OPEN ACCESS

Feeding ecology and reproductive biology of small coastal sharks in Malaysian waters

Kean Chong Lim^{1,2}, Amy Yee-Hui Then^{1,3} and Kar-Hoe Loh¹¹ Institute of Ocean and Earth Science, Universiti Malaya, Kuala Lumpur, Malaysia² Institute for Advance Studies, Universiti Malaya, Kuala Lumpur, Malaysia³ Institute of Biological Science, Faculty of Science, Universiti Malaya, Kuala Lumpur, Malaysia

ABSTRACT

Small coastal demersal sharks form a major proportion of the sharks landed in Malaysia. However, little is known about their feeding ecology and reproduction. This study sought to elucidate the dietary patterns, role of ontogeny in prey consumption, and reproductive biology of four dominant small demersal shark species in Malaysian waters: the Hasselt's bamboo shark, *Chiloscyllium hasseltii*; brownbanded bamboo shark, *C. punctatum*; spadenose shark, *Scoliodon laticaudus*; and Pacific spadenose shark, *S. macrorhynchus*. Dietary analyses revealed a high overlap in prey taxa consumed; clear resource partitioning among co-occurring species based on the percentage Prey-specific Index of Relative Importance (%PSIRI), with higher fish %PSIRI for *Chiloscyllium hasseltii*, higher cephalopod %PSIRI for *C. punctatum*, and higher crustacean %PSIRI for both *Scoliodon* species; and an ontogenetic diet shift, seen through changes in prey size. Based on the examination of reproductive organs, the results showed larger sizes at maturity for males compared to females for all four species; no obvious reproductive cycles, based on hepatosomatic and gonadosomatic indices for all species; female bias in the sex ratio of the embryos of *Scoliodon* species; and increased reproductive output (number of eggs or embryos and size of eggs) with larger female size for *C. hasseltii* and *Scoliodon* species. The partitioning of food resources minimizes direct competition for food and supports coexistence within shared coastal habitats. The reproductive strategies of these small coastal sharks appear to be favorable for supporting short-term population productivity; although a reduction in fishing pressure, especially from bottom trawlers, is essential for the long-term sustainable use of these sharks.

Subjects Aquaculture, Fisheries and Fish Science, Ecology, Marine Biology**Keywords** Diet overlap, Resource partitioning, Ontogenetic, Size at maturity

INTRODUCTION

Sharks play an important role in the top-down control and maintenance of healthy marine ecosystems (Ferretti et al., 2010; Heithaus, Wirsing & Dill, 2012). However, decadal studies suggest that many shark populations worldwide are experiencing a rapid decline owing to increased fishing efforts (Stevens et al., 2000; Schindler et al., 2002; Myers & Worm, 2005; Ferretti et al., 2008). The fishing of small coastal sharks is thought to be more sustainable than that of their larger, oceanic counterparts owing to a combination of lower fishing pressure, higher fecundity, and faster growth (García, Lucifora & Myers, 2008; Dulvy et al.,

2014). However, fundamental information on the general biology and ecology of small coastal sharks is limited compared to that of the larger charismatic species (Huveneers, Ebert & Dudley, 2015; Troudet et al., 2017). These knowledge gaps are particularly problematic because small sharks are relatively abundant in tropical, multispecies fisheries that lack sustainable management (Cochrane, 2002; Arai & Azri, 2019; Booth et al., 2021; Lim et al., 2021).

A key knowledge gap is an understanding of the coexistence mechanisms of sympatric species which are influenced by several abiotic and biotic processes operating at local scales (Valladares et al., 2015). Resource partitioning is a fundamental biotic process that reduces competition for shared food resources, thus shaping the hierarchical dynamics of species and allowing the coexistence of multiple species in a single habitat (Navia, Mejía-Falla & Giraldo, 2007; Treloar, Laurenson & Stevens, 2007; Ruocco & Lucifora, 2016). This process is mainly influenced by a combination of the hunting abilities of predators and spatiotemporal prey dynamics (Laptikhovsky, Arkhipkin & Henderson, 2001; Dicken et al., 2017; Kousteni, Karachle & Megalofonou, 2017; Sánchez-Hernández, Gabler & Amundsen, 2017). The ability to hunt or forage is partially affected by changes in predator size and the competition between predator species that share similar resources. Spatiotemporal prey dynamics can be observed in dietary variations between sites and time of year, owing to changes in prey species diversity, abundance, and distribution (Devadoss, 1989; Saïdi et al., 2009; Torres-Rojas et al., 2015; Kousteni, Karachle & Megalofonou, 2017). These factors require further examination for poorly studied, small coastal sharks.

Understanding the reproductive dynamics in maintaining healthy populations (Coppock & Dziwenka, 2017) is another key knowledge gap for small coastal sharks. Sharks are generally considered highly susceptible to overfishing because of their life history strategies such as low fecundity, slow growth, and late maturity (García, Lucifora & Myers, 2008; Dulvy et al., 2014). However, sharks are known to exhibit a wide range of reproductive patterns (Conrath & Musick, 2012), and these traits may affect resilience to fishing in varying degrees across different species. A review by Cortés (2000) showed that female sharks, especially viviparous species, tend to mature at larger sizes than males. This maturation schedule may be an adaptation to the greater energy demands of females (Goodwin, Dulvy & Reynolds, 2002), although exceptions have been observed in some small sharks such as *Loxodon macrorhinus* (Gutteridge et al., 2013) and *S. macrorhynchus* (Zhao et al., 2022). Therefore, species-specific studies of reproductive patterns are essential to better evaluate the population health and fishery management of threatened but poorly studied sharks.

The bamboo sharks, *Chiloscyllium hasseltii* (Bleeker, 1852) and *C. punctatum* (Müller & Henle, 1838), and the spadenose sharks, *Scoliodon laticaudus* (Müller & Henle, 1838) and *S. macrorhynchus* (Bleeker, 1852), are small demersal sharks commonly found in the coastal waters of various Southeast Asian countries, including Malaysia (Lim et al., 2021; Lim et al., 2022). *C. punctatum* and both *Scoliodon* species are classified as Near Threatened under the International Union for Conservation of Nature and Natural Resources (IUCN) Red List of Threatened Species, whereas *C. hasseltii* is classified as Endangered (Dudgeon, Bennett & Kyne, 2016; Rigby et al., 2020; VanderWright et al., 2020;

[Dulvy et al., 2021](#)). The IUCN status of *C. punctatum* in Southeast Asia may be uplisted to Vulnerable in the near future owing to high fishing pressure in the region ([Dudgeon, Bennett & Kyne, 2016](#)). In Malaysia, these species are mainly caught by bottom trawlers, collectively making up 10–88% of the total number of sharks landed ([DOFM, 2006](#)). All four species reportedly use similar habitats of sandy, muddy, and rocky substrates at depths of 85 m and up to 50 m for *Chiloscyllium* and *Scoliodon* species, respectively ([Dudgeon, Bennett & Kyne, 2016](#); [Rigby et al., 2020](#); [VanderWright et al., 2020](#); [Dulvy et al., 2021](#)). The two *Scoliodon* species exhibited clear spatial segregation within Malaysian waters ([Lim et al., 2022](#)); however, they were found to co-occur individually with both *Chiloscyllium* species. The feeding ecology and coexistence mechanisms of these sympatric shark species in Malaysian waters remain poorly understood.

Limited dietary studies indicate that the four shark species in this study show some degree of specialization in their feeding. *C. hasseltii* from the east coast of Peninsular Malaysia show a preference for shrimp and fish ([Nur-Farhana et al., 2013](#)), whereas *C. punctatum* from Australia prefer crabs and fish ([Gauthier et al., 2019](#)). However, factors influencing the diet composition of these two *Chiloscyllium* species have not yet been examined. Studies have shown that *S. laticaudus* from Pakistan and India consume fish, crustaceans, and cephalopods; and the prey composition varies temporally and between sexes ([Fofandi, Zala & Koya, 2013](#); [Osmany, Manzoor & Zohra, 2018](#)). The diet of *S. laticaudus* has also been shown to shift ontogenetically from slow-moving crustaceans, mainly prawns, to fast-moving fish ([Devadoss, 1989](#)). To the best of our knowledge, no dietary studies on *S. macrorhynchus* have been conducted.

Existing reproductive studies of small sharks suggest that females mature to larger sizes than males. This is observed for *C. punctatum* from Indonesia ([Fahmi et al., 2021a](#)) and *S. laticaudus* from the west coast of Peninsular Malaysia and India ([Teshima, Ahmad & Mizue, 1978](#); [Devadoss, 1979](#); [Sen et al., 2018](#)), but not for *S. macrorhynchus* in the northern South China Sea ([Zhao et al., 2022](#)). *C. punctatum* ([Fahmi et al., 2021a](#)), *S. laticaudus* ([Sen et al., 2018](#)), and *S. macrorhynchus* ([Zhao et al., 2022](#)) also appear to reproduce actively throughout the year, although different peak seasons were identified. Viviparous *Scoliodon* species show a positive correlation between female size and litter size, and a single female may carry up to 20 embryos in a single gestation period lasting 5–6 months ([Teshima, Ahmad & Mizue, 1978](#); [Devadoss, 1979](#); [Sen et al., 2018](#); [Zhao et al., 2022](#)). To date, there have been no reproductive studies on the four shark species in Malaysian waters, and none are globally available for *C. hasseltii*.

The present study aimed to address these knowledge gaps by examining the diet composition and reproductive biology of these four common small shark species found in Malaysian waters. We were particularly interested in examining the role of body size on diet and reproductive output. Our results focus on the resource-partitioning strategies adopted by these co-occurring demersal sharks. Collectively, these findings provide fundamental information for sustainable fishery management plans for these and other demersal resources.

MATERIALS AND METHODS

Field sampling

All field sampling was approved by the Research Council of Universiti Malaya (um.tnc1/606/stu2015 and um.tnc1/606/stu2016). The collection permits and sampling protocol for specimens from Sabah were approved by the Sabah Biodiversity Council (Access License Reference No: JKM/MBS.1000-2/2 JLD.9 (21–23) and Transfer License Reference No: JKM/MBS. 1000-2/3 JLD.4 (18)). Both *C. hasseltii* and *C. punctatum* were the most abundant species landed by fisheries operating in the waters of both the east and west coasts of Peninsular Malaysia. *S. macrorhynchos* was the most common species caught in Sarawak waters, whereas *S. laticaudus* was ranked third in landings from the west coast of Peninsular Malaysia (DOFM, 2006).

Dead specimens of all four species were sampled during survey trips to major landing sites and markets across Malaysia (Fig. 1) from May 2015 to October 2016. Monthly surveys on the central west coast of Peninsular Malaysia were conducted to characterize temporal changes in reproductive effort. Surveys in other areas were conducted at less regular intervals: two on the east coast of Peninsular Malaysia, three in Sarawak, and one in Sabah. Sharks were mainly caught by trawlers operating beyond 12 nautical miles, except for those sampled from Sarawak which were caught using both inshore gill nets and trawlers. The sharks were transported to the laboratory and frozen until further processing. Additional samples were obtained during research-based demersal trawl surveys of Malaysian South China Sea waters organized by the Department of Fisheries Malaysia (DOFM). Owing to logistic limitations, most of the samples from the demersal trawl surveys were assessed for maturity on-site but were not processed for dietary analysis.

Laboratory analysis

All sharks were measured for total length, sex, and maturity stages. The classification of maturity stages, mature or immature, was based on both the external and internal reproductive organs (Lim, 2016). Mature males displayed elongated and calcified claspers with well-developed testes, showing clear formation of lobes; greater than 50% of the total size of the testes. Mature females had enlarged uteri, which in some cases were bearing eggs or embryos, and ovaries with well-developed ova. Immature sharks of both sexes had thread-like or partially developed gonads in addition to small and soft claspers in males and thin uteri in females. The liver (W_L) and gonads (W_G) were dissected and weighed to the nearest 0.01 g. For gravid females, the number and length of eggs in *Chiloscyllium* species, or the number of embryos and their sex in *Scoliodon* species, was recorded.

Stomachs were dissected from the anterior end (esophagus) to the posterior end (immediately after the pyloric sphincter) and preserved in 70% ethanol prior to fixation in 10% formalin. All prey items were identified to the lowest possible taxa and their numbers were recorded. Volumetric contributions of larger prey items were estimated using the water displacement method (Hyslop, 1980), whereas those of smaller prey items were estimated using gridded 1 ml Sedgewick rafter cells examined under a stereomicroscope.

Data analysis

Diet composition was summarized according to species and maturity using percent volume (%V), percent number (%N), percent frequency of occurrence (%F), and percent Prey-Specific Index of Relative Importance (%PSIRI), as outlined by Brown et al. (2012).

$$\%V = V_i V_t^{-1} \times 100\%$$

$$\%N = N_i N_t^{-1} \times 100\%$$

$$\%F = F_i n^{-1} \times 100\%$$

$$\%PSIRI = 0.5 (\%V + \%N)$$

where V_i is the total volume of the prey item i , V_t is the total volume of all prey items, N_i is the total number of prey items i , N_t is the total number of prey items, F_i is the number of stomachs containing prey item i , and n is the number of stomachs examined.

The %PSIRI was used instead of %IRI because the latter showed undesirable mathematical properties for describing prey diets (Brown et al., 2012). Two indices were used to evaluate the general niche breadth of the shark species: Levin's index (B) and its standardized form (B_A) and the adapted Berger-Parker dominance index (D) (Krebs, 1999; Levins, 1968).

$$B = (\sum p_i^2)^{-1} \text{ and}$$

$$B_A = (B - 1)(N - 1)^{-1},$$

where p_i is the proportion of each prey taxon consumed, and N is the total number of food

categories recognized. The adapted Berger-Parker index, based on %PSIRI, directly refers to the proportion of the most important prey items for each species. The standardized form of Levin's index gives a value between 0 and 1; where values less than 0.6 refer to specialist feeders, whereas values greater than 0.6 refer to generalist feeders (Labropoulou & Eleftheriou, 1997). The adapted Berger-Parker index (D) provides values range from 0.01–1. Values closer to 0.01 indicate generalist feeders, whereas values closer to 1 indicate specialist feeders.

A graphical approach using prey-specific abundance (P_{iN}) or volume (P_{iV}) vs %F was applied to further describe species-specific feeding strategies by combining the five most important prey items of each studied species (Amundsen, Gabler & Staldvik, 1996).

$$P_{iN} = (\sum N_i / \sum N_{ti}) \times 100, \text{ or}$$

$$P_{iV} = (\sum V_i / \sum V_{ti}) \times 100,$$

where N_i or V_i is the number or volume of prey i , and N_{ti} or V_{ti} is the total number or volume of predator stomachs that contained prey i . Prey item position in the vertical axis space represents the feeding strategy, either specialist (prey item position in the top half of the graph) or generalist (prey item position in the bottom half of the graph). Starting from upper right quadrant in a clockwise manner, the four quadrants with the center at 50%F and 50% P_{iN} or P_{iV} represent dominant; high within-phenotype component, commonly found but in low quantity; rare; and high between-phenotype component, rarely found but in high quantity.

Dietary data were randomly pooled for every two to eight individuals using the average for V , N , and F and recalculated for %PSIRI according to species and maturity; subsequently referred to as dietary samples. This pooling strategy was employed to reduce intraspecific variability in diet (Pardo et al., 2015; Platell & Potter, 2001). Similarity matrices for the dietary samples were constructed using the Bray-Curtis dissimilarity coefficient after square root transformation. The matrices were then analyzed using PERMANOVA with an additional Monte Carlo test to compare the variation in diet among species and maturity stages. The results based on the Monte Carlo test were used when the number of unique permutations was less than 20, which was insufficient to make a significant statistical inference (Anderson, 2005). The maturity stages were pooled when there was no significant difference identified in the PERMANOVA test.

Similarity percentage analysis (SIMPER) identified the key prey items responsible for dietary differences among species. Species-specific cumulative prey curves were constructed to determine whether the collected samples sufficiently represented the diet of the species (Cortés, 1997) and were plotted as an average of 999 curves based on random orders of non-empty stomachs examined (Clarke & Gorley, 2006). The number of prey taxa ingested individually (N_{pi}) was compared among species using the Kruskal-Wallis one-way analysis of variance (ANOVA), followed by *post-hoc* pairwise comparisons. To examine ontogenetic diet shifts, linear regression analysis between the volume of the largest prey item found in each stomach (PV_{max}) for both overall and dominant prey taxa

and shark size, as total length, was performed after natural logarithmic transformation (Lim et al., 2019).

The maturity of all the specimens was coded binomially (0 = immature and 1 = mature). The size at first maturity (TL_1) was determined from the smallest mature individuals recorded. The total length at which 50% of the individuals attained maturity (TL_{50}) was derived using logistic regression, according to the method by White, Platell & Potter (2001). The proportion of mature individual, P_{mature} , was calculated using $P_{\text{mature}} = 1/[1 + e^{-(a+bTL)}]$, where a and b are constants. These constants were estimated for each species and sex, using a general linear/nonlinear model module with binomial distribution. TL_{50} was then calculated using the equation $TL_{50} = -a/b$.

Only mature sharks collected from the monthly surveys were used to determine the hepato-somatic index ($HSI = 100 W_L/W_T$) and gonadosomatic index ($GSI = 100 W_G/W_T$). Boxplots of monthly HSI and GSI were generated to observe seasonal variations in liver and gonad size in both males and females. The relationship between the reproductive effort (number of embryos or eggs, length of embryos, or eggs) and female size was determined.

PRIMER v6 (Clarke & Gorley, 2006) was used for SIMPER, PERMANOVA, and cumulative prey curves; and Statistica 8.0 software (StatSoft Inc, 1997) was used for ANOVA, linear, and logistic regressions.

RESULTS

Prey diversity and feeding patterns

The stomach contents of 129 *C. hasseltii*, 137 *C. punctatum*, 145 *S. laticaudus*, and 57 *S. macrorhynchus* were examined. Of these, 44 stomachs were found to be empty (Table 1). The size-frequency distribution of the examined specimens encompassed juveniles, subadults, and adults of wide-ranging sizes and maturity levels (Table S1 and Fig. 2). Forty-five prey taxa including 23 families of teleost fish, 11 crustaceans, five cephalopods, four other invertebrates, 'others', and unknown items were identified (Table 2). The category of 'others' included items that were rarely found and potentially ingested accidentally such as fishing net fragment, cephalopod eggs, stingray spine, and tapeworm; while the 'unknown' category referred to partially digested items that could not be identified. Cumulative prey curves indicated that the sample sizes were sufficient (slope < 0.1) for *C. punctatum* and *S. laticaudus* and approximately sufficient for both *C. hasseltii* (0.12) and *S. macrorhynchus* (0.11) (Fig. S1).

Individual sharks consumed between one and seven types of prey taxa, each with a mean N_{pi} of 2.0 (Table S2). *C. hasseltii* showed the highest mean N_{pi} (2.8), whereas *S. macrorhynchus* showed the lowest mean N_{pi} (1.4). N_{pi} was not normally distributed, and comparisons of N_{pi} among shark species were, therefore, based on a *post-hoc* analysis using the Kruskal-Wallis test (Table S2). *C. hasseltii* had a significantly higher N_{pi} than the other species.

Seven prey taxa were found to contribute more than 10%PSIRI to the diet of at least one shark species (Table 2). These included Actinopterygii (maximum %PSIRI = 17.1), Penaeidae (%PSIRI = 15.6), Caridea (%PSIRI = 10.2), Sergestidae (%PSIRI = 10.8), unknown cephalopod (%PSIRI = 17.9), Teuthida (%PSIRI = 27.0), and Octopoda

Table 1 Total stomachs examined according to species, location and their size range.

Species	Location	Total stomachs	Empty stomachs	Size range (cm)	
				Min	Max
<i>C. hasseltii</i>	WP	128	4	37.8	80.6
	Sarawak	1	0	61.0	61.0

(%PSIRI = 18.8). The sharks primarily consumed teleosts (%PSIRI = 3.7–55.2), shrimp (%PSIRI = 0–53.6), and cephalopods (%PSIRI = 10.1–75.3); supplemented with other invertebrates (%PSIRI = 0–24.3) and crabs (%PSIRI = 0–16.0) (Fig. S2). The contribution of smaller crustaceans, such as hermit crabs, calanoid copepods, and ostracods, was found to be negligible (maximum %PSIRI = 1.4). The diet composition of *C. punctatum* was distinctly different from that of the other species and included larger quantities of

Table 2 Prey-specific index of relative importance (%PSIRI) for each prey taxa according to elasmobranch species (Chas—*C. hasseltii*, Cpun—*C. punctatum*, Slat—*S. laticaudus*, Smac—*S. macrorhynchos*) and their respective niche breadth values.

cephalopods; whereas *C. hasseltii* and *S. laticaudus* consumed higher quantities of teleosts and shrimp, respectively (Fig. S2). Equal diet contributions from teleosts, shrimp, and cephalopods were observed for *S. macrorhynchus*. Significant variations in diet among species were confirmed by the PERMANOVA test on dietary samples (main test Pseudo-F = 10.036, *P*-value < 0.01; *P*-value < 0.01 for all pairwise comparisons).

Among the prey items, SIMPER analysis showed that Teuthida was the most important contributor to diet dissimilarity among the shark species, followed by Actinopterygii and Penaeidae (Table S3). For sub-indices of PSIRI, the main contributor to dissimilarity by volume was Teuthida, followed by Penaeidae and Octopoda/Actinopterygii; the main contributor to dissimilarity by number was unknown cephalopods, followed by Actinopterygii and Sergestidae. Intra- and interspecific variations in diet were considered to be large, based on the low similarity index within (<40%, except *C. punctatum*) and between species (<30%) (Table S4).

Based on standardized Levin's index values (<0.6), all four species were categorized as specialist feeders (Table 2). In contrast, the Berger-Parker index values were closer to 0.1, indicating that all four species exhibited a generalist feeding behavior. The graphical approach using prey-specific abundance or volume indicated generalist feeding for both *C. hasseltii* and *S. laticaudus* but specialist feeding for *C. punctatum* and *S. macrorhynchus* (Fig. S3). Prey specialization in *C. punctatum* was observed for Sergestidae, Stomatopoda, and the cephalopods Teuthida and Octopoda (Fig. S3B). *S. macrorhynchus* specialized in predating on nine prey taxa, including Actinopterygii (unidentified fish), Cynoglossidae, Engraulidae, Penaeidae, Caridea, Sergestidae, Stomatopoda, crabs, and Teuthida (Fig. S3D).

There was no obvious change in the prey items with increasing body size for any shark species (Fig. S2). A strong positive correlation between prey volume and shark size was observed for both *Chiloscyllium* species; however, this correlation was weakly positive for both *Scoliodon* species (Fig. S4). The diet contribution of teleosts, particularly the lizardfish Synodontidae, for *C. hasseltii* increased with body size; whereas that of other invertebrates decreased. For *C. punctatum*, limited changes in prey contributions were observed (Fig. S2). The diet of juveniles included crustaceans Caridea, Sergestidae, and Stomatopoda in their diet; however, these prey taxa were replaced with the addition of Anguilliformes, Leiognathidae, Calappidae, Sepiidae, and Bivalvia in adult stomachs. As *S. laticaudus* matured, an increase in its consumption of crustaceans, especially Sergestidae and Stomatopoda, was observed (Fig. S2). In addition, there was a slight decrease in the consumption of teleosts and cephalopods. This pattern differed from that of *S. macrorhynchus* where a greater reliance on teleost prey and less reliance on shrimp and cephalopods was observed after maturation (Fig. S2).

Reproductive biology

With the exception of a particularly small mature *C. punctatum* male, most species showed a size at first maturity (TL_1) that was relatively similar to the estimated size at 50% maturity (TL_{50}) (Fig. 3). Fitted logistic regression showed that in all species, females matured at smaller sizes than the males (Fig. 3). The estimated TL_{50} for female *C. hasseltii* was 53.9 cm (95% confidence interval (CI) [51.9–56.1 cm]), 61.7 cm (95% CI [59.8–63.8 cm]) for male *C. hasseltii*, 67.4 cm (95% CI [65.2–69.8 cm]) for female *C. punctatum*, 70.5 cm (95% CI [68.7–72.3 cm]) for male *C. punctatum*, 27.4 cm (95% CI [26.8–28.0 cm]) for female *S. laticaudus*, 28.8 cm (95% CI [27.3–29.9 cm]) for male *S. laticaudus*, 25.6 cm (95% CI [27.3–27.3 cm]) for female *S. macrorhynchus*, and 30.1 cm (95% CI [28.6–31.1 cm]) for male *S. macrorhynchus*.

Based on monthly sampling, the adult HSI and GSI for all species fluctuated considerably throughout the year (Fig. S5). The combined ranges of HSI and GSI for the sharks from locations other than the west coast of Peninsular Malaysia were as follows: mean HSI 3.7% (range 3.2–4.2%) and mean GSI 3.8% (range 3.7–3.9%) for female *C. hasseltii*; mean HSI 3.7% (2.4–5.4%) and mean GSI 3.5% (1.6–6.2%) for female *C. punctatum*; mean HSI 4.0% (3.3–5.0%) and mean GSI 0.9% (0.6–1.2%) for male *C. punctatum*; mean HSI 3.5% (1.7–5.3%) and mean GSI 0.5% (0.3–0.8%) for female *S. macrorhynchus*; and mean HSI 3.1% (2.1–4.7%) and mean GSI 1.0% (0.5–1.6%) for male *S. macrorhynchus*. No visible temporal trend was observed for the HSI of the three species and sexes examined, except for male *C. hasseltii* which showed peaks in November 2015 and October 2016. A seasonal cycle of GSI was observed in female *C. hasseltii*, male *C. punctatum*, and female *S. laticaudus*; but not in the opposite sexes of these species.

Based on the 80 gravid female sharks (24 *C. hasseltii*, 10 *C. punctatum*, 27 *S. laticaudus*, and 19 *S. macrorhynchus*), the uterine fecundity was determined as 1–4 egg cases (mean = 2) in *C. hasseltii*, 1–2 egg cases (mean = 2) in *C. punctatum*, 1–12 embryos (mean = 5) in *S. laticaudus*, and 1–14 embryos (mean = 5) in *S. macrorhynchus*. The female to male sex ratio for embryos were 1:0.52 and 1:0.68 for *S. laticaudus* and *S. macrorhynchus*.

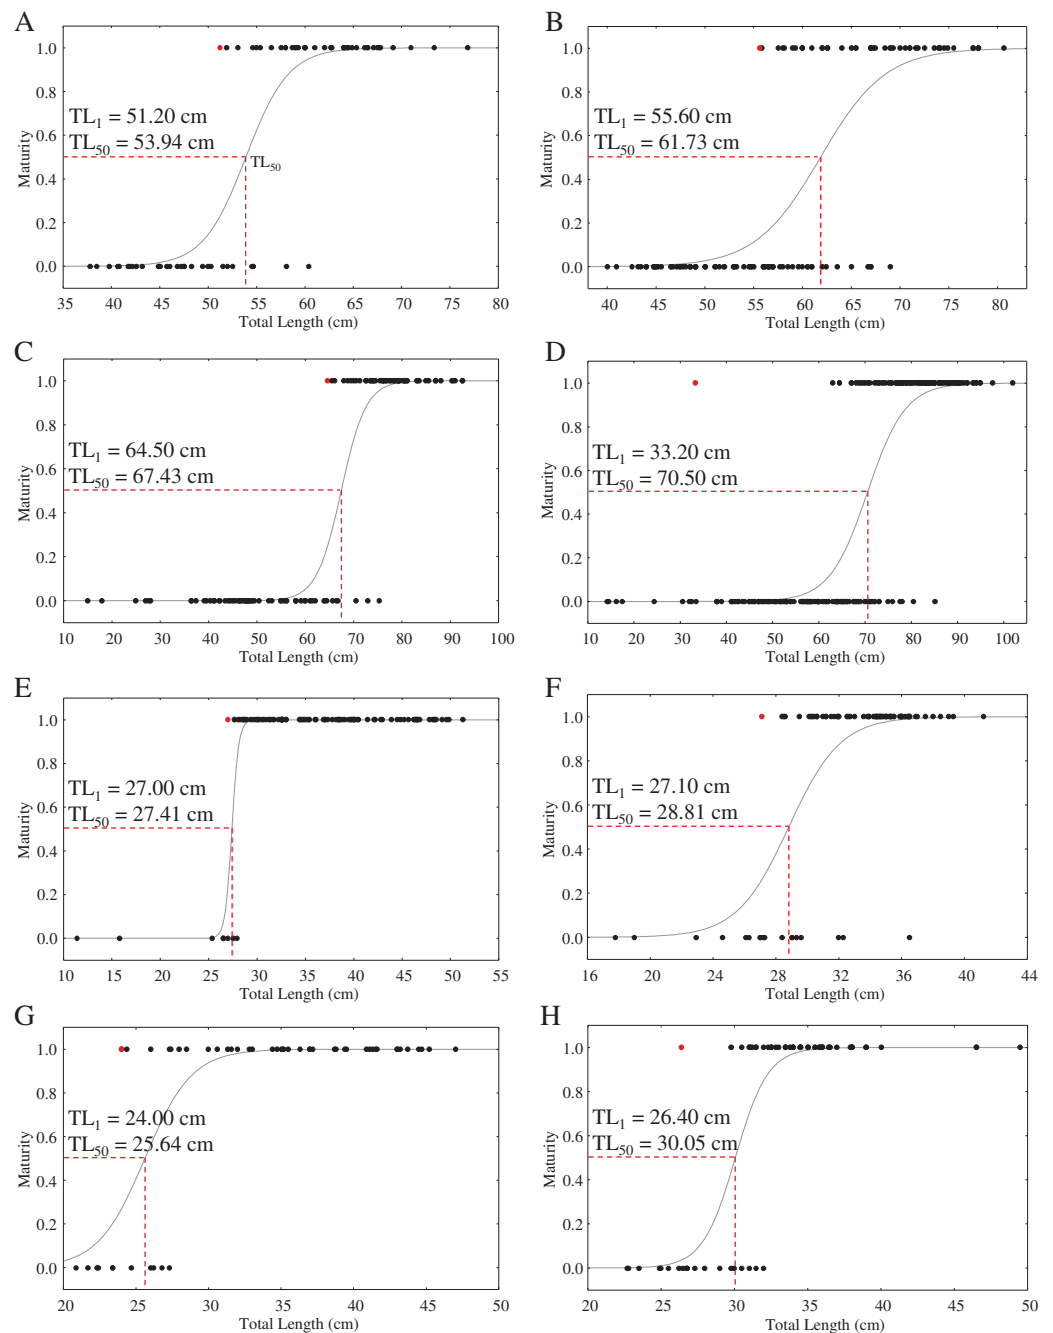

Figure 3 Maturity logistic regression for all sharks according to sex (female—left column, male—right column). (A and B) *C. hasseltii*, (C and D) *C. punctatum*, (E and F) *S. laticaudus*, (G and H) *S. macrorhynchus*. Full-size [DOI: 10.7717/peerj.15849/fig-3](https://doi.org/10.7717/peerj.15849/fig-3)

respectively. The number of eggs or embryos was positively correlated with female size for all species, except for *C. punctatum* (Fig. S6, left column). Egg size positively correlated with female size in *C. hasseltii* (Fig. S6B). In both *Scoliodon* species, large variations in embryo size (TL) were seen within one single adult female *Scoliodon*. This variation ranged from 0–3.0 cm (mean = 0.5 cm) for *S. laticaudus* and 0–6.7 cm (mean = 1.0 cm) for

Figure 4 Observation of either congenital deformity or intrauterine cannibalism in *Scoliodon macrorhynchus*. One underdeveloped embryo with deformed head.

Full-size DOI: 10.7717/peerj.15849/fig-4

S. macrorhynchus. The observation of one headless and underdeveloped embryo, along with three other well-developed embryos, was recorded in one female *S. macrorhynchus*, suggesting either a congenital deformity or intrauterine cannibalism (Fig. 4).

DISCUSSION

Based on data collected across Malaysia, we found clear evidence of resource partitioning among the four co-occurring abundant, small coastal demersal sharks. Ontogenetic shifts in diets were primarily observed in the selection of larger-sized prey rather than in switching to different prey taxa. Females of all the species matured to smaller sizes than males, which is a less common reproductive strategy among sharks. Periodicity during reproduction was not discernible in any of the species. Larger adult *Scoliodon* females with a TL greater than 43 cm were associated with higher numbers of embryos (≥ 8). The possibility of intrauterine cannibalism, which has been reported to occur mainly in larger sharks such as sand tiger sharks, requires further investigation. These findings are one of the first for Malaysia's small shark populations and have implications for fisheries management of these sharks.

Dietary patterns and resource partitioning

All four sharks exhibited generalist feeding patterns and exploited a high diversity of prey taxa, comprising both demersal- and water column-associated species. Among the 20 fish taxa, the benthic lizardfish, Synodontidae, was the most important fish prey; and the pelagic-associated squid, Teuthida, was the most important cephalopod prey in the diets of the four sharks. The types and contributions of consumed prey reflect the diversity in the feeding behaviors of these sharks. This is demonstrated by the large number of demersal organisms in their diets, including eels and polychaetes, which burrow on the seafloor. Sharks are opportunistic feeders, feeding on diverse prey located in close proximity and, thereby, reducing the energy spent and increasing net energy intake (Heller, 1980).

The diversity of prey taxa seen in our study is consistent with previous studies on *S. laticaudus* that showed predation on 16 to 33 prey taxa (Wang et al., 1996; Fofandi, Zala & Koya, 2013; Osmany, Manzoor & Zohra, 2018) and studies on other coastal demersal shark species, such as *C. plagiosum*, *Heterodontus portusjacksoni*, *Mustelus canis*, *M. henlei*, *M. lunulatus*, and *M. mustelus* that showed consumption of 13 to 77 identified prey taxa (Jardas et al., 2007; Navia, Mejía-Falla & Giraldo, 2007; Saidi et al., 2009; Sommerville et al., 2011; Woodland, Secor & Wedge, 2011; Amariles, Navia & Giraldo, 2017; Liu et al., 2020).

Diet composition for a given species differs between locations owing to the variation in both prey and predator species diversity (Heithaus & Vaudo, 2012; Lim et al., 2019). Prey species diversity directly affects prey choice. Our findings showed that fish account for almost half of the diet of *C. hasseltii*, followed by cephalopods. This differs from an earlier dietary study of the same species in Malaysia which found a high proportion of shrimp (Nur-Farhana et al., 2013). We found that *C. punctatum* appeared to prefer cephalopods. This differs from observations of *C. punctatum* in Australia that consume mainly crabs and fish (Gauthier et al., 2019). These spatial differences probably reflect variations in the types of prey available locally. The seasonality of prey availability is another important consideration that could not be examined in our study because of the limited sample size.

Predator species diversity shapes interspecific competition for available food resources. Predators of similar trophic levels may partition themselves by habitat (O'Shea et al., 2013), resources (Navia, Mejía-Falla & Giraldo, 2007; Treloar, Laurenson & Stevens, 2007; Ruocco & Lucifora, 2016), or even feeding times (Cortés, 1997; Bangley & Rulifson, 2017) to avoid the need to directly compete with each other unless resources are abundant (Laptikhovsky, Arkhipkin & Henderson, 2001). Our diet analysis provides evidence of resource partitioning among co-occurring sharks, indicating that available food resources may be limited to a small, shared home range area for these sharks. Reliance on wide-ranging prey taxa allows these small sharks to switch their targets when faced with competition from larger sharks and non-shark predators. Complete prey carcasses, both intact and fragmented, were seen in most of the stomach contents, with no visible signs of body parts being torn apart; suggesting that the sharks did not exhibit food-stealing behavior associated with interference competition (kleptoparasitism) (Heithaus & Vaudo, 2012).

Generalist feeders have a competitive advantage over specialist feeders for thriving in degraded habitats (McKinney & Lockwood, 1999; Layman & Allgeier, 2012). Most shark samples in this study were obtained by bottom trawling, which is highly destructive to bottom habitats and may necessitate the exploitation of multiple food resources, including pelagic ones. A characteristic shared by these four small species is short-distance swimming. For example, *Chiloscyllium* species are inactive swimmers and are commonly found in groups among crevices (Compagno, 2001; Wilga & Lauder, 2004). Niche breadth indices indicated a continuum range of specialist to generalist feeding patterns, suggesting individual specialization of prey taxa within a generalist species, as seen in other predators (Woo et al., 2008; Scholz et al., 2020). Collective evidence using N_{pi} , total prey taxa, B_A , D , and %PSIRI indicated that *C. hasseltii* exhibited the most generalist feeding patterns, followed by *S. laticaudus*, *S. macrorhynchos*, and *C. punctatum*. These dietary patterns are

probably important for ensuring the survival of these sharks in highly degraded environments that experience high fishing pressure (Lim et al., 2021).

Ontogenetic diet shifts are common in sharks (Bornatowski et al., 2014; Dicken et al., 2017; Gračan et al., 2017; Kousteni, Karachle & Megalofonou, 2017; Liu et al., 2020). These shifts with increasing shark size are consistent with the optimum foraging theory owing to increased energy requirements. Additionally, ontogenetic diet shifts also benefit smaller, younger sharks by reducing competition of shared resources, thus increasing overall population survival. Our study showed that the ontogenetic diet shift observed in the four sharks was mediated by the selection of larger-sized, similar prey rather than switching to different prey types. This strategy makes sense energetically for small sharks with a limited swimming range and may be facilitated by enhanced spatial resolving power with increased size, which in turn improves the predatory capability to track larger, more nutrient-rich prey; as seen in *C. punctatum* (Harahush, Hart & Collin, 2014).

Reproductive biology

The size at maturity (TL_{50}) of both *Chiloscyllium* species in Malaysian waters was similar to that reported by Last et al. (2010). Some spatial variation in size at maturity was observed for *C. punctatum*, with females in Malaysian waters having a smaller mature size ($TL_{50} = 67.4$ cm) compared to those from neighboring Indonesia (70.5 cm; Fahmi et al., 2021a). In contrast, male *C. punctatum* in Malaysian waters matured at a larger size ($TL_{50} = 70.5$ cm) than that reported in Indonesia (65.3 cm; Fahmi et al., 2021a). Regional variability in size at maturity, coupled with population genetic structuring (Lim et al., 2021; Fahmi et al., 2021b), supports localized reproductive studies to inform fisheries management at spatially relevant scales.

Sizes at maturity for *S. laticaudus* reported in the present study ($TL_{50} = 27.4$ cm for female, 28.8 cm for males) were smaller than previous records in the same area ($TL_{50} = 32.4$ cm for female, 33 cm for males; Teshima, Ahmad & Mizue (1978)), as well as those in India ($TL_{50} = 35$ cm for female, 33 cm for male; Devadoss (1979), Sen et al. (2018)). The lack of mature size estimates for *S. macrorhynchos* in Sarawak prevented similar comparisons. Compared to *Chiloscyllium* species, the meat of *Scoliodon* species fetches a higher market value, is used in local cuisines (K. C. Lim, A. Y. Then, 2015–2016, personal observations), and is much less likely to be discarded as bycatch. The earlier maturity schedule observed for *S. laticaudus* compared to previous studies probably reflects the high fishing pressure on sharks in the Malacca Strait waters. A reduction in the maturity size of exploited species is a common response to heavy fishing pressure (Stergiou, 2002; Stevens et al., 2000).

A meta-analysis reviewing reproductive strategies in sharks highlighted that females tend to mature at larger sizes than their male counterparts to improve the survival of the young through better nutrient support in their early development (Cortés, 2000). However, our study found the opposite pattern in all four shark species. This pattern is a strategy commonly adopted by small carcharhinids to maximize their lifetime reproductive output while coping with higher natural mortality rates than their larger counterparts (Gutteridge et al., 2013). Given the high fishing pressure experienced by demersal resources in

Malaysia, including sharks; early female maturation may be a population-level response to high natural and fishing mortality rates (Azri & Arai, 2015; Arai & Azri, 2019).

We did not find clear seasonality in the reproductive cycles of any of the four sharks. The high variability in the monthly HSI and GSI data indicates that sharks are in various reproductive stages over time. Both gravid and non-gravid females were found in each sampling trip, and embryos of various sizes were detected each month (1.2–11.2 cm for *S. laticaudus* and 2.2–12.8 cm for *S. macrorhynchus*). The continuous breeding of these sharks is consistent with that of other species from tropical regions (White, 2007; Fahmi et al., 2021a). Without clear seasonality in the reproductive cycle, the gestation period of sharks could not be estimated. No near-term embryos were recorded in this study. This raises the concern of capture-induced parturition, such as premature birth or abortion, (Adams et al., 2018) and further studies using different sampling methodologies will be important to ascertain whether this is a problem for the *Scoliodon* species.

The uterine fecundity of these species was similar to the results of previous studies (Harahush, Fischer & Collin, 2007; Sen et al., 2018; Fahmi et al., 2021a; Zhao et al., 2022) and was higher for the viviparous *Scoliodon* species than for the oviparous *Chiloscyllium* species. According to Harahush, Fischer & Collin (2007) and Chen & Liu (2006), *Chiloscyllium* species lay one to two eggs every four to ten days. Considering the high reproductive frequency, a lower number of eggs per reproductive session allows for higher nutrient reserves for embryonic development. In contrast, *Scoliodon* species give birth to one to 20 embryos after 6 months (Sen et al., 2018; Zhao et al., 2022). This higher uterine fecundity is probably required to compensate for the relatively long gestation period. A positive correlation between fecundity and female size is common among sharks, mainly because of the increase in uterine space in larger individuals or species (Parsons et al., 2008). An exception to this can be seen in species such as the sand tiger shark, *Carcharias taurus*, which shows extreme uterine cannibalism such as adelphophagy or sibling eating. No previous study has documented uterine cannibalism in *Scoliodon* species, and our study suggests the possibility of this occurring in *S. macrorhynchus*. Although additional samples, especially those with near-term embryos, are necessary to verify this, we hypothesize that uterine cannibalism in *S. macrorhynchus* is associated with higher numbers of embryos and greater variability in their size, in the larger females.

Limitations and future studies

The limited temporal sampling of dietary data in this study prevented the clarification of seasonality in shark prey consumption. Stomach content analysis alone provides a snapshot of individual diets but may not reflect what is being assimilated over a longer period of time. Stable isotope analysis of muscle tissue can provide additional insights into spatiotemporal patterns and ontogenetic shifts in the diet of these sharks (Rosende-Pereiro et al., 2020). Our sampling approach, through visits to fish landing sites and adjacent markets, limited the size range of sharks encountered to larger juvenile and adult individuals. Informal conversations with local fishing operators found that unmarketable bycatch may include smaller shark individuals that are usually discarded or sent directly to fish feed processing factories. Investigation of the diet of smaller-sized juveniles will

provide clarity on diet preference during early life stages and any ontogenetic diet shifts. Future studies should also include sampling of the diversity and abundance of candidate prey to elucidate the role of prey selectivity in the shark diets.

CONCLUSIONS

The four dominant small demersal shark species in Malaysian waters, *C. hasseltii*, *C. punctatum*, *S. laticaudus*, and *S. macrorhynchus*, exploit diverse prey taxa that occupy both demersal and pelagic environments but also exhibit clear resource partitioning in their diets. This reflects the possible limitations of available food resources within their small home ranges. The generalist feeding strategy employed reduces intra- and interspecific competition, thus conferring ecological resilience to these species that use degraded bottom habitats. The females of these small sharks, especially *Scoliodon* species, appear to mature earlier than in the previously observed. This reproductive strategy appears to be a response to high fishing pressure, but may be detrimental to long-term population survival owing to increased vulnerability to predation with smaller birth sizes (Cortés, 2000). Given the limitations of both the home range and dispersal abilities of these small coastal sharks; an overall reduction in fishing pressure, especially from bottom trawlers, is important to ensure their sustainability and that of other demersal resources.

ACKNOWLEDGEMENTS

We are grateful to the Department of Fisheries Malaysia and Fisheries Research Institute (FRI) Bintawa, Sarawak for the opportunity to participate in the fisheries-independent demersal trawl survey within the Malaysian Exclusive Economic Zone (EEZ). The comments from three reviewers greatly improved this manuscript.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

This work was supported by the Universiti Malaya Research Grant (UMRG) (No. RP018C-16SUS), the Universiti Malaya research fund assistance (BKP) (No. BK018-2015) and the IOES-DOF trawl survey project (No. J55018-73705). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.
