (70.7%, 58/82), the midpoint between the  
375 two anteroconulids (26.8%, 22/82), or the lingual anteroconulid (2.4%, 2/82). In a very few  
376 specimens (2.4%, 2/84), the anterolophulid possesses two branches that connect to the two  
377 anteroconulids respectively. The bottom of the anterosinusid is significantly higher than that of  
378 the protosinusid. In 43% of the specimens (44/103) (Table 3), a mesolophid is present, which is  
379 consistently low, short, and weak. The mesolophid either connects to the metaconid (18.2%,  
380 8/44) or has a free end (81.8%, 36/44). In the latter case, the longest free-ended mesolophid does  
381 not exceed half the distance from the base to the lingual tooth edge, and in most cases, it only  
382 presents as a spine-like projection. The transitional part from the hypoconid to posterolophid is  
383 generally slender, but subsequently the posterolophid rapidly swells into a well-defined small  
384 cusp. The posterolophid often does not continue anteriorly to connect with the entoconid,  
385 resulting in an open posterosinusid in most cases. The cingulum commonly presents at the  
386 entrances of the protosinusid and sinusid, occasionally forming a small but distinct ectostylid at  
387 the entrance of the latter. The tooth has two roots.

388 **m2** The occlusal outline of m2 exhibits a rounded square shape, with a width greater than that  
389 of m1 and m3. The lingual anterolophid is weakly developed or absent, while the buccal  
390 anterolophid is always well developed. In 95.2% of specimens (158/166) the mesolophid is  
391 present, exhibiting various morphologies that can be essentially categorized into four types  
392 (Table 4): I. having a free end; II. connected to the metaconid; III. reaching the lingual tooth  
393 edge (10.2%, 16/157) (Fig. 5A); and IV. connected to the entoconid (2.5%, 4/157). Within these  
394 morphotypes, I and II are present in most specimens, but the boundaries between the two are  
395 sometimes difficult to distinguish. The length of the mesolophid also varies, but most do not

396 exceed 1/2 of the distance from the base to lingual tooth edge. The morphology of the  
397 posterolophid and the development of the cingulum are similar to those on m1, except that the  
398 lingual edge of the mesosinusid of m2 also occasionally bears the cingulum. The tooth has two  
399 roots.

400 **m3** The posterior part of m3 is generally contracted, though a small number of specimens  
401 exhibit no obvious contraction (Fig. 5G). In most specimens, the entoconid is significantly  
402 reduced compared to that of m1 and m2, while the hypoconid often experiences only slight  
403 reduction. Similar to m2, the lingual anterolophid of m3 is also weakly developed and the buccal  
404 one is comparatively more pronounced; however, the lingual anterolophid is present in nearly all  
405 m3 specimens. The mesolophid is present in all but one specimen (99.2%, 129/130), and its  
406 morphology varies, falling into five types (Table 5): I. unbranched (59.4%, 76/128), connected to  
407 the lingual tooth edge (Fig. 5 A, C, E, G); II. bifurcated (35.2%, 45/128), with one branch  
408 connected to the lingual tooth edge and the other to the metaconid (Fig. 5 B, F); III. trifurcated  
409 (0.8%, 1/128), with branches connected to the lingual tooth edge, metaconid, and junction of the  
410 hypoconid and entoconid, respectively; IV. unbranched (3.9%, 5/128), connected to the  
411 metaconid (Fig. 5D); and V. having a free end (0.8%, 1/128). The posterolophid is somewhat  
412 different from that of m1 and m2, primarily in that it usually merges with the entoconid to close  
413 the posterosinusid. The posterolophid also exhibits some degree of swelling and appears as a  
414 cusp when subjected to slight wear, resulting in three side-by-side cusps on the posterior part of  
415 m3. The cingulum is usually absent at the entrance of the sinusid but is often more developed at  
416 the entrance of the mesosinusid, occasionally merging with the end of the mesolophid to form a  
417 small cusp. The tooth possesses two roots.

418 As observed in upper molars, lower molars also demonstrate variations in some structures  
419 among a limited number of specimens. For example, the m3 of NWUV 1489.e169 exhibits an  
420 ectomesolophid, the sole exception in all lower molars. Moreover, in this particular specimen,  
421 the mesolophids of both m1 and m2, along with m3, bifurcate into two branches, representing a  
422 unique morphology not observed in any other specimens. Furthermore, some morphotypes, such  
423 as the double-branched anterolophid on m1, the mesolophid of m2 connected to the entoconid,  
424 and the III and V morphotypes of mesolophid of m3, can also be viewed as morphological  
425 variations due to their exceptional rarity.

426 Molar measurements are provided in Table 2 and Supplementary datasets 5, 7.

## 427 **Discussion**

### 428 **Identification of the large-sized hamster material from Syz 2**

429 The taxonomies of Cricetinae fossils from Quaternary deposits in China and extant Chinese  
430 Cricetinae species remain highly debated. Based on our observations and recent research  
431 advancements (e.g., Lebedev et al., 2018; Wang, Wu & Qiu, 2020), we preliminarily suggest that  
432 the inclusion of the following 12 genera in the Chinese Cricetinae, ranging from the beginning of  
433 the Quaternary to the present (listed in chronological order of naming; in parentheses are the  
434 common junior synonyms): *Cricetus* Leske, 1779; *Cricetulus* Milne-Edwards, 1867; *Urocricetus*  
435 Satunin, 1902; *Phodopus* Miller, 1910; *Tscherskia* Ognev, 1914 (= *Cricetinus* Zdansky, 1928,

436 *Cansumys* Allen, 1928); *Allocricetus* Schaub, 1930; *Sinocricetus* Schaub, 1930; *Allocricetulus*  
437 *Argyropulo*, 1932; *Neocricetodon* Schaub, 1934 (= *Kowalskia* Fahlbusch, 1969); *Bahomys*  
438 Chow et Li, 1965; *Amblycricetus* Zheng, 1993; *Nothocricetulus* Lebedev, Bannikova, Neumann,  
439 Ushakova, Ivanova et Surov, 2018. Except that the relationship between *Tscherskia* and  
440 *Cricetinus* will be discussed in detail below, providing detailed justifications for our conclusions  
441 is beyond the scope of this paper. Among the mentioned genera, *Allocricetus*, *Sinocricetus*,  
442 *Neocricetodon*, *Bahomys* and *Amblycricetus* are extinct, while the remaining seven are extant.  
443 Among the living genera, *Allocricetulus* and *Nothocricetulus* only have very scarce and doubtful  
444 fossil records (Cai et al., 2004, 2013), whereas *Cricetus* and *Urocrictus* currently have no  
445 known fossil records in China.

446 Aside from *Tscherskia*, the large-sized hamster material from Syz 2 exhibits distinct  
447 differences when compared to other genera listed above. The Syz 2 material can be distinguished  
448 from nearly all of these genera by characters such as on m1-2 mesolophids being present but  
449 rarely reaching the lingual margin of the teeth, M3 possessing an axioph, the degree of  
450 alternating of the opposite main cusps on M1-3 very small, et al. Furthermore, unlike  
451 *Neocricetodon* and *Amblycricetus*, which generally have mesoloph(id)s extending to the tooth  
452 edge, the mesoloph(id)s of the larger hamster material from Syz 2 scarcely reach the tooth edge.  
453 In contrast to *Bahomys* and *Sinocricetus* with comparatively higher crowns, the crowns of  
454 remains from Syz 2 are low. The sizes of molars, skulls, and mandibles of the large-sized  
455 hamsters from Syz 2 are significantly larger than those of *Cricetulus* (Figures 2 to 5, S1 to S3),  
456 *Phodopus*, *Urocrictus*, *Allocricetulus*, and *Nothocricetulus*, but significantly smaller than  
457 *Cricetus*. Some researchers (Zheng et al., 1985, p.117; Cheng et al., 1996, p.40; Jin et al., 2009,  
458 p.178) considered that the absence of the mesolophid on m1-2 of *Allocricetus* is the key  
459 character distinguishing it from *Cricetinus* (i.e., *Tscherskia*). However, this feature actually  
460 pertains to *Cricetulus*, not *Allocricetus*, as *Allocricetus* may not bear the mesolophid on m1 but  
461 can develop it on m2 in some specimens (Table 7). On the other hand, some researchers argued  
462 that the most crucial character of *Cricetinus* (i.e., *Tscherskia*) is the undivided anteroconid of m1  
463 (Kretzoi, 1959; Hír, 1996a, 1997), while that of *Allocricetus* and *Cricetulus* is almost always  
464 well divided (Hír, 1994, 1996a). However, observations of the extant *T. triton* molars have  
465 shown that the degree of separation of the m1 anteroconid in numerous specimens is comparable  
466 to that seen in *Allocricetus* according to Hír (1994, Fig. 4). In *Cricetulus*, the separation degree  
467 of the anteroconid of m1 in the type species *C. barabensis* is indeed small, while *C.*  
468 *longicaudatus* exhibits a well-divided anteroconid of m1 (Figure S3).

469 Meanwhile, the great similarity between the large-sized hamster material from Syz 2 and the  
470 extant *Tscherskia* (i.e., *T. triton*) is readily apparent (Figures 2 to 5, S1 to S3). The molar  
471 dimensions of the former closely align with those of the extant *T. triton*, with some  
472 measurements even being identical (Table 2). Morphologically, the characters of molars and  
473 skulls of the former, such as the degree of alternating of the opposite main cusps on M1-3 small,  
474 the anterocone of M1 deeply bifid posteriorly with nearly equal-sized buccal and lingual cones,  
475 the mesolophs of M1-3 connected to the metacone instead of being free, M3 with the axioph,

476 the anteroconid of m1 undivided or weakly divided, the mesolophids of m1-2 present but rarely  
477 reaching the lingual margin of teeth, nearly all m3s with well-developed mesolophids, and the  
478 interparietal pentagonal, also closely resemble those of the extant *T. triton*. Therefore, we can  
479 confidently refer the large-sized hamster remains from Syz 2 to *T. triton*.

480 In most skull and mandible measurements, however, the mean values of the material from Syz  
481 2 are lightly larger than those of the extant *T. triton* (Table 1, 2), although the measurements of  
482 the single upper and lower molar from both the former and the later are nearly identical (Table 2,  
483 Fig. 6). As will be demonstrated below, there are also minor differences in molar morphology  
484 between the Syz 2 material and the extant species. Therefore, considering these disparities, it  
485 may be more reasonable to further classify these materials from Syz 2 as a chronosubspecies of  
486 *T. triton*, i.e., *T. triton varians* comb. nov. (= *Cricetinus varians*, see below for details). In  
487 addition, the mean values of the lengths of upper and lower toothrows (M1-3 and m1-3) of the  
488 Syz 2 material are also lightly greater than those of the extant *T. triton* (Table 2). However, the  
489 measurements of the single molar imply that this phenomenon, and even certain skull and  
490 mandible measurements, may likely result from the burial deformation (see discussion in Xie,  
491 Zhang & Li, 2021).

492 The structure "axioloph" warrants further elaboration here. Both the M3s of *T. triton varians*  
493 from Syz 2 and the extant *T. triton* possess an anteroposteriorly directed axioloph, which departs  
494 from the junction of the protolophule I and the anterior arm of protocone, and forms a groove  
495 between itself and the protocone (Figures 4, S3). In fact, this structure seems to have been  
496 noticed by Zdansky (1928) and Schaub (1930) in the syntypes of *T. triton varians* from Locality  
497 1 of Zhoukoudian. The term "axioloph," along with several other terms, was first introduced by  
498 Freudenthal & Daams (1988, p.137) to facilitate descriptions of M3 of cricetids. They defined  
499 the axioloph as "an axial connection between paracone and hypocone, fundamentally composed  
500 of the posterior protolophule and the posterior part of the (ancient) entoloph." Morphologically,  
501 the axiolophs of M3s of Syz 2 specimens and the extant *T. triton* are obviously distinct from the  
502 protolophule IIs of the small-sized hamster remains from Syz 2, and even from all other extant  
503 Cricetinae taxa, as their protolophule IIs depart from the posterior wall of the paracone and  
504 extend in the anteromedial direction, not forming a groove between itself and the protocone  
505 (Figure S3). By contrast, fossil Cricetinae taxa from Eurasia since the Late Miocene appear to  
506 more frequently develop an axioloph on M3, especially in the genus *Neocricetodon* (=   
507 *Kowalskia*), such as *N. moldavicus* (see Sinitsa & Delinschi, 2016), *N. hanae* (see Qiu, 1995), *N.*  
508 *yinanensis* (see Zheng, 1984b), and *N. lii* (see Zheng, 1993). This seems to imply a close affinity  
509 between *Neocricetodon* and *Tscherskia*, although the axioloph is also present in some other  
510 genera, such as *Nannocricetus primitivus* (Zhang, Zheng & Liu, 2008), and seems more often  
511 present in cricetid genera of older geologic age (before the late Miocene), such as  
512 *Democricetodon* and *Megacricetodon*. The phylogenetic significance of the axioloph will not be  
513 better understood until a comprehensive phylogenetic analysis covering the taxa mentioned  
514 above is conducted, and the homologous structure of the axioloph itself also requires further  
515 investigation.

**516 Discussion on the validity of *Cricetinus* and *Cricetinus varians***

517 When Zdansky (1928) established *Cricetinus* and *Cricetinus varians*, he solely relied on the  
518 skull specimens of extant *Cricetus cricetus* and *Cricetulus phaeus* (now considered a subspecies  
519 of *Nothocricetulus migratorius*) for comparison. Consequently, he apparently did not have the  
520 opportunity to notice the obvious similarity in molar morphology between the fossils from  
521 Locality 1 of Zhoukoudian and the extant *T. triton*. Zdansky (1928, p.57) seemed to  
522 acknowledge the potential limitation of his study due to the limited number of extant specimens  
523 available for direct comparison with the fossils. Thus, he stated in the monograph that “maybe  
524 later a generic identity with one of these [extant] genera will result” (translated from German).  
525 As expected, doubts about the validity of the genus and species soon emerged. Schaub (1930,  
526 1934) noticed the close resemblance between *C. varians* and *T. triton* in molar morphology, but  
527 still retained the independent status of *C. varians*. Teilhard de Chardin (1940, p.56) concluded  
528 that he “failed to detect any difference between a ‘*Cricetinus*’ dentition and the dentition of f.i.  
529 *Tcherskia* in North China”. Teilhard de Chardin & Pei (1941) reiterated that aside from the  
530 somewhat larger size, the large-sized hamster fossils from Locality 13 of Zhoukoudian (early  
531 Middle Pleistocene in age) showed no appreciable difference from *T. triton* in either skull or  
532 tooth morphology, and they maintained the specific name “*variens*” for the Pleistocene form  
533 primarily due to “geologic convenience.” Zheng & Han (1993) argued that it was challenging to  
534 distinguish *C. varians* from extant *T. triton* in North China and Northeast China based on size  
535 and molar morphologies. Despite these doubts, a large number of such hamster remains  
536 discovered in Pleistocene deposits of China were ultimately assigned to *C. varians*. Meanwhile,  
537 as previously mentioned, new fossil hamster species from the Pliocene and Pleistocene deposits  
538 of Eurasia have continuously been referred to *Cricetinus* since Kretzoi (1959). Therefore, it is  
539 necessary to clarify the issue of validity of *Cricetinus* and *C. varians*.

540 To address the validity of *Cricetinus*, the validity of its type species, *C. varians*, must be  
541 considered first. However, the material Zdansky (1928) utilized for establishing *C. varians* is not  
542 only scarce, but also accompanied by a relatively simple description and unclear plates, making  
543 direct comparison with *T. triton* difficult. All of these make it difficult to compare them with *T.*  
544 *triton* directly. Fortunately, Zheng (1984a) revised most of the hamster fossils collected from the  
545 Zhoukoudian area, including *C. varians* specimens from Locality 1 (type locality) and Localities  
546 3, 9, 13, 15, enabling detailed comparisons with these materials. Except for the material from  
547 Zhoukoudian, the specimens from other fossil sites in China that have yielded abundant *C.*  
548 *variens* fossils were also compared. In the following discussion, we will conduct a detailed  
549 comparison of skull and tooth morphologies between *C. varians* and extant *T. triton*.

**550 (1) Comparisons of the skull morphologies between *C. varians* and *T. triton***

551 When Zheng (1984a) revisited the hamster fossils from Zhoukoudian, he proposed several  
552 distinguishing skull characters to differentiate between *C. varians* and extant *T. triton*. However,  
553 Xie, Zhang & Li (2021) assessed these characters proposed by Zheng (1984a) and concluded that  
554 these differences between *C. varians* and *T. triton* skulls were questionable and required further  
555 verification. Therefore, it is not necessary to reiterate them here.

556 Topachevski and Skorik (1992, p.181) suggested three morphological differences in skull  
557 features between *Cricetinus* and *Tscherskia*. Based on the context, these opinions appear to be  
558 founded only on the observation of the holotype (a maxillary fragment with M1-3) of *Cricetinus*  
559 *gritzai*, rather than the specimens of the type species (*C. varians*) of the genus. Firstly, *Cricetinus*  
560 is said to differ from *Tscherskia* by having a wider and more concave masseteric plate (i.e.,  
561 "zygomatic plate" in the present paper). However, Topachevski and Skorik (1992) did not  
562 provide any measurements of the zygomatic plates of *Cricetinus* and *Tscherskia* to substantiate  
563 this claim, even though the degree of depression of the surface of the zygomatic plate seems  
564 challenging to quantify. Even if this assertion holds, a wider and more concave zygomatic plate  
565 may only be a feature of the *Cricetinus gritzai* species, not the entire *Cricetinus* genus, because  
566 our observations show no obvious difference in the characters of the zygomatic plate between  
567 *Tscherskia triton varians* from Syz 2 and living *T. triton* (Figures 2, S1). Secondly, *Cricetinus* is  
568 said to develop stronger ridges along the posterior side of the incisive foramina [the rim of the  
569 area for the lateral masseter?] than *Tscherskia*. However, we likewise failed to discern any  
570 appreciable difference in the ridges between *T. t. varians* from Syz 2 and extant *T. triton* (Figures  
571 2, S1). Thirdly, the position of the masseteric tuberosity in *Cricetinus* is considered more similar  
572 to that in *Cricetus* than in *Tscherskia*. Our observations show that the position of the posterior  
573 margin of the masseteric tuberosity in living *Cricetus cricetus* (closer to the posterior edge of the  
574 incisive foramen) seems to be slightly further back than that in living *Tscherskia triton* (closer to  
575 the middle of the incisive foramen). The position of the masseteric tuberosity of *T. t. varians*  
576 from Syz 2 more closely resembles that of extant *T. triton* rather than *C. cricetus* (Figures 2, S1).  
577 In conclusion, since the three distinguishing characters between *Cricetinus* and *Tscherskia*  
578 proposed by Topachevski and Skorik (1992) seem to be based on just one specimen of *C. gritzai*  
579 (the holotype), and we were unable to detect the aforementioned differences between extant *T.*  
580 *triton* and *T. t. varians* from Syz 2, the validity of these differences, in our opinion, is  
581 questionable.

## 582 **(2) Comparisons of the teeth morphologies between *C. varians* and *T. triton***

### 583 ***Comparisons of the teeth size***

584 Table 2 and Fig. 6 show the measurements and scatter diagrams of *C. varians* from  
585 Zhoukoudian in Beijing (Zheng, 1984a), Jinniushan in Liaoning Province (Zheng & Han, 1993),  
586 and Renzidong in Anhui Province (Jin et al., 2009), as well as *T. triton* from Syz 2 and extant *T.*  
587 *triton*. It is evident that, with the exception of the material from Renzidong which is significantly  
588 smaller, the average molar sizes from other localities are quite similar, and the data ranges also  
589 substantially overlap. In other words, we cannot differentiate *C. varians* from *T. triton* based on  
590 their size. As to the material from Renzidong, its significantly smaller size and markedly older  
591 geological age—ca. 2 Ma (Jin, Qiu & Zheng, 2009) compared to the Middle Pleistocene age of  
592 other localities—cast doubt on its identification as *C. varians*. It is possible that the material  
593 from Renzidong represents a new form.

594 Additionally, with the reassignment of hamster material initially identified as *Cricetinus*  
595 *variens* (or *Cricetinus* cf. *variens*, *Cricetulus* (*Cricetinus*) *variens*) from several Early

596 Pleistocene sites in China, such as Localities 12, 18 of Zhoukoudian in Beijing, and  
597 Gongwangling in Lantian, Shaanxi, being assigned to the genus *Allocricetus* (Zheng, 1984a),  
598 East cave of Zhoukoudian has become the only Early Pleistocene site in China, besides  
599 Renzidong, yielding *Cricetinus varians* fossils. However, the length of M1-3 of *Cricetinus*  
600 *variens* from East cave is merely 4.83 mm (Cheng et al., 1996, Table 3-11, p.40), smaller than  
601 the lower limit of the variation range for that measurement in “typical” *C. varians* and extant  
602 *Tscherskia triton* (Table 2). More importantly, the m1s of *C. varians* from East cave completely  
603 lack the mesolophid (Cheng et al., 1996, p.40), which markedly differs from “typical” *C. varians*  
604 and extant *T. triton* (Table 3). Therefore, the material identified as *C. varians* from East cave  
605 necessitates reevaluation of its classification. Given the above explanations, except *Tscherskia*  
606 sp. from the Late Pliocene Youhe fauna (Xie, Zhang & Li, 2021), there is now no reliable fossil  
607 of *Tscherskia* in China predating the Middle Pleistocene.

### 608 ***Comparisons of the teeth structures***

609 In a hamster individual, the molars symmetrically distributed in the oral cavity (e.g., the left  
610 and right M3) may exhibit minor morphological differences; therefore, the morphological  
611 structures of both the left and right molars of large-sized hamsters from Syz 2 and living *T. triton*  
612 were statistically analyzed in the present study. The material of *C. varians* used for comparison  
613 here is mainly from Zhoukoudian (Zheng, 1984a) and Jinniushan (Zheng & Han, 1993).

614 **m1** In extant *T. triton*, about 30% of specimens have a mesolophid (Table 3). The  
615 mesolophids are consistently weakly developed and of very short length, with the longest  
616 mesolophid not exceeding 1/5 of the distance from the base to the edge of the tooth. In most  
617 cases, the mesolophid only appears as a small bulge. It is either connected to the metaconid  
618 (9.5%, 2/21) or has a free end (90.5%, 19/21).

619 The localities in Table 3 are listed in descending order, approximately following their  
620 geological age from oldest to youngest (ZKD Loc.1, ca. 0.6-0.2 Ma; Jinniushan, ca. 0.31-0.2 Ma;  
621 ZKD Loc.3, late Middle Pleistocene; Syz 2, ca. 0.2 Ma). Although the frequencies of  
622 mesolophids in *C. varians* and *T. triton* differ across various geological ages, there is no evident  
623 discontinuity between them, and as the age advances, the frequency of the mesolophid decreases.  
624 Given the similarities in other aspects of tooth morphology and the practicality of classification,  
625 it is more appropriate to interpret the differences in mesolophid frequencies as a result of  
626 gradualistic evolution within a single species, specifically the progressive reduction of the  
627 mesolophid, rather than interspecific or intergeneric differences.

628 **m2** Table 4 presents the frequencies of mesolophids on m2s of *T. triton* and *C. varians*. As  
629 shown in the table, throughout their geologic history, the frequencies of mesolophids on m2s in  
630 both *T. triton* and *C. varians* were consistently high and similar, although slightly lower in extant  
631 *T. triton*. A comparable pattern is also observed in the proportions of morphotype III in *C.*  
632 *variens* (excluding Jinniushan specimens) and extant *T. triton*. Therefore, the mesolophid  
633 morphology on m2s in *T. triton* and *C. varians* further substantiates the congruence of the “two”  
634 species, and it appears more plausible to interpret the minor differences between the two as a

635 gradualistic evolution within a single species, specifically the reduction of the mesolophid,  
636 similar to the situation observed in mesolophids on m1.

637 **m3** Table 5 shows the frequencies of mesolophids on m3s of *T. triton* and *C. varians*. As seen  
638 from the table, mesolophids are present in nearly all specimens. The proportions of the  
639 mesolophids morphotype "connected to the lingual tooth edge " are consistently high, but no  
640 clear regularity emerges. Comparing the proportions of more detailed morphological structures is  
641 difficult due to insufficient data. But overall, the characters of m3s of *T. triton* and *C. varians* are  
642 still quite consistent.

643 **M1** The lingual anterocones and protocones on M1s of *T. triton* and *C. varians* are  
644 consistently connected by an anterolophule, whereas the anterolophule behind the buccal  
645 anterocone is not always present. Table 6 illustrates that the occurrence frequency of the  
646 anterolophule behind the buccal anterocone is high in both *T. triton* and *C. varians*. However, as  
647 the statistical data for *C. varians* are based on a relatively small number of specimens, the  
648 reliability of the comparison is diminished. The frequencies of "protolophule I" are unstable and  
649 appear to lack any discernable regularity.

650 **M2 and M3** There is practically no morphological difference between M2s and M3s of *T.*  
651 *triton* and *C. varians*.

652 In summary, *C. varians* and *T. triton* exhibit substantial consistency in skull and tooth  
653 morphologies. Although minor differences in tooth morphology exist between them, these  
654 differences exhibit continuous variation and can only be discerned with statistically abundant  
655 material. Therefore, we propose that *C. varians* should be considered a chronosubspecies of *T.*  
656 *triton*, i.e., *T. triton varians* comb. nov., and *Cricetinus* should be regarded as a junior synonym  
657 of *Tscherskia*.

### 658 **Referred species of *Tscherskia***

659 Apart from *Cricetinus varians*, there are six other species in Eurasia that have been referred to  
660 *Cricetinus*:

661 *Cricetinus europaeus* Kretzoi, 1959. The type locality of this species is Csarnóta 2 in Hungary.  
662 The majority of researchers believe that the geological age of this site is MN 15 (Venczel &  
663 Gardner, 2005). The type specimens of *C. europaeus* consist of only three molars, but one M2  
664 among these three molars was later identified as *C. janossyi* by Hír (1996b). Hír (1994)  
665 discovered additional materials for this species and described them in detail when examining the  
666 materials from the type locality, thus clarifying the nature of the species. Although *C. europaeus*  
667 is among the earliest *Cricetinus* species in Europe (Hír, 1994), it appears to exhibit rather  
668 advanced morphologies. For instance, the presence ratios of mesolophids on m1 and m2 are even  
669 lower than those of extant *T. triton* (Table 7); however, due to the scarcity of material, this  
670 observation requires further validation with additional material in the future.

671 *Cricetinus gritzai* Topachevski & Skorik, 1992. The type locality of this species is Odessa,  
672 Ukraine. A notable character of this species is that all m1s and partial m2s possess a mesolophid  
673 (Koufos et al., 2001). On one hand, this feature indicates a more primitive nature (in other  
674 *Cricetinus* or *Tscherskia* species, the mesolophid frequency of m1 reaches a maximum of 70%).

675 On the other hand, the character itself is also unique, because in cricetids, the mesolophid  
676 frequency of m1 is almost always lower than that of m2, whereas in this species the situation is  
677 reversed. Moreover, other molars of *C. gritzai* are slightly smaller in size than those of *T. triton*,  
678 but only M3 is considerably larger than that of *T. triton* (Topachevsky & Skorik, 1992). If this  
679 discrepancy is not a statistical error (given that there is only one M3), it may also illustrate the  
680 primitive nature of *C. gritzai*.

681 *Cricetinus beremendensis* Hír, 1994. The type locality of this species is Beremend 15 in  
682 Hungary, with a geologic age of 2.7 Ma (Hír, 1994; Pazonyi, 2011). The molar morphology of  
683 this species, particularly the degree of mesolophid development, is markedly different from other  
684 species currently classified in *Cricetinus*, but closely resembles *Allocricetus ehiki* and *A. bursae*  
685 in size and morphology (Table 7). Thus, it seems more reasonable to assign this species to  
686 *Allocricetus* Schaub, 1930.

687 *Cricetinus janossyi* Hír, 1996. The type locality of this species is Osztramos 7 in Hungary,  
688 with a geologic age of approximately 2.3 Ma (Hír, 1996b; Pazonyi, 2011). The molar  
689 morphology of this species is very similar to that of *T. triton varians* from Syz 2 (Table 7),  
690 although the former is slightly larger in size, and their ages are significantly different. *C. janossyi*  
691 is also among the earliest *Cricetinus* species in Europe, first appearing in Csarnóta 2 of Hungary  
692 at the same time as *C. europaeus*.

693 *Cricetinus koufosi* Koliadimou 1996. The type locality of this species is Ravin Voulgarakis in  
694 Mygdonia basin of Greece (Koufos et al., 2001). The age of Ravin Voulgarakis has been dated to  
695 the Nagyarsanyhegy phase of the Biharian (ca. 1.2-0.7 Ma) (Koufos et al., 2001), making this  
696 species the latest among several *Cricetinus* species in Europe. Additionally, this species has been  
697 discovered in Marathoussa of Mygdonia basin, with the age of the locality dated to the Betfia  
698 phase of the Biharian (ca. 1.5-1.2 Ma) (Koufos et al., 2001). Many molar characters of this  
699 species remain unclear, but the absence of the mesolophid on m1 may indicate its relatively  
700 advanced nature.

701 *Cricetinus mesolophidos* Wu & Flynn, 2017. Xie, Zhang & Li (2021) concluded that it was  
702 more reasonable to place *C. mesolophidos* in *Neocricetodon* rather than in *Cricetinus* (i.e.,  
703 *Tscherskia*).

704 In summary, we suggest that *C. europaeus*, *C. gritzai*, *C. janossyi*, and *C. koufosi* should be  
705 transferred to *Tscherskia*, while *C. beremendensis* should be transferred to *Allocricetus*, and *C.*  
706 *mesolophidos* to *Neocricetodon*. However, this treatment is provisional, because the characters of  
707 some of these species remain unclear. Except the type species *T. triton*, the type localities of the  
708 other four *Tscherskia* species are situated within a small area covered by several neighboring  
709 countries in southeastern Europe. This significant geographic distance between *T. triton* and  
710 other species introduces a degree of uncertainty to the above classification (Kretzoi, 1959; Hír,  
711 1994). In addition, Storch (1974) described a species *T. rusa* from the Holocene (dated between  
712 2200–700 B.C.) of northern Iran, whose geographic location and age are highly perplexing.  
713 Although we have tentatively placed it in *Tscherskia*, the validity of this species and whether it  
714 should be referred to *Tscherskia* clearly warrant further investigation. Table 7 provides a

715 summary of comparisons of frequencies of mesolophids on lower molars among the species of  
716 *Cricetinus*, *Tscherskia*, and some related genera (*Cricetulus*, *Nothocricetulus*, and *Allocricetus*).

### 717 **Origin and dispersal of *Tscherskia***

718 Zheng (1984a, b), Zheng et al. (1985), and Zheng & Han (1993) suggested that *Cricetinus* (a  
719 junior synonym of *Tscherskia*) very likely originated from the genus *Kowalskia* (a junior  
720 synonym of *Neocricetodon*), an idea tentatively proposed by Fahlbusch (1969). Qiu & Li (2016)  
721 remarked that this viewpoint merits further investigation. We also concur with this viewpoint,  
722 and the reasons for this deduction have already been fully explained by Zheng (1984b) (as  
723 discussed above, the presence of the axioph on M3 in both genera also appears to support this),  
724 so it is not necessary to reiterate these points here.

725 The question that arises now is: when and where (Asia or Europe) did *Tscherskia* originate?  
726 Based on current evidence, the earliest appearance of *Tscherskia* in Europe predates that in Asia.  
727 The earliest species of *Tscherskia* in Europe, *T. europaeus* and *T. janossyi*, both emerged at  
728 Csarnóta 2 (MN 15, ca. 5-3.5 Ma) in Hungary (Hír, 1994; Venczel & Gardner, 2005). In Asia,  
729 the earliest known *Tscherskia* is *T. sp.*, represented by a fragmentary mandible with m2-m3  
730 from the Youhe fauna in Linwei District, Shaanxi Province, China (Xie, Zhang & Li, 2021), with  
731 an age of the Late Pliocene (ca. 3.15-2.59 Ma, Yue & Xue, 1996). However, as previously noted,  
732 all other credible materials of *Tscherskia* in China (or Asia) are from the Middle Pleistocene or  
733 later. This nearly empty fossil record of *Tscherskia* in East Asia before the Middle Pleistocene is  
734 a major challenge to the idea of an East Asian origin for *Tscherskia*, although species  
735 morphologically similar to *Tscherskia triton* have been found in the Late Pliocene (?) in China  
736 (e.g., *Neocricetodon yinanensis*). Furthermore, Europe exhibits a higher diversity of *Tscherskia*  
737 species compared to Asia.

738 Therefore, based on the available evidence, it seems more probable that *Tscherskia* originated  
739 from *Neocricetodon* during the Early Pliocene in Europe and subsequently spread to Asia. It is  
740 possible that another dispersal event in the same direction occurred during the late Early  
741 Pleistocene, which could account for the absence of credible *Tscherskia* fossils in China  
742 throughout the Early Pleistocene. Meanwhile, the *Tscherskia* that arrived in East Asia during the  
743 first dispersal event likely became extinct shortly thereafter and did not survive into the  
744 Pleistocene. Of course, this hypothesis still requires verification through the examination of  
745 additional material in the future.

### 746 **Conclusions**

747 The detailed morphological description and comparative study of hundreds of large-sized  
748 hamster remains collected from the late Middle Pleistocene Locality 2 of Shanyangzhai (Syz 2)  
749 indicate that they should be referred to a chronosubspecies of the extant *Tscherskia triton*—*T.*  
750 *triton varians* comb. nov. This chronosubspecies is highly similar to extant *T. triton* in size and  
751 most molar characters, but exhibits slightly higher frequencies of mesolophids on m1 and m2. In  
752 most skull and mandible measurements, the mean values of the former may be lightly greater  
753 than those of the later. To resolve the longstanding debate over the validity of *Cricetinus*  
754 Zdansky, 1928 and *C. varians* Zdansky, 1928, a detailed comparison of skull and molar

755 morphology was conducted between *C. varians* and *T. triton*. The results demonstrated that the  
756 differences between the two are very slight; thus, *C. varians* can only be treated as a  
757 chronosubspecies of *T. triton*, i.e., *T. triton varians* comb. nov., and *Cricetinus* should be  
758 considered a junior synonym of *Tscherskia*. We tentatively propose that among the seven species  
759 once referred to *Cricetinus* in Eurasia, *C. europaeus*, *C. gritzai*, *C. janossyi*, and *C. koufosi*  
760 should be transferred to *Tscherskia*, while *C. beremendensis* should be transferred to  
761 *Allocricetus*, and *C. mesolophidos* to *Neocricetodon*. Apart from *Tscherskia* sp. from the Late  
762 Pliocene Youhe fauna, there are no credible fossils of *Tscherskia* in China earlier than the  
763 Middle Pleistocene. Based on the current evidence, *Tscherskia* may have originated from  
764 *Neocricetodon* during the Early Pliocene in Europe and subsequently spread to Asia, with *T.*  
765 *triton* being its sole extant representative now only inhabiting East Asia.

## 766 Acknowledgements

767 We would like to express our sincere appreciation to Prof. Qiu Zhuding for his assistance in  
768 improving the manuscript, to Prof. Zheng Shaohua for valuable discussions, and to Prof. Wu  
769 Wenyu for her warm support (all affiliated with the Institute of Vertebrate Paleontology and  
770 Paleoanthropology, Chinese Academy of Sciences, China). We are grateful to the editor, Dr.  
771 Kenneth De Baets, and reviewers Drs. Maxim Sinitisa, János Hír, and Jordi Agustí for their  
772 insightful comments, which substantially enhanced the original manuscript. We also extend our  
773 thanks to Li Zhixuan (College of Life Sciences, NWU), Wang Kaifeng and Wang Yan (Shannxi  
774 Institute of Zoology, China), Zhang Lixun and Liao Jicheng (School of Life Sciences, Lanzhou  
775 University, China), and Zhang Yanming (Northwest Institute of Plateau Biology, Chinese  
776 Academy of Sciences, China) for their friendly assistance during the examination of extant  
777 hamster specimens. Additionally, we thank Prof. Robert F Diffendal, Jr. for his linguistic help.

## Figure 2

Skulls of *Tscherskia triton varians* from Syz 2.

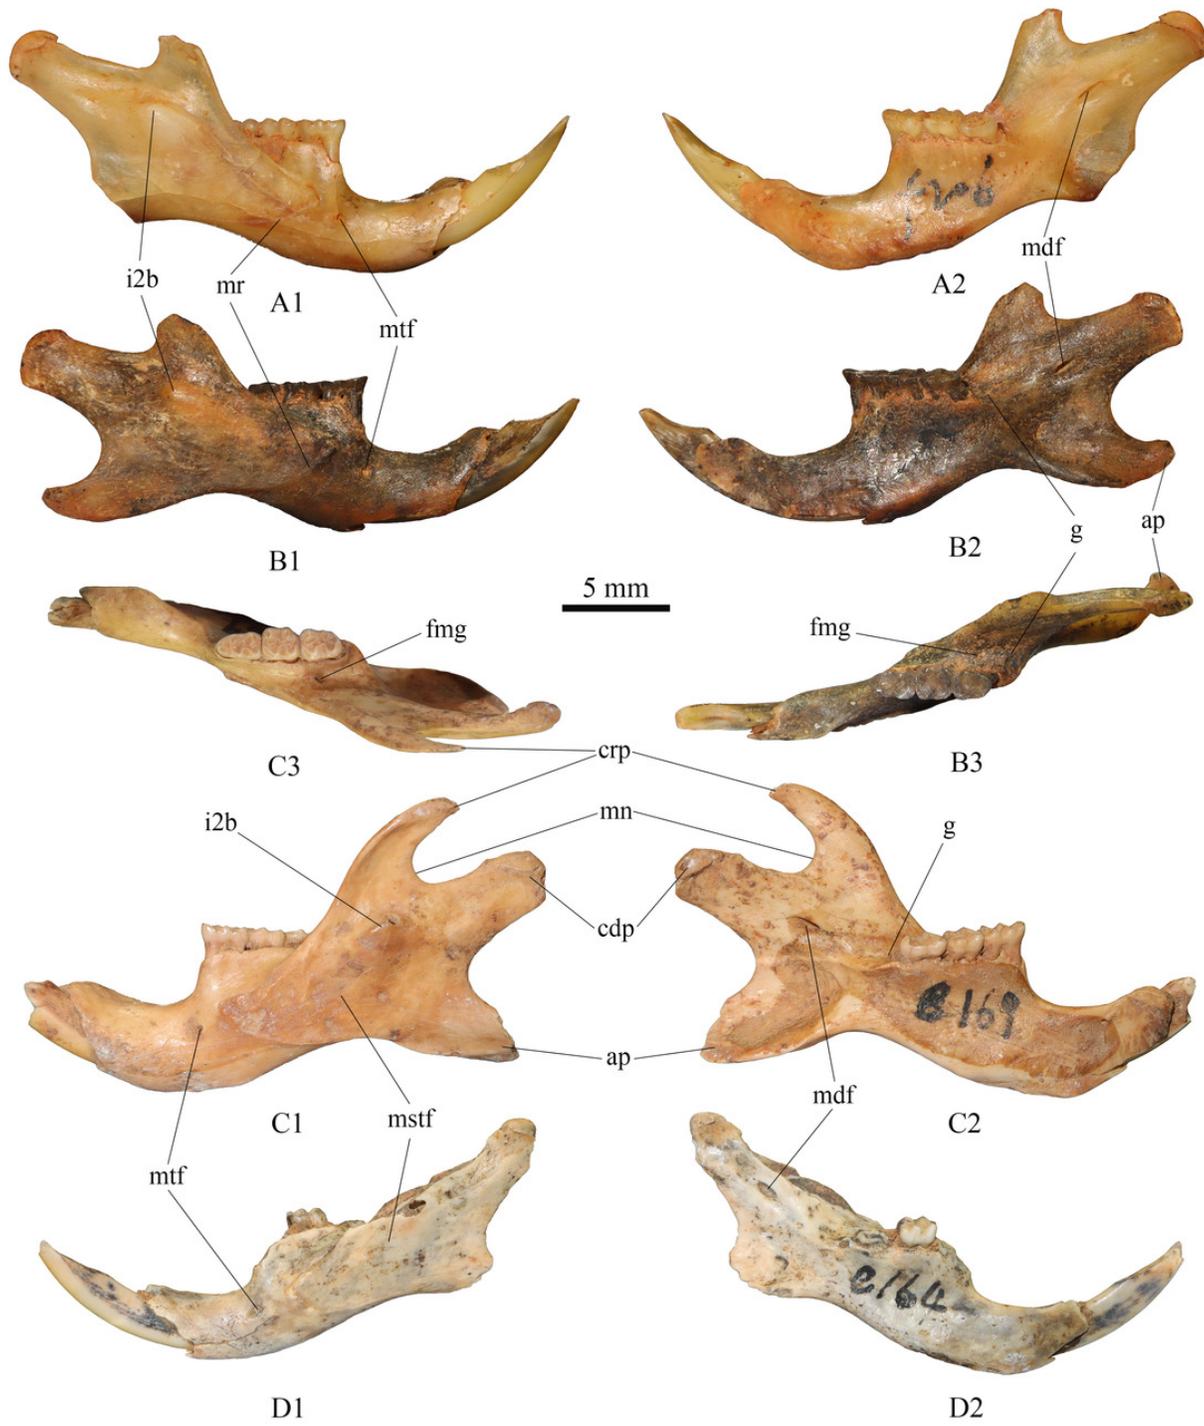

(A) NWUV 1489.a8, incomplete skull; (B) NWUV 1489.a21, incomplete skull; (C) NWUV 1489.a6, incomplete skull; (D) NWUV 1489.a7, incomplete skull. (A1), (B1), (C1), (D), dorsal view; (A2), (B2), (C2), lateral view; (A3), (B3), (C3), ventral view ; (A4), anterior view. The underlined label indicates the image has been reversed. Abbreviations: arza, anterior root of the zygomatic arc; aui, alveolus of the upper incisor; F, frontal; fc, frontal crest; inf, incisive foramen; iof, infraorbital foramen; lp, interparietal; M, maxilla; mt, masseteric tubercle; N, nasal; P, parietal; pbhp, posterior border of the hard palate; Pm, premaxilla; ppf, posterior palatine foramen; sof, supraorbital foramen; zp, zygomatic plate .

## Figure 3

Mandibles of *Tscherskia triton varians* from Syz 2.

(A) NWUV 1489.f206, right mandible; (B) NWUV 1489.f207, right mandible; (C) NWUV 1489.e169, left mandible; (D) NWUV 1489.e164, left mandible. (A1), (B1), (C1), (D1), buccal view; (A2), (B2), (C2), (D2), lingual view; (B3), (C3), occlusal view. Abbreviations: ap, angular process; cdp, condyloid process; crp, coronoid process; fmg, foramen in the middle of the groove (g); g, groove between the alveolus of molars and the base of the coronoid process; i2b, bulge formed by i2; mdf, mandibular foramen; mn, mandibular notch; mr, masseteric ridge; mstf, masseteric fossa; mtf, mental foramen.

## Figure 4

Left upper molars of *Tscherskia triton varians* from Syz 2.

(A) NWUV 1489.a5; (B) NWUV 1489.a14; (C) NWUV 1489.a21; (D) NWUV 1489.b1; (E) NWUV 1489.c3; (F) NWUV 1489.c5; (G) NWUV 1489.c16. The arrow indicates the axioloph.

## Figure 6

Scatter diagrams of lengths and widths of the first molars of "*Cricetinus*" *varians* and *Tscherskia triton*.

Data source refers to Table 2. The boxes in the figure represent the upper and lower bounds of the length and width values of specimens from specific sites, as the raw data of individual specimen measurements are not available in the original references.

**Table 1** (on next page)

Measurements and comparisons of skulls and mandibles of *Tscherskia triton varians* from Syz 2 and extant *T. triton* (mm) #

1

	<i>T. triton</i> varians of Syz 2						the extant <i>T. triton</i>					
	N	Min.	Mean	Max.	SD	CV	N	Min.	Mean	Max.	SD	CV
Palatal length	4	16.39	18.01	20.04	1.57	8.7%	40	13.72	17.21	20.13	1.70	9.9%
