

## Trophic ecology of sea urchins in coral-rocky reef systems, Ecuador

Nancy Cabanillas-Terán, Peggy Loo-Andrade, Ruber Rodríguez-Barreras, Jorge Cortés

Sea urchins are important grazers and influence reef development in the Eastern Tropical Pacific (ETP). *Diadema mexicanum* and *Eucidaris thouarsii* are the most important sea urchins on the Ecuadorian coastal reefs. This study provided a trophic scenario for these two species of echinoids in the coral-rocky reef bottoms of the Ecuadorian coast, using stable isotopes. We evaluated the relative proportion of algal resources assimilated, and trophic niche of the two sea urchins in the most southern coral-rocky reefs of the ETP in two sites with different disturbance level. Bayesian models were used to estimate the contribution of algal sources, niche breadth, and trophic overlap between the two species. The sea urchins behaved as opportunistic feeders, although they showed differential resource assimilation. *Eucidaris thouarsii* is the dominant species in disturbed environments; likewise, their niche amplitude was broader than that of *D. mexicanum* when conditions were not optimal. However, there was no niche overlap between the species. The Stable Isotope Analysis in R (SIAR) indicated that both sea urchins shared limiting resources in the disturbed area, mainly *Dictyota* spp. (contributions of up to 85% for *D. mexicanum* and up to 75% for *E. thouarsii*). The Stable Isotope Bayesian Ellipses in R (SIBER) analysis results indicated less interspecific competition in the undisturbed site. Our results suggested a trophic niche partitioning between sympatric sea urchin species in coastal areas of the ETP, but the limitation of resources could lead to trophic overlap and stronger habitat degradation.

24 **Abstract**

25 Sea urchins are important grazers and influence reef development in the Eastern Tropical Pacific  
26 (ETP). *Diadema mexicanum* and *Eucidaris thouarsii* are the most important sea urchins on the  
27 Ecuadorian coastal reefs. This study provided a trophic scenario for these two species of  
28 echinoids in the coral-rocky reef bottoms of the Ecuadorian coast, using stable isotopes. We  
29 evaluated the relative proportion of algal resources assimilated, and trophic niche of the two sea  
30 urchins in the most southern coral-rocky reefs of the ETP in two sites with different disturbance  
31 level. Bayesian models were used to estimate the contribution of algal sources, niche breadth,  
32 and trophic overlap between the two species. The sea urchins behaved as opportunistic feeders,  
33 although they showed differential resource assimilation. *Eucidaris thouarsii* is the dominant  
34 species in disturbed environments; likewise, their niche amplitude was broader than that of *D.*  
35 *mexicanum* when conditions were not optimal. However, there was no niche overlap between the  
36 species. The Stable Isotope Analysis in R (SIAR) indicated that both sea urchins shared limiting  
37 resources in the disturbed area, mainly *Dictyota* spp. (contributions of up to 85% for *D.*  
38 *mexicanum* and up to 75% for *E. thouarsii*). The Stable Isotope Bayesian Ellipses in R (SIBER)  
39 analysis results indicated less interspecific competition in the undisturbed site. Our results  
40 suggested a trophic niche partitioning between sympatric sea urchin species in coastal areas of  
41 the ETP, but the limitation of resources could lead to trophic overlap and stronger habitat  
42 degradation.

## 53 Introduction

54 As a consequence of increasing human pressure, coastal ecosystems are facing a wide range of  
55 threats, such as resource exploitation and habitat modification (Wilkinson, 1999; Dumas et al.,  
56 2007; Costello et al., 2010; Rossi, 2013). Several studies have evaluated the development of  
57 rocky bottom disturbances by analyzing the densities of echinoids and the development stage of  
58 habitats (Phillips & Shima, 2006; Alvarado, Cortés & Reyes-Bonilla, 2012; Hereu et al., 2012).  
59 Some of these studies have correlated different phases of benthic substrate degradation,  
60 considering sea urchin density and their association with functional algae groups (Steneck, 1983;  
61 Steneck & Dethier, 1994). Another approach to decipher benthic dynamics is through the trophic  
62 relationships between consumers and resources using stable isotopes (Behmer & Joern, 2008).  
63 Stable isotope analysis (SIA) has been a powerful tool to study trophic ecology, especially for  
64 those species with foraging habits for which it is difficult to use traditional techniques, such as  
65 stomach contents. Several studies have focused on sea urchins from a stable isotope approach  
66 (e.g., Minagawa & Wada, 1984; Tomas et al., 2006; Vanderklift, Kendrick & Smith, 2006; Wing  
67 et al., 2008; Cabanillas-Terán, 2009; Rodríguez-Barreras et al., 2015).

68 Stable carbon and nitrogen isotope ratios provide time-integrated information regarding feeding  
69 relationships and energy flow through food webs (DeNiro & Epstein, 1981; Peterson & Fry,  
70 1987; Vander-Zanden & Rasmussen, 2001; Carabel et al., 2006). Stable isotopes can be used to  
71 study the trophic niche of a species due to the “ $\delta$ -space”. This is comparable to the n-dimensional  
72 space that ecologists refer to as a niche because an animal’s chemical composition is directly  
73 influenced by what it consumes, as well as the habitat in which it lives (Newsome et al., 2007;  
74 Parnell et al., 2010; Boecklen et al., 2011).

75 Carbon is a conservative tracer used to track energy sources in food webs, while nitrogen helps  
76 determine the trophic position (Minagawa & Wada, 1984; Vander-Zanden & Rasmussen, 2001;  
77 Post, 2002; Phillips, 2012; Phillips et al., 2014). Carbon ( $\delta^{13}\text{C}$ ) and nitrogen ( $\delta^{15}\text{N}$ ) stable  
78 isotopes have been used in marine ecosystems to determine the food habits of species (Peterson  
79 & Fry, 1987), nutrient migrations within food webs, the trophic position of organisms and their  
80 contribution at every level (Vander-Zanden & Rasmussen, 1996), the origin and transformation  
81 of the ingested organic matter (Peterson, Howarth & Garrett, 1985), or how some ecosystems

82 have organisms that occupy similar trophic positions coexisting in high densities (Vanderklift,  
83 Kendrick & Smith, 2006). Moreover, SIA are useful to assess the ecosystem health (e.g., Cole et  
84 al., 2004; Hamaoka et al., 2010; Karube et al., 2010). For example human influence on lake  
85 ecosystems were studied by Karube et al. (2010) and those authors found that signatures of  $\delta^{13}\text{C}$   
86 and  $\delta^{15}\text{N}$  in macroinvertebrates of the littoral zone are indicators of anthropogenic impacts from  
87 the watershed. Inorganic nitrogen loading from the watershed was recorded in  $\delta^{15}\text{N}$  of snails.

88

89 Reef degradation currently has significant consequences for morpho-functionality of marine  
90 environments (Hoegh-Guldberg, 1999; Mumby, Foster & Fahy, 2005), and the Ecuadorian reefs  
91 are no exception (Glynn & Wellington, 1983; Glynn, 1993; Guzmán & Cortés, 1993; Glynn,  
92 2003). Anthropogenic stressors can have synergistic effects on reefs, such as the harmful algae  
93 blooms that are becoming increasingly important drivers of variation in the sea urchin  
94 populations, as seen in other areas (Hunter & Price, 1992; Lapointe et al., 2005; Lapointe et al.,  
95 2010).

96

97 Coral-rocky reefs have rarely been studied along the Ecuadorian mainland, despite the serious  
98 threat by eutrophication, fisheries and other anthropogenic impacts (Guzmán & Cortés, 1993;  
99 Cortés, 1997; Cortés, 2011). Ecuadorian coral communities are important because they represent  
100 the southernmost distribution in the Eastern Tropical Pacific (ETP). Ecuador has no extensive  
101 reef systems, as the majority of reefs are small rocky patches with some coral colonies.  
102 Nevertheless, those areas are characterized by high biodiversity, including more than a quarter of  
103 the Ecuadorian continental fishes and a great number of echinoderms, sea fans, and scleractinian  
104 corals (Glynn et al., 2001; Glynn, 2003; Rivera & Martínez, 2011).

105

106 Sea urchins have the capability to modify the community structure through foraging, as several  
107 authors have previously mentioned (e.g., Carpenter, 1981; Carpenter, 1986; Hay, 1984; Hay &  
108 Fenical, 1988; Sala, Boudouresque & Harmelin-Vivien, 1998), and we need to elucidate what

109 occurs in areas where there are more than one sea urchin species which dominate the substratum  
110 and their role in controlling fleshy macroalgae. The sea urchins *Diadema mexicanum* (Agassiz,  
111 1863) and *Eucidaris thouarsii* (Agassiz & Desor, 1846) are two of the most dominant benthic  
112 grazers in the ETP (Guzmán & Cortés, 1993). These two echinoids exert a strong influence on  
113 the community structure (Lawrence, 1975; Glynn, Wellington & Birkeland, 1979; Andrew,  
114 1989; Underwood, 1992). In the ETP, the sea urchin *E. thouarsii* could be described as a major  
115 herbivore in rocky reef bottoms. Its preferential resource appeared to be benthic algal turf and  
116 macroalgae, but if those were not available, it feeds on other organisms, such as the corals  
117 *Pavona clavus*, *Pocillopora* spp. and *Porites lobata* (Glynn et al., 1979; Glynn & Wellington,  
118 1983; Reaka-Kudla, Feingold & Glynn, 1996).

119  
120 The ratios of  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  in consumers are strongly influenced by their food resources  
121 (Phillips et al., 2014) and it is necessary to identify their ecological role, not only by their  
122 capacity to structure the environment, but to understand the dynamics of coexistence of the sea  
123 urchin populations along the Ecuadorian coast. The relative position of  $\delta^{13}\text{C}$  vs.  $\delta^{15}\text{N}$  echinoids  
124 species can be displayed in a bi-plot and help to understand food web structure and organism  
125 responses to niche shifts, diet variability and human impact (Layman et al., 2007). The aim of  
126 this study was to improve the knowledge and understanding of the trophic biology of *D.*  
127 *mexicanum* and *E. thouarsii* in Ecuadorian rocky reefs. We determined the stable isotopes of  
128 carbon and nitrogen isotope for both sea urchin species. The complexity of the littoral zone was  
129 analyzed using stable isotopes to understand the trophic interactions of these two echinoids in  
130 areas with different degree of human impact. We assume that the more developed rocky-reef and  
131 substrate associated to coral coverage will favor habitats with complex trophic interactions (see  
132 Duffy et al., 2007; Álvarez-Filip, et al., 2009; Graham & Nash, 2013), resulting in wider isotopic  
133 echinoids niche breadth.

## 134 **Material & Methods**

135 Site descriptions: This study was conducted between May and September of 2013, at two  
136 localities, Los Ahorcados (LA: 01°40'42"S; 80°51'58"W) and Perpetuo Socorro (PS: 0°55'40"S;  
137 80°44'25"W), in Manabí province, Ecuador (Fig. 1). The LA site was a small group of rocky  
138 islets located near Machalilla National Park. Although this area was not considered a protected

139 area, it had a very high diversity of scleractinians and octocorals (Rivera & Martínez, 2011). LA  
140 presented a rocky bottom with clear geomorphologic differences between the leeward and  
141 windward areas. The leeward area were 25 m depth, and the windward side was mainly build by  
142 octocorals (22 species), and hexacorals, such as *Pavona* spp., the branching corals *Pocillopora*  
143 spp. and solitary corals. The PS site is located in front of the Port of Manta (1.5 km), one of the  
144 most important ports in Ecuador for large pelagic fisheries (Villón & Beltrán, 1998a; Villón &  
145 Beltrán, 1998b; Martínez-Ortíz *et al.*, 2007) and greatly impacted by anthropogenic activities  
146 (See details in Table 1). PS rocky reef is a homogenous bottom of 7-9 m depth, and had a  
147 substrate consisted mainly of a mixture of rock and sand with scarce scleractinian corals (*Pavona*  
148 spp. and *Pocillopora* spp.) and gorgonians (mainly *Leptogorgia alba*).

149 In order to distinguish both sites, a coral-rocky reef category was used for this study, which was  
150 developed taking into account habitat complexity and type of disturbance to establish two  
151 categories, namely disturbed and undisturbed (Table 1). The distance of human impact to the  
152 sites, size of the fleet and type of human disturbance were considered. The rugosity index (RI),  
153 which is the ratio of a length of chain following the reef contour to the linear distance between its  
154 start and end point (modified of Risk, 1972) was used. To calculate the RI, we used a three-meter  
155 chain five times equitably-distributed along 15 transects (20m). The average RI obtained with  
156 transects was used to determine the rugosity level per site, where larger numbers indicate higher  
157 complexity following Alvarez-Filip *et al.* (2009) and Alvarez-Filip *et al.* (2011). Therefore  
158 values of  $RI < 1.5$  were considered low complexity and  $RI > 1.5$  were defined as complex.

159

160 Collecting and processing data: We collected algal samples for identification, to calculate  
161 biomass, and to carry out SIA. Algal biomass was measured using twelve 50 x 50 cm quadrats  
162 per site. The quadrats were located randomly within the sea urchin habitat. The substrate inside  
163 each quadrat was scrapped, carefully removed, collected in bags, and frozen for later analysis.  
164 Macroalgae were identified to the lowest possible taxonomic level using the available keys  
165 (Abbot & Hollenberg, 1976; Afonso-Carillo & Sansón, 1999; Littler & Littler, 2010). The  
166 sampled invertebrate and algal species for this study are not threatened. The necessary permits  
167 were obtained from the Ministry of Environment of Ecuador (014AT-DPAM-MAE).

168 In areas where the algal cover was dominated mainly by turf species (following the morpho-  
169 functional category of Guidetti, 2006), we used a sniffer with a dense mesh bag coupled to a  
170 compressed air tank. In the laboratory, individuals were separated into species and gently washed  
171 with distilled water and dried in an oven at 50 °C for 24 h to measure the dry weight.

172 We collected four individuals of *D. mexicanum* and six of *E. thouarsii* in LA and twelve  
173 individuals of *D. mexicanum* and eight of *E. thouarsii* in PS at the same depth range (8-10 m).  
174 Only individuals greater than 5.0 cm in test diameter were collected to avoid any effect of the  
175 development stage. The samples were frozen shortly after collection and processed at the  
176 laboratory. The muscles of Aristotle's lanterns were removed carefully and washed from the  
177 stomach contents to estimate algal assimilation by *D. mexicanum* and *E. thouarsii*. This tissue  
178 provides a time-integrated measure of assimilated sources (e.g., Michener & Schell, 1994; Ben-  
179 David & Schell, 2001; Polunin et al., 2001; Phillips & Koch, 2002; Rodríguez, 2003; Tomas et  
180 al., 2006).

181 The algal and echinoids muscle samples were rinsed with filtered water, dried at 50 °C during 24  
182 hours, ground to a fine powder and placed in glass vial for isotope analyses. To remove  
183 carbonates from some algal species (*Lobophora variegata* and *Polysiphonia* spp.), the samples  
184 were washed with diluted HCl at 1 N prior to drying to avoid disturbance in the mass  
185 spectrometer reading. A subsample was taken of each alga and muscle (~1 mg) to evaluate the  
186 <sup>13</sup>C/<sup>12</sup>C and <sup>15</sup>N/<sup>14</sup>N ratios using a Thermo Electron Delta V Advantage Mass Spectrometer.  
187 Carbon and nitrogen samples were analyzed in a dual isotope mode at the Geology Department,  
188 University of Florida, Gainesville, Florida.

189 The isotope samples were loaded into Eppendorf capsules and placed in a 50-position automated  
190 Zero Blank sample carousel on a Carlo Erba NA1500 CNS elemental analyzer. After combustion  
191 in a quartz column at 1020 °C in an oxygen-rich atmosphere, the sample gas was transported in a  
192 He carrier stream and passed through a hot reduction column (650 °C) consisting of elemental  
193 copper to remove oxygen. The effluent stream then passed through a chemical (magnesium  
194 perchlorate) trap to remove water, followed by a 3 m Gas chromatography (GC) column at 45 °C  
195 to separate N<sub>2</sub> from CO<sub>2</sub>. The sample gas next passed into a ConFlo II preparation system and  
196 into the inlet of a mass spectrometer running in continuous flow mode, where the sample gas was

197 measured relative to laboratory reference N<sub>2</sub> and CO<sub>2</sub> gases. The carbon isotopic results were  
198 expressed in standard delta notation relative to Vienna Pee Dee Belemnite (VPDB). The nitrogen  
199 isotopic results were expressed in standard delta notation relative to atmospheric air. The  
200 standard deviations of δ<sup>13</sup>C and δ<sup>15</sup>N replicate analyses were estimated; the precision values were  
201 0.074 and 0.148 for carbon and nitrogen isotope measurements, respectively. Carbon and  
202 nitrogen samples were analyzed in a dual isotope mode. Ratios are expressed as:

$$203 \delta X (\text{‰}) = [ (R_{\text{sample}} / R_{\text{standard}}) - 1 ] \times 1000; \text{ where } R_{\text{sample}} = {}^{13}\text{C}/{}^{12}\text{C} \text{ or } {}^{15}\text{N}/{}^{14}\text{N}.$$

204

205 *Data analysis:* The relative contribution of algae to the diet of the sea urchins *D. mexicanum* and  
206 *E. thourarsii* was estimated with a Bayesian isotopic mixing model (SIAR, Parnell & Jackson,  
207 2013), which included the isotopic signatures, fractionation and variability to estimate the  
208 probability distribution of the contribution of the food source to a mixture. This procedure  
209 supplied accurate information about the contribution of algal species to the sea urchin tissues  
210 recognized the main components of the diet under different conditions (Peterson, 1999; Fry  
211 2006; Wing et al., 2008). Lipid extractions in sea urchins was not necessary since Aristotle  
212 lantern's muscle is low in lipids, on the other hand when the C:N ratios are lower than 3.5 it is  
213 not recommended (Post et al., 2007) see Table S1. The isotopic discrimination factor values used  
214 to run the model were 2.4±1.6 ‰ (mean ± SD) for δ<sup>15</sup>N, and 0.4 ±1.3 ‰ for δ<sup>13</sup>C (Fry & Sherr,  
215 1984; Minagwa & Wada, 1984; Michener & Schell, 1994; Moore & Semmens, 2008). The  
216 results of the mixing model showing the calculated sea urchin dietary proportions were  
217 represented as box plots, indicating the 25%, 75%, and 95% of credibility intervals (Fig 2).

218 The niche width and overlap for the sea urchins were estimated with Stable Isotope Bayesian  
219 Ellipses in R (SIBER) (Jackson et al., 2011) from the SIAR package (Parnell & Jackson, 2013).  
220 This analysis uses metrics based on ellipses and provides the standard ellipse corrected area  
221 (SEA<sub>c</sub>) used as the trophic niche breadth and the overlap between ellipses, where values close to  
222 1 represent a higher trophic overlap.

223 Prior to the statistical analysis, the homogeneity and normality of variance were tested by  
224 performing a Kolmogorov-Smirnov and a Cochran's test (Zar, 2010). Statistical difference was  
225 performed comparing δ<sup>15</sup>N and δ<sup>13</sup>C values between species. In addition, the algal biomass

226 between sites was evaluated with a one-way ANOVA, with site as a fixed factor. The statistical  
227 analyses were performed using R with an alpha of 0.05 (R Core Team, 2014).

228

## 229 Results

230 The benthic communities in Ecuadorian rocky reefs ranged between habitats dominated by  
231 macroalgae and live corals (LA), and habitats dominated by turf and coral skeletons (PS). Site  
232 estimates for perturbation and complexity are outlined in Table 1. LA is a site with structural  
233 complexity and dominance of branched erect algae, while PS has low structural complexity and  
234 dominance of turf (Table 1).

235

236 The algae collected in LA were *Asparagopsis armata*, *Dictyota dichotoma*, *Lobophora*  
237 *variegata*, *Polysiphonia* spp., and *Sargassum* spp, while in PS were *D. dichotoma*, *L. variegata*,  
238 and *Polysiphonia* spp. The greatest algal biomass was recorded for *L. variegata* at both sites,  
239 while *D. dichotoma* was the algae with the lowest biomass at both localities (Table 2). Overall,  
240 the biomass average values ranged from  $35.8 \pm 9.73$  g (dry weight)  $m^{-2}$  for PS to  $143.00 \pm 20.67$   
241  $g m^{-2}$  in LA. We found significant differences between both sites (ANOVA,  $df= 1$ ,  $F= 3.60$ ,  $p<$   
242  $0.01$ ). The overall algal  $\delta^{15}N$  fluctuated from 5.05 to 9.49‰ (Table 3). PS displayed the highest  
243 mean values of nitrogen with *D. dichotoma* ( $7.60 \pm 0.53$ ‰). At LA, *Polysiphonia* spp. exhibited  
244 the highest mean value for nitrogen ( $7.19 \pm 1.13$ ‰). We found significant differences in  $\delta^{15}N$   
245 between sites (ANOVA,  $df= 1$ ,  $F= 5.29$ ,  $p= 0.02$ ), taking into account all the algae isotopic  
246 signatures. As for  $\delta^{13}C$ , ratios fluctuated from -23.65 to -6.90‰, with LA displaying the most  
247 negative values (*A. armata*). There was no significant difference in  $\delta^{13}C$  among sites (ANOVA,  
248  $DF=1$ ,  $F= 1.41$ ,  $p>0.05$ ).

249

250 Values of  $\delta^{15}N$  were particularly different between the two species of sea urchins (ANOVA,  $df=$   
251  $1$ ,  $F= 20.10$ ,  $p < 0.001$ ). The isotopic value of  $\delta^{15}N$  for *D. mexicanum* ranged from 11.38 to  
252 12.99‰, whereas *E. thouarsii* displayed values from 12.31 to 14.15‰. The average values of  
253  $\delta^{13}C$  and  $\delta^{15}N$  estimated for *D. mexicanum* in LA were  $-16.67 \pm 0.04$  and  $11.53 \pm 0.14$ ‰,  
254 respectively, while *E. thouarsii* displayed  $-15.46 \pm 0.16$ ‰ and  $12.84 \pm 0.40$ ‰, respectively. In

255 PS, the *D. mexicanum* isotopic signals were  $-16.25 \pm 0.39\text{‰}$  for  $\delta^{13}\text{C}$  and  $12.62 \pm 0.22\text{‰}$  for  
256  $\delta^{15}\text{N}$ ; while *E. thourarsii* displayed  $-15.41 \pm 0.43\text{‰}$  for  $\delta^{13}\text{C}$  and  $13.54 \pm 0.47\text{‰}$  for  $\delta^{15}\text{N}$ . We  
257 found significant differences in  $\delta^{13}\text{C}$  between species (ANOVA, df 1,  $F= 49.31$ ,  $p < 0.0001$ ), and  
258 the most negative values were found at LA. The  $\delta^{15}\text{N}$  showed the same patterns as those algae  
259 (higher values for PS).  $\delta^{15}\text{N}$  ratios of both sea urchins differed between the study sites, as LA  
260 reported lower values than PS (ANOVA, df 1,  $F= 7.59$ ,  $p < 0.01$ ). The most notorious difference  
261 was due to *D. mexicanum* (ANOVA, df 1,  $F= 82.41$ ,  $p < 0.0001$ ).

262

263 The mixing models provided evidence for the contribution of different algal resources for both  
264 sites and species. The SIAR analysis showed that *Sargassum* spp. was the most important  
265 resource for *D. mexicanum* in LA (up to 43%), followed by *D. dichotoma* and *A. armata* as  
266 secondary resources (up to 37% for both). Likewise, *Sargassum* spp. was the main algal resource  
267 for *E. thourarsii* in the same locality (up to 44%), followed by *Polysiphonia* spp. (up to 41%)  
268 (Table 4). Contrasting, at PS the main macroalgal contributor was *D. dichotoma* for both sea  
269 urchins (Fig. 2), with up to 85% of the proportional contribution for *D. mexicanum* and close to  
270 75% for *E. thourarsii*. Table 5 shows data on isotopic niche breadth as measured by the corrected  
271 standard ellipse area (SEAc). The main difference in the trophic niche breadth was caused by *E.*  
272 *thourarsii* with a difference probability of 52%; overlap between species isotopic niches was not  
273 found in any case (Fig. 3), but the SEAc was higher for *E. thourarsii* in both sites with 0.25 in LA  
274 and 0.46 in PS (Table 5).

275

## 276 Discussion

277 There is very little information on the ecology of the Ecuadorian coast, and no data pertaining to  
278 trophic relationships among sea urchins, apart from this study. The majority of the available  
279 information on Ecuador came from studies conducted on Galapagos reefs (Glynn, Wellington &  
280 Birkeland, 1979; Glynn & Wellington, 1983; Glynn, 2003; Glynn 2004; Glynn et al., 2009). The  
281 rocky reefs examined in this study were selected to establish the baseline of the trophic ecology  
282 of two rocky reef areas, with different disturbance levels in the Ecuadorian mainland coast. The  
283 presence of *D. mexicanum* was related to the rocky bottoms of LA, where algal presence were  
284 more frequent than in the disturbed site (PS). The population density of *E. thourarsii* was higher

285 at the disturbed site (N. Cabanillas-Terán, unpublished data). This study demonstrated that algal  
286 abundance is not always equivalent to assimilation by the consumer. For instance, *L. variegata*  
287 displayed the lowest dietary contribution at PS and LA for both sea urchins, although it exhibited  
288 the highest average biomass at both sites. Grazing preference by *D. mexicanum* and *E. thouarsii*  
289 was not related to algal biomass.

290 The isotopic results characterized different algal assemblages that were specific to each rocky  
291 reef bottom (branched macroalgae for LA and turf for PS). The values of  $\delta^{15}\text{N}$  in algae in this  
292 study ranged from 5.05‰ to 9.49‰. This result agreed with the ranges of variation reported in  
293 other studies (Owens, 1987). The values of  $\delta^{13}\text{C}$  fluctuated from -23.65 to -6.90‰ and agreed  
294 with data from Fry & Sherr (1984), who reviewed the  $\delta^{13}\text{C}$  data of benthic algae, noting that  
295 values ranged between -30 to -5‰. The different algae species constituting the community of LA  
296 showed isotopic values that were closer together, but with a broader cloud distribution in the C  
297 vs N biplot of points relative to what was observed in PS. This suggests a more complex trophic  
298 net and shows how primary consumers interact with their resources (McClanahan, 1988; Phillips  
299 & Gregg, 2003).

300 The isotopic ratios of  $\delta^{15}\text{N}$  could be influenced by two main factors. One factor pertains to  
301 changes in dissolved nitrogen, although these changes primarily affect the microscopic algal  
302 communities or communities living near upwelling zones (Jennings et al., 1997; Polunin &  
303 Pinnegar, 2002). The other factor is the anthropogenic impact (Bode, Alvarez-Ossorio & Varela,  
304 2006), affecting the communities near the coastline. In this case, the community most affected by  
305 urban impact was PS, located in front of Manta Port. In this port, human density is higher than  
306 1000 ind/km<sup>2</sup>, and artisanal and industrial fishery contribute to nitrogen input, as well as the  
307 hotel zone and discharges from tuna processing.

308

309 For algae found in both sites (*D. dichotoma*, *L. variegata* and *Polysiphonia* spp.), the average  
310  $\delta^{15}\text{N}$  were higher in PS. This agrees with other areas with high anthropogenic influence where  
311  $\delta^{15}\text{N}$  values tended to be higher (Wada, Kadonaga & Matsuo, 1975; Michener & Schell, 1994).  
312 Although both localities shared species, the isotopic values for both localities were different

313 because each system had its own structure. The erected branched algae *A. armata* and *Sargassum*  
314 spp. (not found in PS), contributed to the structural complexity founded in LA.

315

316 Variations in carbon and nitrogen ratios gave us information on trophic spectrum inherent to  
317 each site and the contribution of algal species to the sea urchin tissues display information about  
318 how consumers assimilate the resources when they inhabit disturbed and/or undisturbed sites.  
319 Although both sea urchin species can share the same food resources, we found that their  
320 ecological roles were different and there are differences between species in terms of assimilation.  
321 This could explain the fact that  $\delta^{15}\text{N}$  values in the tissues of *E. thourarsii* were higher for both  
322 localities, even though both sea urchin species showed a preference for the same species *D.*  
323 *dichotoma*. No overlap of isotope niche breadth of the echinoids was found between the two  
324 species (Fig. 3), but the isotopic values between species at PS were closer, suggesting increased  
325 competition due to the lack of resources. This result coincided with the mixing model because  
326 the two species of sea urchins preferentially consumed similar proportions of the same species.  
327 Moreover the SEAc was larger for *E. thourarsii* at both sites, and in LA the niche trophic distance  
328 between *D. mexicanum* and *E. thourarsii* was very conspicuous, while in PS the two species of  
329 sea urchins are closer (Fig. 3). A low degree of feeding specialization suggests that the sea  
330 urchins adapt their foraging behavior to algae availability, being most evident for *E. thourarsii*,  
331 that exhibits a broader trophic niche.

332 The grazing behavior of these sea urchins agreed with the findings by Glynn, Wellington &  
333 Birkeland (1979) in the Galápagos Islands, as their grazing was stronger in those areas with 30%  
334 or less coral cover. Previous studies highlighted that *E. thourarsii* limited coral growth, as this  
335 echinoid interfered with the development of the reef frame and with the ability to modify the  
336 habitat structure (Bak, 1994; Carpenter, 1981; Sonnenholzner, Ladah & Lafferty, 2009). We  
337 considered *D. mexicanum* to be an important grazer for the rocky bottoms ecosystems,  
338 considering that changes in its population caused significant changes in the algal cover of those  
339 areas.

340 Our results supported the evidence that *D. mexicanum* and *E. thourarsii* were coexistent species  
341 that play a significant role as herbivores. Nevertheless, they apparently eat whatever they find,  
342 and the food items are incorporated differentially between the species. *Diadema mexicanum*

343 grazing effect on algal diversity and community structure is important in the process of  
344 formation and maintenance of rocky reefs in Ecuador. This has also been observed in other areas  
345 of the ETP where *D. mexicanum* has a relevant role in the recruitment of corals (Alvarado,  
346 Cortés & Reyes-Bonilla, 2012). This was also observed in Caribbean reefs with *D. antillarum*  
347 (Macintyre, Glynn & Hinds, 2005; Mumby et al., 2006; Idjadi, Haring & Precht, 2010; Sandin &  
348 McNamara, 2012), and in sublittoral ecosystems of the Canary Islands with *D. africanum* (Alves  
349 et al., 2003; Tuya et al., 2004; Hernández et al., 2005; Hernández et al., 2008; Sangil et al., 2014;  
350 Cabanillas-Terán et al., 2015).

351 The standard ellipses areas values (Table 5) indicated that niche partitioning may vary depending  
352 on different disturbance levels between sites; however, the diets of *D. mexicanum* and *E.*  
353 *thouarsii* not only depend on the disturbance condition. For instance, *Dictyota dichotoma* was an  
354 important component of the diet of *D. mexicanum* and *E. thouarsii* in the disturbed and  
355 undisturbed sites, while *Polysiphonia* spp. was important in disturbed bottoms, where isotopic  
356 algal signals are closer to each other. This could lead to a greater number of resource overlap at  
357 PS than at LA.

358 Differential assimilation and niche partitioning are just snapshots, It is important to depict how  
359 the shape of the food web varies in time and space (Layman et al., 2007 & Schmidt et al., 2007),  
360 so it is necessary to carry out more extensive spatial and temporal research. Likewise it is  
361 necessary to deepen research to analyze if the narrower niche amplitude (SEAc) of *D.*  
362 *mexicanum* and its associated presence to scleractian corals (at LA) is consistent to what is  
363 happening in the Caribbean, where its presence provides suitable habitat for coral recruitment.  
364 The feeding success of herbivores is associated with the competition level for resources;  
365 therefore, sympatric species are exposed to a potential trophic overlap. The most pristine zone  
366 (LA) exhibited smaller SEAc (considering values per species) and nitrogen values, which  
367 indicate a trophic niche partitioning between the main sea urchins on the Ecuadorian coast. But,  
368 the limitation of resources could lead to trophic overlap and stronger habitat degradation.  
369
