ABSTRACT

Coral reefs are exposed worldwide to several global and local human pressures including climate change and coastal development. Assessing the effects of such pressures on coral reef communities and the changes they undergo over time is mandatory to understand their possible future trends. Nonetheless, some coral reefs receive no or little scientific attention, as in the case of Huvadho Atoll that is an under-studied region in the southernmost area of the Maldives (Indian Ocean). This study analyzes the changes occurring over time in eight coral reefs (four inner reefs within the atoll lagoon and four outer reefs on the ocean side) at Huvadho Atoll, firstly surveyed in 2009 and revisited in 2020 using the same field methods. The cover of 23 morphological benthic descriptors (including different growth forms of *Acropora*) was taken into account and then grouped into three categories (*i.e.*, hard coral, other benthic taxa and abiotic descriptors) to analyze the change in the composition of the coral reef community. Significant changes (*e.g.*, increase in hard coral cover and decrease in abiotic descriptors) were observed in the inner reefs as compared to the outer reefs, which showed less variability. A significant decrease in tabular *Acropora* cover was observed in both inner and outer reefs, with possible negative effects on reef complexity and functioning. By comparing two time periods and two reef types, this study provides novel information on the change over time in the community composition of Maldivian coral reefs.

INTRODUCTION

Coral reefs are one of the most biodiverse ecosystems in the world, but also one of the most highly threatened. The synergistic effect of climate change and local human pressures (*e.g.*, thermal anomalies, coastal development, tourism, fisheries) is leading to a global decrease in coral cover and diversity (Souter *et al.*, 2021). The increasing frequency and

intensity of such pressures is raising concerns about the long-term survival of coral reefs and the ecosystem goods and services they provide (*Pratchett, Hoey & Wilson, 2014*).

In the face of severe disturbances due to climate change (e.g., associated with El Niño events), coral reefs are generally able to recover within a time frame of one or two decades (*Connell, 1997; Done et al., 2007*). However, in more anthropized areas, their ability to recover is reduced by local human impact (*Van Woesik, 2000; Bruno & Selig, 2007; De'ath & Fabricius, 2010; Birkeland, 2019*). More remote coral reefs, farther from the source of such pressures, represent less vulnerable and more resilient ecosystems that can recover faster from disturbances than reefs altered by human activities (*Fabricius, 2005; Lotze et al., 2011; Zaneveld et al., 2016; Wear, 2019; Abelson, 2020*).

The reduction in coral abundance and diversity results in a decrease in associated fish and invertebrate communities and may lead to dramatic consequences for the structural complexity of reefs (*Alvarez-Filip et al., 2013; Hughes et al., 2018; Gissi et al., 2021*). Low reef structural complexity is reflected in a reduction of microhabitats and refugia (*Alvarez-Filip et al., 2013; Perry & Alvarez-Filip, 2019*) as well as food for corallivorous taxa (*Cole, Pratchett & Jones, 2008*), leading to a decline in reef productivity (*Alvarez-Filip et al., 2013; Graham & Nash, 2013; Rogers, Blanchard & Mumby, 2014*). Such changes in the benthic and taxonomic composition of coral reefs are increasingly common in several regions of the world including the Indo-Pacific (*Ledlie et al., 2007; Bozec et al., 2019*), the Great Barrier Reef (*Hughes et al., 2007*), and the Atlantic Ocean (*Roff & Mumby, 2012*).

The Maldivian archipelago (Indian Ocean) is one of four atoll nations in the world, and with a maximum elevation of 2.4 m above sea level (*Graham & Nash, 2013; Stevens & Froman, 2019*) is particularly subject to the negative effects of coral reef decline and sea level rise (*Gerrard & Wannier, 2013*). In the central atolls of the Maldives, local human pressures are rapidly increasing due to population growth, tourism intensification, and coastal works such as land reclamation and filling (*Pancrazi et al., 2020*). Under these pressures, Maldivian coral reefs are becoming increasingly vulnerable to the effects of climate change (*Nepote et al., 2016*).

Huvadhu Atoll, located in the southernmost area of the Maldives, can be considered “remote” due to less tourism and lower levels of anthropization compared to the central atolls (*National Bureau of Statistics, 2014; National Bureau of Statistics, 2020*). Huvadhu Atoll is divided into two administrative provinces: Gaafu Alifu in the north and Gaafu Dhaalu in the south. The first tourist facilities were built in 2009 and 2011, respectively, with a slight increase in recent years. Moreover, the population has not grown significantly, unlike it has in the central atolls of the Maldives (*National Bureau of Statistics, 2020*).

A profound understanding of the effects of climate change and human pressures on coral reefs requires data and monitoring over long periods of time (*Gross & Edmunds, 2015; Morri et al., 2015; Mellin et al., 2020*). In the absence of such historical data, revisiting sites already surveyed in the past represents a useful tool to assess change over time of coral reef benthic communities (*McClanahan, 2017; Bianchi et al., 2022* and references therein).

In the present study, eight coral reefs of Huvadhu Atoll, first surveyed in 2009, were revisited in 2020 using the same field methods in an effort to investigate the changes over time in the benthic community composition. As the second survey was carried out only

four years after the 2016 bleaching event, one of the most severe ever recorded ([Hughes et al., 2018](#)), our expectation was that hard coral (HC) cover was reduced with respect to the first survey. In both surveys, two different types of reefs were considered: inner reefs, on the side of the atoll facing the lagoon, and outer reefs, on the side facing the ocean, under the hypothesis that they respond differently to potential drivers of change, as already observed in the central atolls of Maldives ([Montefalcone, Morri & Bianchi, 2020](#)). The latter, however, are more anthropized than the remote atoll of Huvadhoo: might it therefore show a different pattern of change with respect to the central atolls?

MATERIALS & METHODS

Study area

Huvadhoo Atoll, located in the southern part of the Maldives (0.533333°N; 73.283333°E), is the largest atoll of the archipelago, including 241 coral reefs and having a total area of 437.9 km² ([Naseer & Hatcher, 2004](#)). Reaching a depth of 80 m, its lagoon is the deepest of the Maldives.

Field surveys

The aim of the first survey carried out at Huvadhoo Atoll in 2009 was to characterize the benthic community of eight coral reefs. In 2020 the same coral reefs were revisited using the same field methods in order to evaluate the changes over time. To reduce bias in data collection, the diving scientist who collected data in 2009 trained the diving scientist who collected data in 2020. In both survey years, the eight reefs were located using the same GPS waypoints from which the transect direction was taken with a compass ([Fig. 1](#)).

Two reef types, characterized by different location and hence exposure, were considered: four inner reefs (*i.e.*, located on the side of the atoll facing the lagoon), and four outer reefs (*i.e.*, located on the outer side of the atoll and directly exposed to ocean waters).

At each reef, nine replicates of 20 m transects were conducted at a depth of 10 m (*i.e.*, on the upper slope of the reef), at least 10 m apart. To analyze benthic community composition, the percent cover of 23 morphological benthic descriptors, which can infer reef structure and complexity ([Morri, Aliani & Bianchi, 2010](#); [Morri et al., 2015](#) and references therein; [Table 1](#)), was visually estimated by the diving scientist following the plain view technique of [Wilson, Graham & Polunin \(2007\)](#).

Data analysis

The collected data were organised in a matrix (time × reef type) × morphological benthic descriptors and transformed applying arcsine $\sqrt{(x/100)}$ where x is the percent cover data ([Legendre & Legendre, 1998](#)). Two different time periods were considered: (i) 09, for data collected in 2009; (ii) 20, for data collected in 2020. Two reef types were studied: (i) I = inner reefs; and (ii) O = outer reefs.

The data matrix was submitted to non-metric multidimensional scaling (nMDS) based on the Bray Curtis similarity index to highlight potential changes over time and differences between reef type in coral reef communities. Stress values indicated that a 2-dimensional representation was adequate. Analysis of the nMDS plot suggested that the first axis

Figure 1 Geographical location of the study area. The eight coral reefs surveyed at Huvadhoo Atoll (Maldives, Indian Ocean) in 2009 and 2020 include four inner reefs inside the lagoon (I) and four outer reefs on the ocean side of the atoll (O). Coral globose	CG	Tunicates	TU		
Coral massive	CM	Whip and wire corals	W		
Fungiidae	Cfu				
<i>Heliopora</i> coerulea	H				

(nMDS1) was mostly an expression of reef type, while the second axis (nMDS2) was an expression of time.

To test the differences in percent cover over time and between inner and outer reefs, a two-way permutational multivariate analysis of variance (PERMANOVA) was performed on orthogonal factors; ‘time’ (2 levels: 2009, and 2020) and ‘reef type’ (2 levels: inner and outer reefs).

Pythagoras’ theorem was applied to the first two nMDS axis scores to measure the time trajectories between the two time intervals (2009 and 2020) in inner and outer reefs (De Cáceres et al., 2019). A time trajectory is defined as the geometric distance on the scatter plot of the nMDS: the greater the distance between two samples in time, the greater the measure of change. For example, the time trajectory between inner reef one (I1) in 2009 and in 2020 was calculated as the geometric distance between the centroids of the inner reef in 2009 and the centroids in 2020 as follows:

$$Tt_{I1} = \sqrt{(x_{20} - x_{09})^2 + (y_{20} - y_{09})^2}$$

where Tt_{I1} is the length of the time trajectory of I1, x_{09} and y_{09} are the axis scores of the I1 centroid of 2009, and x_{20} and y_{20} are the axis scores of the I1 centroid of 2020. Analogous formulas were applied to measure the time trajectories between the two years in all eight surveyed reefs.

In addition, the 23 morphological benthic descriptors were grouped into three main categories (Table 1): (i) Hard Coral (HC), which includes primary and secondary builders (i.e., *Acropora* branching, *Acropora* digitate, *Acropora* palifera, *Acropora* tabular, coral branching, coral encrusting, coral foliose, coral globose, coral massive, Fungiidae, *Heliopora coerulea*); (ii) Other Benthic Taxa (OBT), which includes both encrusting organisms that consolidate reef structure, and soft-bodied organisms that contribute to sediment retention (i.e., clams, coralline algae, fans and feather corals, fleshy algae, soft azooxanthellatae corals, soft zooxanthellatae corals, sponges, tunicates, whip and wire corals); and ABioTic descriptors (ABT), which includes coral rock (including dead coral), coral rubble and sand. The total cover of each category was obtained by summing the cover of the morphological benthic descriptors included in it. Two-way ANOVA, followed by Tukey’s post-hoc tests, was performed considering the two independent variables ‘reef type’ and ‘time’ to assess changes in HC cover, OBT and ABT between 2009 and 2020. ANOVA assumptions of normality and homoscedasticity were assessed graphically (Kozak & Piepho, 2018).

In addition, similarity percentage analysis (SIMPER) was applied to highlight the morphological benthic descriptors that mainly contributed to the differences in coral reef benthic communities between the two years and between inner and outer reefs. To determine how the morphological benthic descriptors changed over time, in both inner and outer reefs, their percent cover was compared by Student’s *t*-test between the two years (2009 vs 2020).

All statistical analyses were performed using the open-source software PaSt (Hammer, Harper & Ryan, 2001). All data presented in the text, figures and tables are expressed as mean \pm standard error (SE).

RESULTS

The non-metric multidimensional scaling (nMDS) plot provided a visualisation of the differences in coral reef communities of the inner and outer reefs in the two time periods (Fig. 2). A clear segregation of replicates between the inner and outer reefs was observed along the first nMDS axis. Furthermore, segregation between the benthic communities of 2009 and 2020 was observed along the second nMDS axis. Considering the two time periods, inner reefs showed greater change over the time than outer reefs, where only a slight change in benthic community composition was observed. Multivariate dispersion of replicates was generally low. A comparative greater dispersion was observed in inner reefs (especially in 2020) than in outer reefs, reflecting greater variability in the benthic community composition (Fig. 2).

PERMANOVA results evidenced a significant interaction between time and reef type factors (Table 2), indicating that the differences in benthic community composition between inner and outer reefs were not consistent between the two years.

The time-trajectories of inner reefs were always higher than those of outer reefs, highlighting that the greatest changes in coral reef communities occurred in the former (Fig. 3).

Two-way ANOVA applied on HC cover showed a significant interaction ($p = 1.25E-14$, $F = 74.39$) between the 'time' and 'reef type' factors (Table 3). In 2009, the HC cover of inner and outer reefs was very similar (47.31 ± 1.74 and 46.44 ± 0.99 , respectively) (Fig. 4A). On the contrary, in 2020 the HC cover of inner reefs was significantly higher ($p < 0.001$) than that of outer reefs (Fig. 4A, Table 3). In 2020, HC cover of inner reefs increased ($59.47\% \pm 0.99$) compared to 2009, while that of outer reefs decreased ($38.50\% \pm 0.67$) (Fig. 4A). Two-way ANOVA applied on OBT cover showed a significant difference between years ($p = 0.04$, $F = 4.134$) and between reef type ($p = 3.37E-19$, $F = 108.8$) (Table 3). In outer reefs, the total cover of OBT in the two sampling years was very similar (17.22 ± 0.67 and 16.81 ± 1.05 , respectively) (Fig. 4B), but in the inner reefs, OBT cover decreased significantly ($p < 0.05$) from 2009 (10.61 ± 0.56) to 2020 (8.06 ± 0.56) (Fig. 4B, Table 3). Two-way ANOVA applied on ABT cover showed significant interaction ($p = 1.93E-11$, $F = 53.35$) between the 'time' and 'reef type' factors (Table 3). In 2009, total ABT cover of inner reefs (42.08 ± 1.62) was significantly higher ($p < 0.01$) than that of outer reefs (36.33 ± 0.87) (Fig. 4C, Table 3). In 2020, a significant decrease ($p < 0.01$) in ABT cover of inner reefs (32.50 ± 1.19) and a significant increase ($p < 0.001$) in ABT cover of outer reefs (44.69 ± 1.11) was observed (Fig. 4C, Table 3).

SIMPER analysis highlighted that the differences in the inner reefs between 2009 and 2020 were mainly (50%) due to the decrease in *Acropora* tabular and sand, and to the increase in *Acropora* branching and *Acropora* digitate (Table S1). Student's *t*-test (Table S2) applied on the percent cover of morphological benthic descriptors showed a significant decrease in *Isopora palifera*, *Acropora* tabular, coral branching, coral globose, sand, soft zooxanthellatae corals, sponges, tunicates, and whip and wire corals (Fig. 5A). On the other hand, a significant increase in *Acropora* branching, *Acropora* digitate, coral encrusting, coral foliose, coral massive, fleshy algae, and Fungiidae was observed (Fig. 5A).

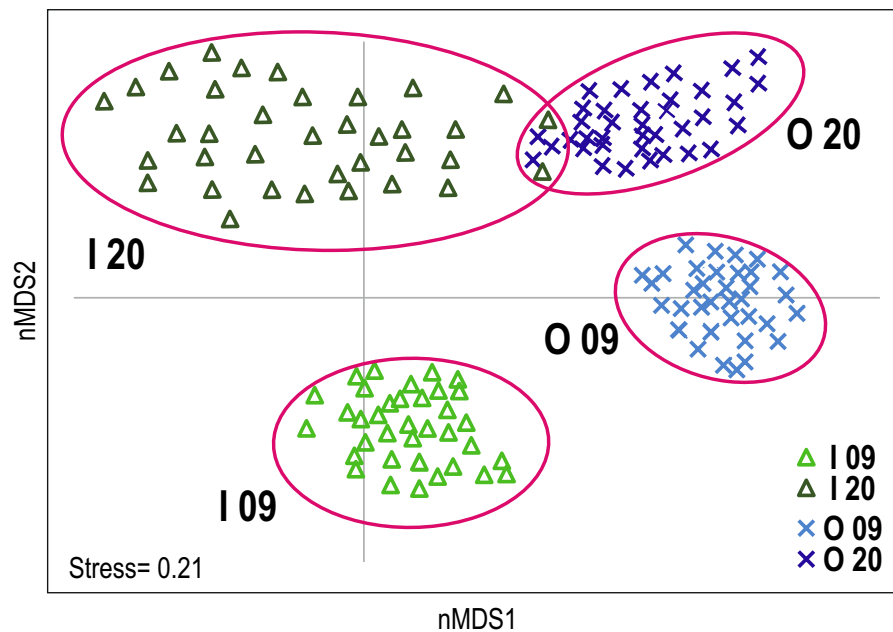

Figure 2 Non-metric multidimensional scaling (nMDS) plot of Huvadhoo Atoll survey data illustrating differences in coral reef benthic composition between reef type (inner and outer) and years (2009 and 2020). Individual observation points are represented by triangles for inner reefs and Xs for outer reefs. Light blue and light green indicate observation points in 2009; dark blue and dark green in 2020. Clusters are identified by alphanumeric codes with reef types (I: inner; O: outer) followed by year (09: 2009; 20: 2020).

DISCUSSION

Revisiting Huvadhoo Atoll eleven years after the first studies, revealed significant changes in the coral reef communities from 2009 to 2020. Comparing the inner and outer reefs, a different trend of change was observed indicating that the most important factor influencing benthic communities was their location inside or outside the atoll lagoon, the latter being more exposed to ocean waves. The inner reefs displayed greater variability with an increase in HC cover and a decrease in ABT (*i.e.*, coral rock, coral rubble, and sand). On the contrary, the outer reefs showed slighter change with a decrease in HC cover and an

increase in ABT. As for the central atolls of the Maldives, differences between these two reef types involved not only morphology and topography (Rovere *et al.*, 2018), but also the species composition of the communities (Lasagna *et al.*, 2010a). Inner reefs were typically dominated by fast-growing branching, digitate and tabular *Acropora*, compared to outer reefs dominated by encrusting, globose and massive corals (Bianchi *et al.*, 1997; Lasagna *et al.*, 2010b).

The significant increase in HC cover observed in Huvadhoo inner reefs was mainly due to the increase in branching and digitate *Acropora*, and of encrusting, foliose and massive corals. On the other hand, the decrease in the HC cover observed in outer reefs was mainly due to a significant decrease in digitate and tabular *Acropora*, and of encrusting and foliose corals. This trend was found to be the contrary to what was observed in the central atolls of the Maldives, where corals in the outer reefs proved to be more resistant than those in the inner reefs (Kinlan & Gaines, 2003; Montefalcone, Morri & Bianchi, 2020). Since they

are on the inner side of the atoll, inner reefs experience high water temperature variations and are usually more vulnerable to the effects of rising global temperatures than outer reefs that are close to deep, cooler waters and are subject to greater water movement (Muir et al., 2017; Montefalcone, Morri & Bianchi, 2018). Compared to Huvadhoo, the central atolls of the Maldives are much more anthropized and the inner reefs usually undergo a combination of global and local human pressures (Montefalcone, Morri & Bianchi, 2020; Pancrazi et al., 2020). In addition, the topography of the Huvadhoo lagoon, which is the deepest in the Maldives, may provide better environmental conditions in terms of water quality and may mediate a greater increase in water temperature. On the other hand, outer reefs are generally exposed to intense wave action that can cause constant turnover

associated with breakage, scratching, and abrasion ([Madin & Connolly, 2006](#); [Muir et al., 2017](#); [Lange et al., 2021](#)) and this would explain the slight change in the benthic community composition exhibited by outer reefs.

By contributing significant amounts of calcium carbonate, HCs are key species for tropical marine ecosystems as they are the main builders of reefs ([Perry et al., 2012](#); [Graham & Nash, 2013](#)). Therefore, HC cover is a widely used indicator for assessing the health status and changes over time of coral reefs ([Montefalcone, Morri & Bianchi, 2020](#), and references therein). However, despite the positive trend of increasing HC in inner reefs, a further finding of the present study is the significant reduction of tabular *Acropora*, which have almost disappeared from both the inner and outer reef between 2009 and 2020. Tabular *Acropora* play a key role in coral reefs, providing three-dimensional habitat structure and shelter for fish at different life stages ([Kerry & Bellwood, 2012](#); [Graham & Nash, 2013](#)). However, tabular *Acropora* are vulnerable to multiple stressors and disturbances ([Madin & Connolly, 2006](#); [Pratchett, 2007](#)). During the two mass bleaching events documented in the Maldives (1998 and 2016) they showed the highest bleaching-related mortality among all coral types ([Baker, Glynn & Riegl, 2008](#); [Lasagna et al., 2008](#); [Morri, Aliani & Bianchi, 2010](#); [Pisapia et al., 2016](#); [Sakai, Singh & Iguchi, 2019](#)). In the present study, the analysis of each morphological descriptor was therefore crucial to highlight the reduction of key taxa (e.g., tabular *Acropora*), not detectable with the exclusive HC cover indicator. The functional trait approach can provide general and predictable rules for community ecology ([Darling et al., 2012](#)) and would be desirable in the studies of changes over time of coral reefs.

Although the comparison of only two time periods limits the possibility to infer cause–effect relationships between a given pressure and the significant reduction of tabular *Acropora* in the Huvadhu Atoll coral reefs ([Perry & Morgan, 2017](#)), a possible explanation could be the 2016 El Niño event that caused mass coral bleaching throughout the Maldives ([Montefalcone, Morri & Bianchi, 2018](#); [Montefalcone, Morri & Bianchi, 2020](#) and references therein). This extreme event led to a significant reduction in HC cover, mainly due to the death of branching and tabular *Acropora*. In an inner reef of Huvadhu Atoll, [Ibrahim et al. \(2017\)](#) estimated that 50–75% of corals bleached in 2016. Rapid recovery of tabular *Acropora* has been observed in other regions of the world ([Osborne et al., 2011](#)), however the increasing intensity and frequency of extreme events may lead to reduced coral reef recovery capacity ([Cowburn et al., 2019](#)).

By comparing two time periods and two reef types, this study provided novel information on the changes that coral reef community composition undergo over time. The different trends of HC cover observed at Huvadhu Atoll reefs compared to those of central atolls highlight the need for further studies to better understand the future trends of Maldivian coral reefs. These ecosystems will be increasingly threatened by the effects of global and local human pressures (e.g., rising temperatures and rising mean sea level, tourism, increasing population, coastal works) and only through continuous monitoring will it be possible to define the resilience and recovery capacity of the Maldivian coral reefs.

CONCLUSIONS

Studies on changes over time of coral reefs are needed to understand their possible future trends under increasing global and local human pressures. Revisiting sites surveyed in the past is a useful tool in this direction ([McClanahan, 2017](#); [Bianchi et al., 2022](#) and references therein). In the present work the magnitude of change in coral reefs of the remote Huvadho Atoll in Maldives was evaluated for the first time. Although comparing two points in time may not suffice to assess when changes actually occurred and under what pressure ([Azzola et al., 2022](#) and references therein), this study provides novel information to illustrate change over time in Maldivian coral reefs.

ACKNOWLEDGEMENTS

Albatros Top Boat (Verbania and Malé) organised our scientific cruises in the Maldives: we would especially like to thank Donatella ‘Dodi’ Telli, Massimo Sandrini and Herbert Fontana for their support, and all the crew of Conte Max and Duke of York boats for their assistance during the field work. We would also like to thank Irene Pancrazi and Hassan Ahmed (Save the Beach Maldives) and all participants in survey activities. The authors are grateful for the proofreading by Valerie Perricone.
