Background: Aquatic plants play a crucial role in nature-based wastewater treatment and provide a promising substrate for renewable energy production from anaerobic digestion. The study describes the potential of using water lettuce to reduce pollutants from husbandry anaerobic digester effluent and feed back to the biogas digester.

Methods: The first experiment was piloted using styrofoam boxes containing husbandry anaerobic digester effluent. Water lettuces were arranged by 50%, 25%, and 12.5% surface coverage. Each treatment was conducted in 5 replicates through natural conditions. In the second experiment, WL was fed into an existing continuous anaerobic digester to examine biogas production on a farm scale.

Results: The effluent treatment efficiency of TSS, BOD₅, COD, TKN, and TP was 93.75 - 98.44%, 79.65 - 85%, 79.6 - 83.62%, 64.5 - 68.25%, and 91.07 - 91.93%, respectively. The doubling time of water lettuce was estimated at around 12 days for all treatments. For the second experiment, the biogas yield varied between 190.6 and 333.3 L.kg VS⁻¹. The CH₄ content reached over 54%.

Conclusions: Water lettuce offered better management in effluent recirculation through a plant-based pollutant removal system and produced biomass for biomethanation.

Water lettuce (Pistia stratiotes L.) increases biogas effluent pollutant removal efficacy and proves a positive substrate for renewable energy production

Abstract

Background: Aquatic plants play a crucial role in nature-based wastewater treatment and provide a promising substrate for renewable energy production using anaerobic digestion (AD) technology. This study aimed to examine the contaminant removal from AD effluent by water lettuce (WL) and the biogas production from WL biomass co-digested with pig dung (PD) in a farm-scale biogas digester.

Methods: The first experiment used styrofoam boxes containing husbandry AD effluent. WLs were initially arranged in 50%, 25%, 12.5%, and 0% surface coverage. Each treatment was conducted in five replicates under natural conditions. In the second experiment, WL biomass was co-digested with PD into an existing anaerobic digester to examine biogas production on a farm scale.

Results: Over 30 days, the treatment efficiency of TSS, BOD₅, COD, TKN, and TP in the effluent was 93.75%–97.66%, 76.63%–82.56%, 76.78%–82.89%, 61.75%–63.75%, and 89.00%–89.57%, respectively. Higher WL coverage increased the pollutant elimination potential. The WL biomass doubled after 12 days for all treatments. In the farm-scale biogas production, the biogas yield varied between 190.6 and 292.9 L kg VS_{added}⁻¹. The methane content reached over 54%.

Conclusions: WL removed AD effluent nutrients effectively through a phytoremediation system and generated significant biomass for renewable energy production in a farm-scale model.

Introduction

Agricultural production is the main economic activity in the Vietnamese Mekong Delta (VMD), of which livestock production constitutes more than 20% (GSO, 2021). Within this sector, pig livestock dominates in most local areas. It is estimated that the VMD has 2.08 million pigs (GSO, 2022). Mostly, pig farms temporarily raise livestock on a small scale (< 10 pigs) without suitable waste treatment measures (Nam *et al.*, 2021). Therefore, waste management from pig raising is a significant challenge owing to the considerable amount of pig excrement directly released to the external environment (Ngan, 2012; Nam *et al.*, 2022). Environmental issues have emerged seriously in rural areas, where local communities use surface water sources from rivers/canals as the primary water supply source for agriculture production and domestic utilization (Roubik *et al.*, 2018; Kanya *et al.*, 2022). Consequently, sustainable livestock production requires responsible waste management to minimize negative influences on the surrounding environment and ecosystems.

Anaerobic digestion (AD) is an effective technology for treating biodegradable waste and producing eco-friendly energy (Markphan *et al.*, 2020; Ye *et al.*, 2013; Szaja *et al.*, 2020; Wang *et al.*, 2022). In the 1990s, this technology was introduced in the VMD to treat animal waste and recapture biogas for cooking and heating (Ngan *et al.*, 2012). However, the scale of raising livestock of the VMD's households is modest, leading to a shortage of feedstock substrate for producing biogas (Nam *et al.*, 2022). Accordingly, substitute or additional feedstocks, such as rice straw, water hyacinth, and potential biomass, are encouraged for use as co-substrates for biogas digesters to achieve higher biogas yields (Nam *et al.*, 2023). The co-digestion of animal waste and biomass provides a more flexible digestion process in small livestock household digesters. This approach potentially enhances biogas production by adjusting the carbon/nitrogen (C/N) ratio to a more favorable range for anaerobic biodegradation regression (Nam *et al.*, 2021; Yadvika *et al.*, 2004).

Although biogas production is offered not only for livestock waste treatment but also for renewable energy production, the AD process shows limitations in waste treatment efficiency and outlet

effluent quality when solely substrate is applied. The AD effluent quality regularly does not meet the national technical regulations on husbandry wastewater (QCVN 62-MT:2016/BTNMT) before it is released into the exterior environment (MoNRE, 2016). It is commonly accepted that treatment efficacy from AD is about 30% of the organic matter, while the rest remains as digestate and sludge (Gurung, 1997). Consequently, AD effluent contains much more indigestible matter and high concentrations of identified nutrients, such as nitrogen, phosphorous, and potassium (Ngan, 2012; Le, 2008, Abe *et al.*, 2016; Wang *et al.*, 2018; Kalaimurugan *et al.*, 2022). As such, reutilizing nutrients from wastewater or AD effluent to grow aquatic plants is a promising option for bioremediation because it is cheap and eco-friendly (Nor *et al.*, 2023).

In the rural areas of the VMD, households typically own a large plot of land to develop a traditional farming system known as VAC (V - garden, A - pond, and C - livestock cage) or VACB (V - garden, A - pond, C - livestock cage, and B - biogas plant) (Ngan, 2011). The pond is commonly used as a buffer unit for receiving AD effluent before discharging it into the external environment. Ordinarily, several types of aquatic plants, such as water lettuce (*Pistia stratiotes*), water hyacinth (*Eichhornia crassipes*), and duckweed (*Lemna minor*), are grown on the pond to eliminate onsite AD effluent nutrients. These plants are identified as invasive plants that are grown popularly in the tropical conditions of the VMD (Coelho *et al.*, 2005; Šajna *et al.*, 2007). In addition, these plants are known for their efficient nutrient-absorbing ability, metal and toxic elimination, and biogenic element accumulation (Lu *et al.*, 2010; Brix, 1991). Aquatic plant biomass could be valuable for promoting renewable energy production through AD technology (Barua *et al.*, 2018; Nam *et al.*, 2021).

Although water hyacinth is a good candidate for nutrient removal and biomass harvest, its high content of hemicellulose (30.8%–48.0%) slows biogas production, resulting in overloading in a long-term operation (Nam *et al.*, 2023; Lin *et al.*, 2015; Bote *et al.*, 2020). The possibility of duckweed biomass production is slight, albeit with high biomethanation potential, resulting in an inadequate substrate for household-scale biogas production. In contrast, water lettuce (WL) has demonstrated its effectiveness for domestic wastewater contaminant removal of BOD, NH₃, TN, and TP by 83.5%–97.53% in a 5-day treatment (Gaballah *et al.*, 2019). The rapid elimination of nutrients in wastewater can reduce the risk of water body eutrophication. Moreover, WL has great biomass production potential due to its fast-growing nature. WL's biomass production is about 2.4 tons of dry biomass per hectare per year, indicating stable substrate-providing feasibility for biogas production (Sutaryo *et al.*, 2022). This plant can also grow in various environments, including clean water and wastewater, signifying its adaptability for AD effluent nutrients in varying amounts (Whangchai *et al.*, 2021). WL's chemical composition is 34.4% cellulose, 11.6% lignin, and 26.3% hemicellulose, which is promising for renewable energy production from biodegradation compared to other agricultural terrestrial plants (Güngören Madenoğlu *et al.*, 2019). Previous studies have demonstrated the concordance of biogas production from WL exclusively and from co-digestion with cow dung and waste sludge (Cong *et al.*, 2022; Sutaryo *et al.*, 2022; Güngören Madenoğlu *et al.*, 2019). Biogas yields of WL range from 533–707 L kg VS⁻¹ (Güngören Madenoğlu *et al.*, 2019), while the potential of biogas production from water hyacinth

and duckweed varies from 102 L kg VS_{added}⁻¹ to 478 L kg VS_{added}⁻¹ (Nam *et al.*, 2017; Patil *et al.*, 2014; Gunnarsson & Petersen, 2007) and from 250 L kg VS_{added}⁻¹ to 390 L kg VS_{added}⁻¹, respectively (Tonon *et al.*, 2017). As such, WL is promising for contaminant removal, as well as its availability and sustainable use for biogas production at a farm scale. Although WL's potential has been identified, the effectiveness of removing contaminants in AD effluent and biogas production from co-digestion of WL with pig manure at the household scale has remained unclear. This study, therefore, aimed to (i) examine the contaminant removal of WL applied to AD effluent and (ii) investigate the biogas production potential of WL co-digested with pig manure in a farm-scale biogas digester.

Materials & methods

Study site

All the experiments were implemented in a farmer household in Thanh My village (9°59'24.44", 105°47'43.57"), Cai Rang district, Can Tho city, Vietnam. The household had raised pigs for a long time and owned a 2-year-old HDPE (high density polyethylene) biogas tube plant of 7.64 m³ (Fig. 1), but only one pig of 40 kg was being raised in the pigsty at the study implementation time. The field experiments were approved by the College of Environment and Nature Resources, Can Tho University (ID 101/KMT).

Experimental design

Experiment 1: water lettuce phytoremediation performance

The WL was collected from the pond adjacent to the experiment site. The plants chosen were from 4–6 cm in length, and each plant had from 5 to 7 leaves at the initiation. We removed all the bad parts from the plants and rinsed them with tap water to eliminate any debris of other macrophytes. Then, the WL was placed into a plastic barrel filled with husbandry anaerobic digester effluent (HADE) for one week, allowing it to adapt to its environmental conditions. The experiment was designed in a batch system using styrofoam boxes (60 cm long × 45 cm wide × 41 cm high). Each box contained 30 L of HADE, which was not added to during the experiment. The WL was placed into boxes for different treatments by the plants arranged in 50%, 25%, and 12.5% of the box's surface area. In parallel, a control treatment (0%) was set up without WL. Each treatment was replicated in five boxes. Accordingly, a total of 20 boxes were prepared. All the experimental boxes were randomly arranged on a scaffold under natural conditions. A plastic film was set up to cover the experiment boxes if it rained. The experiment ended in 30 days. The pollution elimination percentage was calculated as shown in the basic equation (1):

$$\text{Removal efficiency (\%)} = \frac{C_i - C_e}{C_i} \times 100 \quad (1)$$

in which C_i is the initial concentration of pollutants and C_e is the final concentration of pollutants remaining in the effluent.

The HADE was collected from the existing PE biogas plant at the experiment site and installed in the boxes without any dilution. The HADE was examined before the initial experiment and after the phytoremediation tests at 6, 12, 18, 24, and 30 days. The water samples were collected as mixed

samples from each treatment to achieve a pooled sample. The physicochemical parameters of pH, TSS, BOD₅, COD, total Kjeldahl nitrogen (TKN), and total coliforms were chosen as required by the QCVN 62-MT:2016/BTNMT National Technical Regulation on Livestock Effluent. The collected HADE samples were analyzed according to the Standard Methods for the Examination of Water and Wastewater (APHA, 1998).

The growing ability of the WL was recorded before and after the phytoremediation process every 5 days for the 30 days of the experiment. The plants' fresh weight was determined using a digital balance to weigh all the plants within each box. The root length and leaf length were measured by randomly choosing three plants from each box and recording the average value of the three maximum values of the root and leaf (Fig. 2).

Experiment 2: anaerobic digestion performance

WL from the nearby pond was collected and fed into the existing PE biogas plant as supplementary material. After each collection time, the WL was dried within a day in shady conditions to avoid nutrient loss, and it was then fed into the biogas digester. The quantity of WL co-fed every 2 days into the PE biogas plant was 10 kg wet weight within the first 10 days, 40 kg wet weight in the next 30 days, and 24 kg wet weight in the last 20 days. At the start, the volatile solids (VS) content of the WL was determined by drying a sample of the biomass at 105°C for 24 hours and then heating it at 550°C for 2 hours. The VS value was then calculated based on the weight of the dried sample.

The daily produced biogas was recorded onsite by a VIGADO G1.6 gas meter (PDM 095-2008, Vietnam). For the gas components, biogas samples were collected in an aluminum bag after feeding the WL every 4 days for 60 days. The gas samples were transported to the biogas laboratory at Can Tho University and analyzed using a portable biogas analyzer (Biogas Pro 5000, Landtec, USA) for the biogas components, including CH₄, CO₂, and other compositions (Fig. 3).

Data processing

The data were plotted using the RStudio software package (R Foundation for Statistical Computing, R version 4.1.3 for Windows). The Pearson correlation coefficient was employed to assess the correlation between the HADE pollutant variables (TSS, BOD₅, COD, TKN, and TP) and the WL biomass (leaf length, root length, and fresh weight biomass). The correlation significance is indicated as follows: * represents 0.05 < P < 0.01, ** represents 0.01 < P < 0.001, and *** represents P < 0.001.

Results and discussion

Initial HADE characteristics

The HADE collected initially and used for the phytoremediation experiment had a high organic concentration compared to the National Technical Regulation on Livestock Effluent (Table 1). Compared to a previous study on the effluent of similar PE biogas plants operated in the VMD (Ngan, 2012), the tested values were lower, as only one pig was being raised at the time of the study. This HADE concentration is well suited for the WL phytoremediation process. Thus, the collected HADE was initially applied to set up the experiment without dilution. Within the study period, the daily ambient temperatures (recorded randomly between 08:00 and 16:00) at the

experiment site ranged from 27.3°C to 30.7°C (Fig. 4). The variation was appropriate for the optimum temperature (22°C–30°C) for growing WL (Pettet & Pettet, 1970). The water levels in the experimental boxes were also recorded to ensure the growing conditions for the WL. At the beginning, all the experimental boxes were filled with a water level of 21 cm. At the end of the experiment time, the water levels were 14.54 cm, 15.54 cm, 15.52 cm, and 16.40 cm for the WL surface cover of 50%, 25%, 12.5%, and 0%, respectively. Thus, the water loss was estimated at 0.93 cm day⁻¹, 0.82 cm day⁻¹, 0.81 cm day⁻¹, and 0.72 cm.day⁻¹ under 50%, 25%, 12.5%, and 0% WL surface cover (Fig. 5).

Phytoremediation process experiment

Pollution removal

Figure 6a shows the phytoremediation performance of the HADE using WL every 6 days for 30 days. The pH levels slightly decreased during the phytoremediation process for all treatments. Although the treatment with 12.5% surface cover showed the largest change in pH values between days 12 and 18, the difference in pH across all treatments was negligible.

The concentration of contaminants (TSS, BOD₅, COD, TKN, and TP) rapidly reduced in the first 6 days of running the experiment (Fig. 6b–f). There was a slight decrease for the rest of the period. The higher coverages of WL displayed better treatment efficacy of HADE. All the WL treatments demonstrated a higher potential for pollutant elimination than the control treatment (0%) (Fig. 6). Figure 7 shows the pollutant treatment efficiency of WL in the effluent from the digester. In the first 6 days, there was a sharp decrease in the treatment efficiencies of the WL on the HADE, but then a slight decrease between days 6 and 30 was shown. The TSS removal efficiency in the first 6 days of TSS was highest at 80.47%–94.53% (Fig. 7a), followed by TP (68.36%–82.86%, Fig. 7e), BOD₅ (44.19%–59.30%, Fig. 7b), COD (44.3%–59.73%, Fig. 7c), and TKN (38.25%–46.75%, Fig. 7d). After 30 days, the reduction efficiency of TSS and TP did not continuously increase much compared to the first 6 days, while the treatment efficiencies of BOD₅, COD, and TKN rose much higher than during the first 6 days (Fig. 7).

Recent studies have confirmed high treatment efficiency on BOD₅ (83.3%–92.8%) and COD (79.2%–85.9%) when the phytotreatment of polluted river water, palm oil mill wastewater, and sewage wastewater using macrophytes was applied (Shahid *et al.*, 2019; Wei, 2019; Schwantes *et al.*, 2019). However, other research has reported lower removal efficiencies of phytotreatment. Jyotsna *et al.* (2015) confirmed removal efficiencies of 44.8% of TSS, 62.4% of BOD₅, and 63.8% of COD for pulp and paper mill effluent after 30 days by lesser duckweed. Tang *et al.* (2009) recorded reduction efficiencies of 33.2% of COD and 21.8% of TKN for wetland constructed to treat eutrophic river water. However, the organic concentrations in the pulp and paper mill effluent and eutrophic river water were much higher than in this study. Treatment effectiveness can vary depending on various factors, such as the initial pollutant levels, the duration of treatment, and the specific conditions of the treatment environment.

In our study, the removal efficiency of COD was slightly lower than that of BOD₅, which is similar to the study by Hamzah *et al.* (2016) of phytoremediation testing on palm oil mill final discharge wastewater (84.7% of BOD₅ and 22.3% of COD). In fact, recalcitrant compounds, such as high

humic acid in pig dung (PD), are known to cause low treatment efficiency of COD of the phytoremediation (Norulaini, 2001; Zhang *et al.*, 2012).

High removal efficiencies of over 89% of TP were recorded for all the WL treatment coverages after 30 days. The utility of phosphorus in aquatic plants is essential in various physicochemical and biological processes. In addition, values from 61.8% to 65.0% were the reduction efficiencies of TKN after 30 days of phytoremediation. In a similar approach using swine wastewater, Sudiarto *et al.* (2019) documented that TKN and TP removals within 21 days were 71.4% and 32.2%, respectively. Similarly, Parwin and Paul (2019) reported the highest removal efficiencies of 94.4% of TKN and 98.1% of TP using water hyacinth to treat kitchen wastewater within 4 weeks. In contrast, the lowest reduction efficiencies of BOD₅, COD, and TKN using water caltrop to treat municipal wastewater have been recorded as 18.3%, 14.2%, and 27.2%, respectively (Kumar & Chopra, 2018).

Water lettuce biomass

Previous findings disclosed that the biomass of WL increased up to the first 10 days and then diminished as the basal leaves decayed (Fonkou *et al.*, 2002) or due to their maximum uptake limit of nutrients (Hamzah *et al.*, 2016). Our study showed that the biomass gradually increased through the experiment period (Fig. 8). The difference compared to the previous report was due to the required space for the growth of WL. Based on the produced WL, the doubling time for the wet-weight biomass from the treatments of 50%, 25%, and 12.5% surface coverage were estimated at 12.32 days, 12.11 days, and 12.28 days, respectively (Table 2). The rapid increase in WL's biomass indicates its potential for eliminating pollutants and providing valuable material for biogas production.

Fig. 9a shows that the root lengths of the WL increased over time. Root lengths were recorded from 6.66 cm to 8.08 cm (an increase of 21.3%), 6.52 cm to 8.06 cm (an increase of 23.6%), and 6.16 cm to 8.04 cm (an increase of 30.5%) after 30 cultivated days for the treatments of 50%, 25%, and 12.5% surface coverage, respectively. The maximum leaf length of growth recorded in the treatment of a surface cover of 12.5% WL show that with fewer bodies (Fig. 9b). The nutrients were absorbed and formed up to the root system instead of the leaves. During the first 15 days, the length of the WL's leaves increased in all treatments but then decreased as a result of the decay of the lower leaves and the emergence of new leaves. Consequently, a high amount of biomass was recorded as the WL continuously grew in the experimental containers.

Figure 10 depicts the Pearson correlation of the pollutant parameters in the HADE among the treatments, as indicated by the color and size of the circles. The magnitude of the correlation is reflected by these visual cues. A strong positive relationship was found between pollutant concentrations, with *r* values ranging from 0.8 to 1.0. The BOD₅ and COD displayed the highest correlation. The Pearson correlation revealed adequate interdependence between the pollutant composition and the prospect of WL to effectively eliminate pollutant levels in the HADE. Similarly, leaf length and root length showed a moderate correlation (*r* = 0.53), while root length and fresh biomass exhibited a high correlation (*r* = 0.85) (Fig. 11). No relationship was found between leaf length and fresh biomass. As such, the root length played a crucial role in increasing

the WL's biomass. Macrophyte roots are vital for reducing contaminants in the aboveground part of their bodies. Moreover, macrophytes also secrete biopolymer from their roots, which assist in flocculation (Sharma, Singh, & Manchanda, 2015). Non-settling and colloidal particles are also removed, at least partially, by bacterial growth, which results in the removal of some colloidal solids and the microbial decay of other organic pollutants.

Biogas production from water lettuce biomass

The biogas produced from the HDPE digester is shown in Fig. 12. The analyzed WL result showed that the VS value was 4.9%, which was higher than the VS value reported by Abbasi & Nipanay (1991). For a co-substrate of WL and PD, feeding the material to the HDPE digester every 2 days is recommended (Ngan *et al.*, 2018). In the current study, 10 kg of WL (approximately 0.49 kg of VS) was fed every 2 days for the first 10 days, allowing microorganisms to adjust slowly to the new feed. Afterwards, 40 kg of WL (about 1.96 kg of VS) was fed every 2 days for the next 30 days, and 24 kg of WL (equivalent to 1.18 kg of VS) was fed each time during the final 20 days. The loading rates of WL were low compared to those suggested by Eder & Schulz (2007) for the AD process, but PD was also fed into the biogas plant.

On the first day of the WL feeding, 365 L day⁻¹ of biogas production was recorded, which was transformed solely from the PD. On day 2, the produced biogas was slightly reduced (321 L day⁻¹), announcing a small "shock" within the fermentation process. From days 3 to 10, biogas production increased and ranged from 266 L day⁻¹ to 597 L day⁻¹ (411.7 ± 104.4 L day⁻¹ on average). The biogas production volume increase due to the WL addition was estimated to be 46.7 L day⁻¹. This amount is equivalent to a biogas yield of 190.6 L kg VS_{added}⁻¹.

During the second period, biogas production decreased after increasing the feeding amount, as the microorganisms required some time to adjust to the large feedstock. The results show that a large variation in biogas production was recorded from 234 L day⁻¹ (day 14) to 1280 L day⁻¹ (day 32). Several peaks in biogas production appeared during the period. The average volume of biogas produced in this period was 676.2 ± 293.4 L day⁻¹. One pig was being raised in the pigsty at that time. We assumed that the amount of PD increased by 5% compared to the first period due to the pig's increasing weight. It is estimated that an amount [365 + (365 × 5%)] = 383.3 L day⁻¹ of biogas was produced solely from the PD in the second period. Therefore, the biogas production volume increased due to the WL contribution by around 292.9 L day⁻¹. As such, the biogas yields for the period were estimated at 292.9 L kg VS_{added}⁻¹.

During the third period, biogas production gradually decreased compared to the second period. The maximum and minimum biogas productions were recorded on days 46 (1039 L day⁻¹) and 57 (260 L day⁻¹). The average biogas production in this period was 518.6 ± 224.1 L day⁻¹. If the amount of PD increased by 10% due to the growth of the pig, it is estimated that the biogas produced solely from the PD would amount to 401.5 L day⁻¹ in the second period, calculated as [365 + (365 × 10%)] = 401.5 L day⁻¹. Consequently, the average biogas volume produced from the WL was estimated to be approximately 117.1 L day⁻¹. This resulted in an estimated biogas yield of 198.5 L kg VS_{added}⁻¹.

The biogas yields increased gradually as the feeding material from the WL increased, demonstrating WL's potential for renewable energy production. However, changes in the feeding amount can result in temporary disruptions, as microbes need time to break down the organic matter and nutrients in WL and convert them into biogas. It is worth noting that only a portion of the WL fed into the digester during the first 10 days was converted into biogas. In the next 30 days, the remaining WL from the previous period combined with the new feeding was digested, increasing biogas production in the second and third periods.

As shown in Fig. 12, the cumulative biogas production exhibits sigmoid growth curves, as described above. In the first phase, the curve showed a slow increase (lag phase) at the start of the co-feeding with WL. The second and third periods showed a rapid increase that approached exponential growth (log phase) due to the significant amount of WL added to the digester.

In this study, the biogas yields from WL fermentation ranged from 190.6 L.kg VS⁻¹ to 292.9 L.kg VS⁻¹, comparable to previous reports involving the co-digestion of WL and cow manure and digestion of solely WL substrate (Phuong *et al.*, 2015; Cong *et al.*, 2022). It should be mentioned that these previous experiments were implemented in a lab-scale batch anaerobic digester with strict control over operating parameters, while this study was carried out in a farm-scale digester. Despite the differences in scale, this study demonstrated that WL is a promising material for biogas production.

Biogas composition

Figure 13 shows the change in biogas composition over time. The biogas composition recorded on the first day was 55.3% CH₄ and 30.5% CO₂. During the experiment, the CH₄ content varied from 54.1% to 59.9% and the CO₂ content varied from 21.9% to 31.7%. Nam *et al.* (2015) reported 47.7%–56.6% and 46.5%–54.4% methane content for onsite experiments of co-digestion of rice straw and water hyacinth, respectively, with PD using PE biogas plants in the VMD. Another study on co-digestion of cow dung and WL found CH₄ content from 50.6% to 54.8% after 2 weeks of fermentation (Phuong *et al.*, 2015), while Cong *et al.* (2022) discovered that solely digesting WL produced the highest concentration of methane by 62.2% on day 35. This study noted a high methane content from the start of the experiment, as the HDPE plant had been in operation for two years and was being fed with PD. The biogas could be applied to energy consumption due to its high methane content, particularly for household cooking in the VMD.

Feasibility of farm-scale biogas production and AD effluent removal systems

Biogas production can be considered a renewable energy source in most localities. Unlike other renewable energy sources, such as solar and wind power, biogas energy sources are used directly by households. Accordingly, biogas plants are more appropriate for decentralized energy production areas in the VMD. It is notable that bio-gasification from AD depends on several factors, such as carbon/nitrogen (C/N), hemicellulose content, pH, and the buffering capacity of the substrate (Güngören Madenoğlu *et al.*, 2019). In farm-scale experimentation, WL showed great biogas production potential for co-digestion with PD. CH₄ concentration was achieved by more than 50% after 2 weeks, implying conformity for household cooking and heating (Ngan *et al.*, 2020).

Under these circumstances, WL source availability is the main challenge in expanding the system for households. In the VMD, many household farms have sufficient land area to install biogas, as well as a pond for growing WL combined with aquacultural activities. WL can be grown on a pond with a nutrient source provided by the livestock biogas plant. The contaminant-eliminating productivity of WL was reliable throughout the current study. Nutrient removal by WL involves not only eutrophication reduction of surrounding water bodies, but also significant biomass production for renewable energy generation. WL biomass can be used to feed the biogas plant directly or applied as simple bio-pretreatment technologies (soaking in biogas effluent or anoxic mud for a 5-day period) to enhance the biogas yield, as suggested by Nam *et al.* (2021) and Nam *et al.* (2023). The co-digestion of WL and PD could solve common issues concerning insufficient animal waste sources for biogas production, because many farms in various localities typically have a smaller standing stock of animals (permanently or temporarily) (Nam *et al.*, 2017; Nam *et al.*, 2021). Our study encourages the co-digestion of WL with PD to enhance renewable energy production. Notably, the use of renewable energy produced from AD allows for energy independence in the context of high energy consumption demand. Moreover, the application of household biogas plants to produce low-cost energy increases household economic efficacy owing to saving electrical use, liquefied petroleum gas (LPG) and firewood, while reducing greenhouse gas emissions from agricultural activities (Jan, Truc & Nam, 2018).

Conclusions

This study applied WL as a post-treatment method to AD effluent and achieved impressive removal efficiencies of pollutants after 6 days, including 84.4%–94.5% TSS, 80.0%–82.9% TP, 50.3%–59.7% COD, 50.0%–59.3% BOD₅, and 38.3%–46.8% TKN. Over 30 days, the treatment efficiencies of TSS, BOD₅, COD, TKN, and TP in the effluent were 93.8%–97.7%, 76.6%–82.6%, 76.8%–82.9%, 61.8%–63.8%, and 89.0%–89.6%, respectively. Based on the wet weight biomass, the doubling times for WL grown on surface coverages of 50%, 25%, and 12.5% were 12.32 days, 12.11 days, and 12.28 days, respectively. Thus, WL could be used as a supplementary substrate for biogas production. The biogas yield was recorded from 190.6 to 292.9 L kg VS_{added}⁻¹ when converted solely from WL. The CH₄ content was verified from 54.1% to 59.9%, making it suitable for biogas consumption. In general, WL could be applied in the post-treatment stage for AD effluent and as an additional substrate for biogas plants to produce renewable energy. Further research should explore the potential of using WL as a substitute substrate for livestock waste to generate energy.

Acknowledgement

We thank Mr. Liem, who allowed us to process the experiments on his household site, and Nguyen Hoang Phuong at Can Tho University for assisting with the experiment activities.
