The harvest of the edible sea urchin *Paracentrotus lividus* is intensively practiced in some regions of the Western Mediterranean Sea. The removal of the largest individuals can determine an overall reduction in population size and a size class truncation that can lead to a drastic drop the self-sustenance. The aim of this study is to evaluate the reproductive cycle and reproductive potential across five years of a population in one the main harvest hotspots of Sardinia (Italy). The breeding stock consists of commercial and under-commercial size individuals and for this reason they were sampled on a monthly basis to estimate their GonadoSomatic Index. The reproductive potential of the population - Total Gamete Output - was calculated across the five-year period in relation with the variation of the density of the major breeding stock. Moreover, during the last year, the reproductive cycle and reproductive potential were also estimated in a well-conserved population of the nearby Marine Protected Area, as a reference control. No variation in GonadoSomatic Index and Individual Gamete Output was found over the five years nor when compared with the ones of protected population in the last year. However, the intensive harvesting drastically rescaled the population body-size: although density of the commercial size class was stable on minimum values, density of the under-commercial size-class halved from the beginning to the end of the monitoring. Accordingly, the proportional decrease of their gamete output contribution led to loss 40% of the reproductive potential of the whole population in the five-year period. On the basis of these results, if harvest pressure would continue, the local population in ten years will not be able to contribute to the recruitment. Interestingly, whilst the Total Gamete Output decreased as consequence of the drastic decrease of the major population breeding stock, the inter-annual trends of

GonadoSomatic Index and Annual Gamete Output slightly decreases and increases respectively. These patterns suggest that a potential compensatory response as reproductive investment of the survivors in gonad production rate or spawning intensity in front to the lack of the largest sea urchins need to be investigated. Definitively, this work brings clear evidence of the direct effect of the size-selective harvesting in the rapid loss of the population self-sustenance. Furthermore, it lays new prospective for future research of the indirect effects of the rescaling population body-size in functional traits of key herbivores species such as *P. lividus* in Mediterranean Sea that could become important both for the sustainable exploitation and ecosystems conservation management.

## Abstract

The harvest of the edible sea urchin *Paracentrotus lividus* is intensively practiced in some regions of the Western Mediterranean Sea. The removal of the largest individuals can determine an overall reduction in population size and a size class truncation that can lead to a drastic drop the self-sustenance. The aim of this study is to evaluate the reproductive cycle and reproductive potential across five years of a population in one the main harvest hotspots of Sardinia (Italy). The breeding stock consists of commercial and under-commercial size individuals and for this reason they were sampled on a monthly basis to estimate their GonadoSomatic Index. The reproductive potential of the population - Total Gamete Output - was calculated across the five-year period in relation with the variation of the density of the major breeding stock. Moreover, during the last year, the reproductive cycle and reproductive potential were also estimated in a well-conserved population of the nearby Marine Protected Area, as a reference control. No variation in GonadoSomatic Index and Individual Gamete Output was found over the five years nor when compared with the ones of protected population in the last year. However, the intensive harvesting drastically rescaled the population body-size: although density of the commercial size class was stable on minimum values, density of the under-commercial size-class halved from the beginning to the end of the monitoring. Accordingly, the proportional decrease of their gamete output contribution led to loss 40% of the reproductive potential of the whole population in the five-year period. On the basis of these results, if harvest pressure would continue, the local population in ten years will not be able to contribute to the recruitment. Interestingly, whilst the Total Gamete Output decreased as consequence of the drastic decrease of the major population breeding stock, the inter-annual trends of GonadoSomatic Index and Annual Gamete Output slightly decreases and increases respectively. These patterns suggest that a potential compensatory response as reproductive investment of the survivors in gonad production rate or spawning intensity in front to the lack of the largest sea urchins need to be investigated. Definitively, this work brings clear evidence of the direct effect of the size-selective harvesting in the rapid loss of the population self-sustenance. Furthermore, it lays new prospective for future research of the indirect effects of the rescaling population body-size in functional traits of key herbivores species such as *P. lividus* in Mediterranean Sea that could become important both for the sustainable exploitation and ecosystems conservation management.

## 1. Introduction

97  
98

Fishing is the most widespread human exploitative activity in the marine environment, and it is size-selective by definition (Longhurst, 2006). Worldwide fishery is based on removing individuals above a minimum legal size (Jackson et al., 2001) and in theory, juveniles can grow large enough to reproduce at least once before being harvested, guaranteeing their own replacement (Law, 2000). However, nowadays fishing is so intense (Baum et al., 2003; Myers & Worm, 2003; Pauly et al., 1998) that affects many aspects of the biology of a target species, such as demography, life history and ecology (Fenberg & Roy, 2008).

105

108  
109  
110  
111  
112  
113

One of the main effects of the size-selective harvest is the deep change in demographic structure of the population. Specifically, the continuous removal of the largest individuals rather than the smallest ones can determine an overall reduction in population abundance and body-size (Fenberg & Roy, 2008). Thus, under heavy size-selective harvest, an age-size truncation of the populations occurs, leading to a multitude of consequences (Festa-Bianchet, 2003; Heino & Godo, 2002). This phenomenon is critical for the self-sustenance of populations that need relying totally on the youngest specimens and that eventually results in a serious decline of the population growth rate (Enberg, Jørgensen & Mangel, 2010). Effectively, it is widely demonstrated that in general large individuals give the greatest contribution to successful

114 offspring and the size and quality of larvae of some exploited marine fish have been shown to be  
115 positively correlated with maternal length and age (Berkeley, Chapman & Sogard, 2004; Trippel,  
116 1995; Vallin & Nissling, 2000). Thus, the removal of the largest and oldest individuals generally  
117 decreases the population ability to replenish itself.

118         Moreover, the body-size is central to ecology from the organismal physiology to the  
119 functioning of communities and ecosystems (Peters, 1983). The intensive size-selective  
120 harvesting can cause alterations in the growth rate and in the timing of maturation of the  
121 youngest specimens (Hamilton et al., 2007). The decrease in mean size and abundance of the  
122 target fishes can also generate negative effects on non-target species through the food web  
123 interactions (Audzijonyte et al., 2013), for example reducing the predator-prey interactions and  
124 causing the proliferation of preys (e.g. Pinnegar et al., 2000). This mechanism is widely  
125 demonstrated in the tri-trophic interactions fish, sea urchins and macrophytes in temperate reefs.  
126 Overfishing depletes populations of predatory fish and the substantial loss of the large predators  
127 that exert a top-down control mechanism determines an unregulated increase in sea urchin  
128 population densities (Guidetti, Boero & Bussotti, 2005; McClanahan & Shafir, 1990; Micheli et  
129 al., 2005; Sala et al., 2012; Sala, Boudouresque & Harmelin-Vivien, 1998; Shears & Babcock,  
130 2003).

131         The indirect impact of the size-selective harvesting on the ecosystems largely depends on  
132 the functional role and competitive dominance of the target species (Kaiser & Jennings, 2001).  
133 For example, heavy size-selective harvest of sea urchin predatory fishes generates cascading  
134 effects pushing the system beyond the resilience tipping points (Ling et al. 2015) and facilitates a  
135 shift from vegetated coastal marine ecosystem to a bare rocky area - barrens – hosting low  
136 biodiversity (e.g., Bianchelli & Danovaro 2020).

137 In the last decades the lower-trophic-level fisheries intensified the exploitation on  
138 remaining commercial species, including invertebrates (e.g., Anderson et al., 2011), among  
139 which sea urchins represent a relevant economic resource (Andrew et al., 2002). Sea urchin  
140 fisheries further worsen the health of the ecological system. In the extreme cases, in addition to  
141 low density and biomass of predatory fishes due to overfishing, the intensive sea urchin  
142 harvesting leads to the abrupt decline of these herbivores and, ultimately, determining the  
143 collapse of their populations (e.g., Johnson et al. 2012).

144 Since the gonads are proportional to the sea urchin size and are more mature and  
145 developed in the largest individuals (Mita et al., 2007), the size-selective harvesting of the largest  
146 sea urchins can gradually compromise the population fertility (Brewin et al., 2000; Byrne, 1990;  
147 Guettaf, San Martin & Francour, 2000). Many studies demonstrated strong correlations between  
148 the reproductive potential of the harvested populations and the harvesting pressure (Levitan &  
149 Sewell, 1998; Levitan, Sewell & Chia, 1992; Pennington, 1985; Tegner & Dayton, 1977).  
150 Populations under heavy harvesting pressure are often destined to collapse unless they receive  
151 enough larval supply from the outside (Dubois et al., 2016).

152 Furthermore, the sea urchin species commercially harvested are led to such a strong  
153 reduction in population density that consequent changes in the community structure of  
154 macrophytes ecosystems have also been observed (Steneck et al., 2002; Vadas & Steneck, 1995;  
155 Villouta, 2000). Moreover, the size-selective harvesting of the edible sea urchin species can  
156 increase the individual growth rate, size, and abundance of others non-harvested sea urchin  
157 species because of release from competitive pressure, for example *Arbacia lixula* is favored by  
158 the removal of *Paracentrotus lividus* (Guidetti, Terlizzi & Boero, 2004).

159           The edible sea urchin *P. lividus* (Lamarck 1816) is the most exploited species in the  
160 Mediterranean Sea for its appreciated gonads but, at the same time, it is an indispensable  
161 functional herbivore in controlling macroalgal communities through the grazing activity (Boada  
162 et al., 2017; Guarnieri et al., 2014; McClanahan & Sala, 1997; Prado et al., 2007). In some  
163 regions of the Western Mediterranean Sea, the intensive harvest of *P. lividus* locally re-scaled  
164 population body-size determining an evident cut-off of the population structure above the  
165 commercial size-class of 50 mm (test diameter without spines; TD) and with the depletion of the  
166 major breeding stock (Couvray et al., 2015; Gianguzza et al., 2006; Guidetti, Boero & Bussotti,  
167 2004).

168           In Sardinia (Italy), despite regional decrees regulating quotas, fishing calendar and the  
169 minimum size, *P. lividus* is extensively harvested all-year-round since the early 2000s  
170 (Ceccherelli et al., 2011; Pais et al., 2012, 2007; Pieraccini, Coppa & De Lucia, 2016). The  
171 intensive exploitation (given by the sum of authorized and illegal harvesting) has dramatically  
172 reduced the sea urchin density in many coastal areas (Ceccherelli et al., 2021). In some cases, the  
173 loss of the largest and oldest individuals, as the major breeding stock of the population, is  
174 shifting all the reproduction activity onto the shoulders of the youngest fertile sea urchins (Loi et  
175 al., 2017). Thus, monitoring the gamete production of the overexploited populations can be  
176 crucial to manage the local fishery sustainability but also to prevent the population collapse. The  
177 spatial and temporal variation of the gamete production can be assessed through the analysis of  
178 the annual reproductive cycle (Brewin et al., 2000). The reproductive cycle is generally  
179 evaluated through the estimation of the GonadoSomatic Index, as fluctuations in gonad size and  
180 spawning periods (Gianguzza et al., 2013; Shpigel et al., 2004; Spirlet, Grosjean & Jangoux,  
181 1998), and from which the reproductive potential of a population (the total gamete output)

182 depends on (Brewin et al., 2000). The variation of the reproductive cycle is strictly associated to  
183 environmental factors changes, such as sea surface temperature (Beddingfield & McClintock,  
184 1998; Levitan, 1991; Levitan, Sewell & Chia, 1992; Spirlet, Grosjean & Jangoux, 2000; Spirlet,  
185 Grosjean & Jangoux, 1998), but also wave height or food quality (Brady & Scheibling, 2006;  
186 Byrne, 1990; Gianguzza et al., 2013; Lozano et al., 1995; Minor & Scheibling, 1997; Sellem &  
187 Guillou, 2007). Overall, the largest *P. lividus* adults represent at the same time the major  
188 breeding stock of the population and the target commercial size-class ( $TD \geq 50$  mm), whilst the  
189 smaller fertile individuals, the under-commercial size-class ( $40 \leq TD < 50$  mm), are still  
190 important contributors for the self-sustenance of the population (e.g. Loi et al., 2017) and  
191 represent the future stock of fishing. These fertile size-classes can produce more than one cohort  
192 of mature gametes in a single breeding season (Mita et al., 2007) and their reproductive cycle  
193 generally has one or two seasonal peaks (Boudouresque & Verlaque, 2001; Ouréns, Fernández &  
194 Freire).

195         The aim of this study is to estimate the variability across five years of the reproductive  
196 cycle and the reproductive potential of *P. lividus* in one of the main harvest hotspots of Sardinia  
197 (Italy). The reproductive cycle was evaluated through the estimation of the GonadoSomatic  
198 Index and the potential relation of the Sea Surface Temperature and Sea Wave Height with the  
199 spawning events was explored. Whilst, the reproductive potential was calculated as the Total  
200 Gamete Output produced by the whole population, as it is strictly related to the density of the  
201 fertile sea urchins (commercial and under-commercial size-classes). Finally, during the last year  
202 of sampling, the reproductive cycle and the reproductive potential were also compared with those  
203 of a well-conserved population of the nearby Marine Protected Area as control reference.  
204 Although the reproductive cycle is expected no differing across the years, the reproductive

205 potential of the whole population is expected to drastically decline due to the phenomenon of the  
206 rescaling population body-size.

207

## 208 **2. Material and Methods**

209

### 210 *2.1. Study site*

211

212 This study was conducted at Su Pallosu Bay (40.0489° N, 8.4161° E), located in the north  
213 of the Peninsula of Sinis (Sardinia, Western Mediterranean), a high natural density area of sea  
214 urchins that has been overexploited by fishermen for many years (e.g. Fois et al., 2020; Farina et  
215 al., 2020; Coppa et al., 2018; Guala, Simeone & Baroli, 2009; Pais et al., 2007). The favourable  
216 environmental conditions, such as the shallow calcareous plateau with *Posidonia oceanica*  
217 patches (De Falco et al., 2008) and the low predatory fish density (Marra et al., 2016), seem to  
218 support a high sea urchin colonization (Oliva et al., 2016). Moreover, the low current speed  
219 determining recirculation cells of water surface in the Bay (Farina et al., 2018) is probably  
220 favourable for the reproduction success of the local sea urchin population (Ouréns et al., 2013).  
221 Su Pallosu Bay is considered one of the main harvest hotspots (harvest locality, H hereafter) in  
222 Sardinia (Fig.1). In this area, and along the entire coast of the island, the professional sea urchin  
223 harvesting is officially open from November to April and it is allowed with scuba diving.  
224 Nowadays the daily catches amount to 1500 per fisherman or 3000 per boat, while the minimum  
225 catch size is above 5 cm diameter size (RAS, Autonomous Region of Sardinia, decree no.  
226 2524/DecA/102 of 7 October 2009).

227 In the last year of sampling, a control population was selected at Cape Seu (39.8980° N,  
228 8.4010° E) in the nearby Marine Protected Area ("Penisola del Sinis - Isola di Mal di Ventre",  
229 established in 1997; Fig.1), where the harvesting is strongly restricted (Control locality, C from

230 now on) in terms of number of fishing licenses (only residents), areas, modality (only free diving  
231 is admitted) and catch quotas per day (Farina et al. 2020; Ceccherelli et al., 2022).

232 The study area is far from urbanizations, harbours, aquaculture activities and rivers and,  
233 accordingly, there was no anthropogenic influence on the dissolved nutrient concentration on  
234 macroalgal composition and abundance over the years (Loi et al., 2017).

235 The annual average of the Sea Surface Temperature (SST) ranged between 17.5° C and  
236 19° C with colder open waters and warmer coastal waters (Cucco et al., 2006). The wind-waves  
237 are generated on a wide fetch by the prevailing winds that, in the form of severe winter storms,  
238 can produce intense Sea Wave Height (SWH) of up to 5m (Simeone et al. 2016). Data of the  
239 daily SST (C°) were extrapolated from NOAA dataset and free downloaded from “Asia-Pacific  
240 Data Research Centre” webpage (<http://apdrc.soest.hawaii.edu/las/v6/dataset?catitem=1233>).  
241 Data of the hourly SWH (m) were free downloaded from Copernicus Marine Environmental  
242 Monitoring Service  
243 ([https://resources.marine.copernicus.eu/?option=com\\_csw&task=results&pk\\_vid=20be7e57367a](https://resources.marine.copernicus.eu/?option=com_csw&task=results&pk_vid=20be7e57367a57a51616599440425bbc)  
244 [57a51616599440425bbc](https://resources.marine.copernicus.eu/?option=com_csw&task=results&pk_vid=20be7e57367a57a51616599440425bbc)). The monthly mean SST and SWH were calculated choosing an  
245 intermediate point between the two sampling sites and that represents the trend of the SST and  
246 SWH in each locality during the sampling periods.

## 247 248 2.2. *GonadoSomatic Index and Annual Gamete Output*

249  
250 Sea urchins were monthly sampled across five years from 2013 to 2019 at the H locality  
251 and in 2018-19 at the C locality. The estimated GonadoSomatic Index (GSI) from May of one  
252 year to June of the year after representing a sampling period of a complete annual reproductive  
253 cycle. Thus, GSI was monthly estimated for five sampling periods (P1-P5) at the H locality and

254 for the last sampling period (P5) at the C locality and for both commercial and under-commercial  
255 size-classes.

256 The sea urchins were collected by scuba diving at two sites few hundred meters apart and  
257 over a rocky bottom at the bathymetry of  $5 \pm 1$  m (mean depth at which the harvesters usually  
258 work). Depending on the year, 12 to 20 individuals were sampled for each site, both for the  
259 commercial (CS, test diameter  $TD \geq 50$  mm) and the under-commercial size-class (US,  $40 \leq TD$   
260  $< 50$  mm). Size and wet weights of urchins were measured, while the gonads were removed and  
261 weighted and the GSI was estimated for each sampled individual as:

262

$$263 \quad [gonad\ wet\ weight / total\ wet\ weight] \times 100 \quad (\text{Lawrence et al., 1965})$$

264 Since 1:1 sex ratio is usually observed, female and male were pooled together to obtain a  
265 single mean of GSI value per month (monthly mean GSI; e.g. Loi et al., 2017). The annual mean  
266 GSI was also estimated for the whole population as the average of the monthly mean GSI values  
267 for each sampling period. The highest and the lowest peaks of the monthly mean GSI recorded  
268 over a sampling period correspond to the time before the beginning (pre-spawning) and after the  
269 end (post-spawning) of a spawning event.

270 The mean individual gamete output (IGO) was then calculated as the difference between  
271 the monthly mean pre-spawning GSI and the monthly mean post-spawning GSI in units of  
272 gamete wet weight per urchin per spawning event ( $g\ g^{-1}\ se^{-1}$ ). The sum of the all-year-round  
273 differences (IGOs) represents the Annual Gamete Output (AGO), which is the reproductive  
274 contribution of each fertile size-class per year ( $g\ g^{-1}\ yr^{-1}$ ).

275

276 2.3. *Population reproductive potential*

277

278 Sea urchin population structure was estimated during the first P1 and the last P5 sampling  
279 periods (2013-14 and 2018-19) at the H locality, and in the last sampling period P5 (2018-19) at  
280 the C locality. Density and size frequency distribution of sea urchins were estimated in both of  
281 sites of the localities by independent underwater counts (Guala et al. 2018). The counts were  
282 carried out in three replicates of 5m<sup>2</sup> (20 contiguous 50x50cm quadrats) each, the minimum  
283 optimal surface to detect aggregative distribution of sea urchins, as consequence of the habitat  
284 heterogeneity.

285 All the sea urchins found in the sampling quadrats were counted and measured with  
286 callipers. The sea urchin abundance was then estimated as density (ind/m<sup>2</sup>) and the individuals  
287 were grouped in size-classes of 10 mm of test diameter to build the population structure (e.g.  
288 Farina et al., 2020, 2022).

289 Finally, the population reproductive potential was estimated as the Total Gamete Output  
290 (TGO) of the whole population per m<sup>2</sup> per year that is defined as the sum of the AGO of each  
291 fertile size-class multiplied for the sea urchin density (g g<sup>-1</sup> m<sup>-2</sup> yr<sup>-1</sup>).

292

#### 293 2.4. *Data analysis*

294

295 Variability of the monthly mean SST at the H locality was evaluated among the sampling  
296 periods P1-P5 (from 2013 to 2019) throughout the non-parametric analysis of variance Kruskal-  
297 Wallis test (Kruskal & Wallis, 1952). Moreover, the monthly mean SST of the last sampling  
298 period P5 was compared with the temperature of the C locality (Mann-Whitney test; Mann &  
299 Whitney, 1947). Similarly, difference in the monthly mean SWH was estimated among the  
300 sampling periods with parametric Analysis of variance (Anova 1-way, Underwood, Underwood  
301 & Underwood, 1997). In order to exclude the statistical effects induced by the sea water

302 temperature and wave height, because non-significantly different among the sampling periods,  
303 these variables were successively set as further predictors with random distribution and  
304 independent from the response variables in the following analysis.

305         Exploration of the GSI and IGO data was carried out to test the data assumption (i.e.,  
306 normal distribution and homogeneity of the variance) before the analysis of variance (Zuur, Ieno  
307 & Elphick, 2010). Since the GSI data were characterized by a different number of replicates  
308 collected during the years, and non-normal distribution, General Linear Mixed Model (GLMM)  
309 with Poisson family was chosen as the best tool for analysis of variance of unbalanced data  
310 involving random factors (temperature and waves).

311         A GLMM was performed to assess the variance of the monthly mean GSI of the H  
312 locality with “period” (five levels) and “size-class” (two levels) as fixed factors, “temperature”  
313 (twelve levels) and “wave height” (twelve levels) nested “period” and “site” (two levels) as  
314 random factors in order to exclude their statistical effects on the response variable. A second  
315 GLMM was carried out to evaluate differences in the monthly mean GSI between the localities  
316 (H locality versus C locality) during the sampling period P5. This analysis was set with  
317 “locality” (two levels) and “size-class” (two levels) as fixed factors and, “temperature”, “wave  
318 height” and “site” as random factors. Finally, a LMM was achieved with log transformed IGO as  
319 variable response, “period” and “size” as fixed factors, “temperature” and “wave height”  
320 (referenced to the months average when spawning occurred) as random factors.

321         Graphical validations of all the models are provided in the supplementary materials. All  
322 the described procedures and analyses were performed using the Nortest and lme4 packages in R  
323 software (Venerables & Smith, 2010).

324

### 325 3. Results

326

327 The monthly mean SST did not change significantly in the H locality over the sampling  
328 periods (Kruskal Wallis test: chi-squared = 0.43005, p-value = 0.9799) neither between the H  
329 and the C localities during P5 (Mann-Whitney test: p-value = 0.7561; see Fig.2 and Table S1 of  
330 Supplementary Material). Difference in the monthly mean SWH was also not significant across  
331 the five-year periods (Anova one-way test: p-value=0.579; Table S2 of Supplementary Material).

332

#### 333 3.1. *GonadoSomatic Index and Annual Gamete Output*

334

335 Overall, an annual average of 400 sea urchins of both fertile size-classes (CS and US)  
336 were collected during the five-year period to estimate the monthly mean GSI trend of the  
337 population in the H locality. The monthly mean GSI was significantly influenced by the Size but  
338 not by the Period of sampling (AIC=5903.2,  $R^2=0.39$ ; Table 1a, Fig. S1). Also, Locality resulted  
339 no significant when the monthly mean GSI was compared between the H and C locality during  
340 P5 (AIC=2171;  $R^2=0.45$ ; Table 1b, Fig. S2). In both GLMM analyses, a high estimate coefficient  
341 was assigned to the random effect of the monthly mean SST and SWH (Table 1).

342 In general, the main pre-spawning GSI was in March, except for the P3 that was in  
343 August, while smaller spawning events were also observed in Autumn (Fig. 2). The main pre-  
344 spawning GSI ranged between  $5.5\pm 0.71\%$  in P2 and  $7.07\pm 0.43\%$  in P5 for the CS urchins, while  
345 for the US urchins it ranged between  $4.27\pm 1.34\%$  and  $4.59\pm 0.32\%$  in P3 and P4, respectively. At  
346 the C locality the main pre-spawning GSI was also found in March and it was  $6.30\pm 0.50\%$  and  
347  $5.41\pm 0.61\%$  in the CS and US urchins, respectively (Fig.2; Table S2). The annual mean GSI  
348 estimated for the whole population at H locality decreased over the year ( $R^2=0.36$ ; Fig.3a) and it

349 reached the lowest values of  $4.91 \pm 0.66\%$  in P5. In the same period (P5) at the C locality the  
350 annual mean GSI was  $6.71 \pm 0.78\%$  (Fig.3a, Table 3).

351 The annual mean IGO was not significantly different among the sampling periods and  
352 between the size-classes (see Table 2 and Fig. S3). The highest IGO was recorded in P5 and it  
353 was  $4.96$  and  $3.75 \text{ g g}^{-1} \text{ se}^{-1}$  for CS and US urchins, respectively (Table S3). At the C locality, the  
354 annual mean IGO calculated during P5 was  $4.13$  and  $4.06 \text{ g g}^{-1} \text{ se}^{-1}$  for CS and US, respectively  
355 (Table S3). However, the pattern of the AGO at the H locality tends to increase over the year  
356 even if not significantly ( $R^2=0.27$ , Fig.3b). The highest AGO was  $0.12 \text{ g g}^{-1} \text{ yr}^{-1}$  and  $0.11 \text{ g g}^{-1}$   
357  $\text{yr}^{-1}$  during P3 and P5, respectively, while the lowest AGO was  $0.08 \text{ g g}^{-1} \text{ yr}^{-1}$  during P2. Finally,  
358 the population AGO calculated during P5 in urchins of the C locality was  $0.11 \text{ g g}^{-1} \text{ yr}^{-1}$  (Table  
359 3, Fig3b).

360

### 361 3.2. *Population reproductive potential*

362

363 At the H locality the density of CS urchins was  $0.6 \pm 0.2 \text{ ind/m}^2$  and  $0.5 \pm 0.1 \text{ ind/m}^2$  in P1  
364 and P5 respectively, while the US density was  $2.7 \pm 0.3$  and  $1.2 \pm 0.4 \text{ ind/m}^2$  in the same periods  
365 (Fig.4, Table 3, Table S4). Accordingly, the reproductive potential of CS urchins was calculated  
366 as  $0.034$  in P1 and  $0.036 \text{ g g}^{-1} \text{ m}^2 \text{ yr}^{-1}$  in P5, whilst in the same periods for the US urchins it was  
367  $0.116$  and  $0.05 \text{ g g}^{-1} \text{ m}^2 \text{ yr}^{-1}$  (Fig. 5 and Table 3). Accordingly, the population reproductive  
368 potential (TGO) at the H locality was estimated to be  $0.15 \text{ g g}^{-1} \text{ m}^2 \text{ yr}^{-1}$  in P1 and  $0.086 \text{ g g}^{-1} \text{ m}^2$   
369  $\text{yr}^{-1}$  in P5.

370 Finally, at the C locality, urchin density of CS and US classes was  $0.9 \pm 0.4 \text{ ind/m}^2$  and  
371  $0.8 \pm 0.4 \text{ ind/m}^2$ , respectively, and the population reproductive potential (TGO) during P5 was  
372  $0.09 \text{ g g}^{-1} \text{ m}^2 \text{ yr}^{-1}$  (Fig. 5, Table 3, Table S3).

373

374 **Discussion**

375

376           The temporal pattern of the monthly mean GSI at the H locality was not significantly  
377 different over the years but, it was significantly higher in the large individuals (CS) rather than in  
378 the smaller (US), confirming the role of major population breeding stock of the commercial size  
379 urchins. The main spawning events occurred generally in spring according with Spirlet, Grosjean  
380 & Jangoux (1998), except for P3 when there was no evidence of abrupt spawning events. Finally,  
381 during the last sampling period (P5), the monthly mean GSI of the population at H locality was  
382 not significantly different from the C locality one.

383           Due to the overexploitation in the H locality, the low density of CS urchins remained  
384 essentially stable on minimum values across the five-year period (less than one individual for  
385 square meter). However, density of US urchins strongly decreased from more than two  
386 individuals to less than one individual for square meter and the proportional decrease of their  
387 gamete output contribution led to the loss of 40% of the reproductive potential of the whole  
388 population. In general, in the North-Western Sardinia, the intensive size-selective harvesting  
389 strongly affects the density of the largest CS sea urchins (Pais et al., 2007; Ceccherelli et al.,  
390 2021) and in the harvest hotspot of Su Pallosu Bay have been at their minimum amount for many  
391 decades (Loi et al. 2017). The systematic removal of the largest sea urchins at the H locality has  
392 determined a truncated demographic structure of the population above the commercial size-class.  
393 However so far, the scarcity of the major population breeding stock was buffered by a high  
394 natural density of youngest fertile sea urchins (US) that would correspond to the future stock and  
395 that suggests the population sustainability could be partially supported by their offspring  
396 production (Farina etl a. 2018; Loi et al., 2017). Nevertheless, our results also highlight that the

397 intensive harvesting is drastically rescaling the population body-size breaking down the legal  
398 limit of the commercial size, affecting the portion of the youngest part of the breeding stock. The  
399 natural density of the US urchins was almost halved in five years. Thus, in accordance with the  
400 mortality increase of fertile individuals, a drastic drop of the reproductive potential of the H  
401 population has occurred and its self-sustenance could be seriously threatened in a decade. No data  
402 are available to estimate the genetic flow of the H population with outside populations, but our  
403 results indicate that if harvest pressure will not attenuate urchin recruitment has to rely totally on  
404 settlers coming from other populations.

405 Overall, the condition of continuous and inexorable deterioration of the population  
406 reproductive potential at the H locality seems to be a direct consequence of the illegal harvesting  
407 activity aiming to market the gonads of the individuals under the commercial size legal limit  
408 (Furesi et al. 2016). In fact, density of CS and US urchins at the C locality was also low during  
409 the last sampling year (P5), but, although the protection from illegal harvesting is evidently not  
410 still totally achieved in this MPA (Marra et al., 2016; Pieraccini, Coppa & De Lucia, 2016), the  
411 population structure is much more balanced in all its size-classes. Thus, on this population there  
412 is no evidence of a truncated demographic structure and the low density can depend on the low  
413 natural recruitment in this area or high post-settlement predation typical inside a Marine  
414 Protected Area (Guala et al. 2018; e.g., Farina et al. 2022).

415 Since the key role that *P. lividus* plays in the ecosystems (Boudouresque & Verlaque,  
416 2001), sea urchin harvesting can have indirect effects also at community scale (Kaiser &  
417 Jennings, 2001). In the Mediterranean Sea, the intensive harvesting of *P. lividus* encourages the  
418 proliferation of the competitor species *A. lixula* that is non-harvested by human and weakly  
419 preyed on in nature (Guidetti, 2004). However, the rescaling population body-size can also

420 impair the fertility in terms of gamete quality, size of the eggs (Moran & McAlister, 2009), larval  
421 development and survival (Berkeley, Chapman & Sogard, 2004), and it pushes the smallest  
422 fertile sea urchins to increase their reproductive investment (Fenberg & Roy, 2008). Consistently  
423 with this hypothesis, the annual mean of GSI was estimated to decline, whilst the AGO slightly  
424 increased over the five-year period of observations. Although a long time series of data needed to  
425 confirm these patterns, a compensatory response as reproductive investment of the survivors in  
426 gonad production rate or spawning intensity front to the lack of the largest sea urchins could  
427 have occurred. Overall, the opposite trends of the annual mean GSI and AGO can suggest a more  
428 frequent and constant gamete release. In effect, the reproductive investment is a well-  
429 documented compensatory response that induces physiological and behavioural changes in the  
430 survivors, such as alterations in the timing of maturation or growth and metabolism rates (Ali,  
431 Niecieza & Wootton, 2003; Enberg et al., 2012). If this mechanism was confirmed, the systematic  
432 removal of the major breeding stock of the population due to the human harvest could induce  
433 negative indirect effects also at community scale. In effect, the truncated demographic structure  
434 could lead to the exacerbation of the youngest sea urchin grazing on macroalgal community by  
435 accelerating their metabolisms to produce gonads and by increasing their gamete emission in the  
436 environment.

437

## 438 **Conclusions**

439

440       The intensive size-selective harvest has deeply changed the demographic structure of the  
441 sea urchin population and determined a drastic decrease of its reproductive potential, as it is  
442 affecting the portion of the youngest part of the breeding stock. However, an in-depth analysis of

443 the results also suggests possible stress effects on the youngest survivors that tend to increase  
444 their gonad production and the gamete release.

445 Due to such evidence, mitigating the ecological consequences of size-selective  
446 exploitation of commercial target species probably requires a shift in management strategies  
447 designed to modulate yields on the natural variability of size-classes characterizing the sea  
448 urchin population structure. However, to redefine the fishery history would be needed in order to  
449 address a balanced harvest of individual sizes, avoiding the complete depletion of the largest  
450 classes (e.g., Law & Plank 2018).

451 Such an approach should necessarily go through a shared vision with the stakeholders  
452 that includes rise of awareness of fishermen and much more effective control of illegal practices.  
453 Accordingly, a deeper understanding of the effects of the rescaling population body-size on the  
454 functional herbivore *P. lividus* can contribute to developing an ecosystem-based-management,  
455 ensuring the long-term persistence of the sustainable exploitation of the resource and the  
456 ecosystems conservation.

457

# Figure 1

## Map of the study area

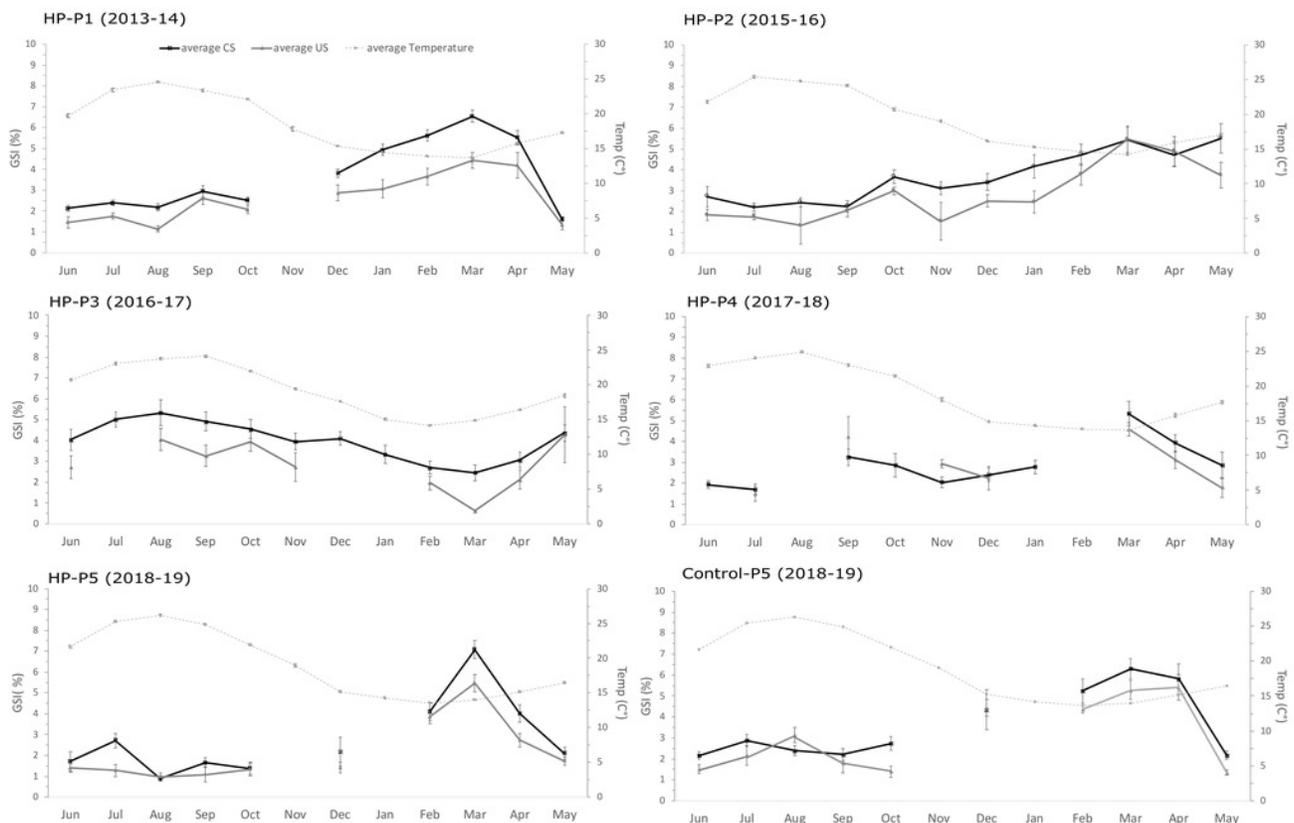

Su Pallosu Bay, in the North of Sinis Peninsula, is a heavy harvesting pressure locality (H), while Cape Seu is the Control locality (C) within the nearby Marine Protected Area monitored during the last period. Sampling sites are represented by the black dots.

## Figure 2

### Graphs of GSI over the sampling periods

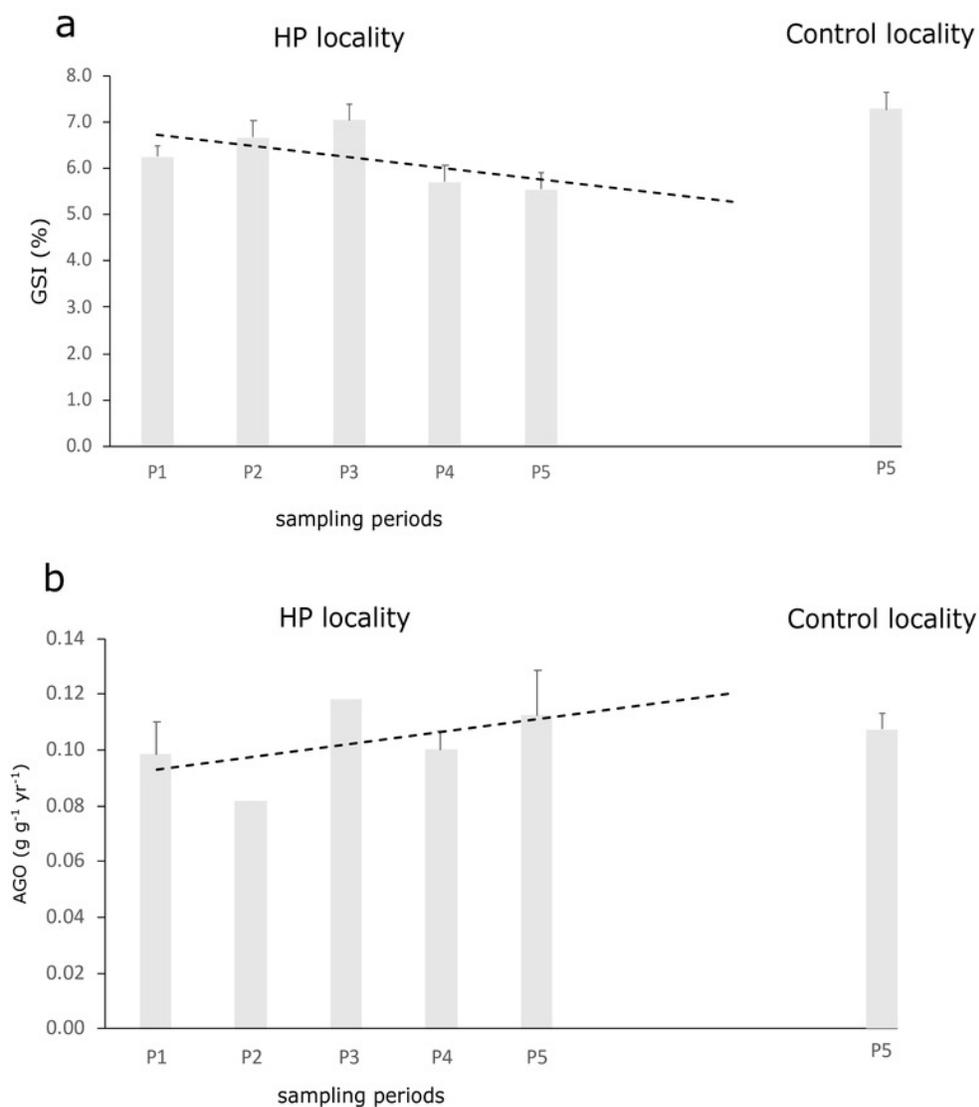

Annual trend of the GonadoSomatic Index during the sampling periods (P1-P5) in H locality and during the last sampling period (P5) in the C locality. GSI is represented as mean  $\pm$  standard error for CS size-class (black line) and US size-class (gray line). Due to adverse marine weather conditions, not all months were sampled. The reproductive cycle of 2014-15 was no estimated. Mean SST was also plotted (thinner gray line).

## Figure 3

Graphs of annual GSI and AGO over the sampling periods

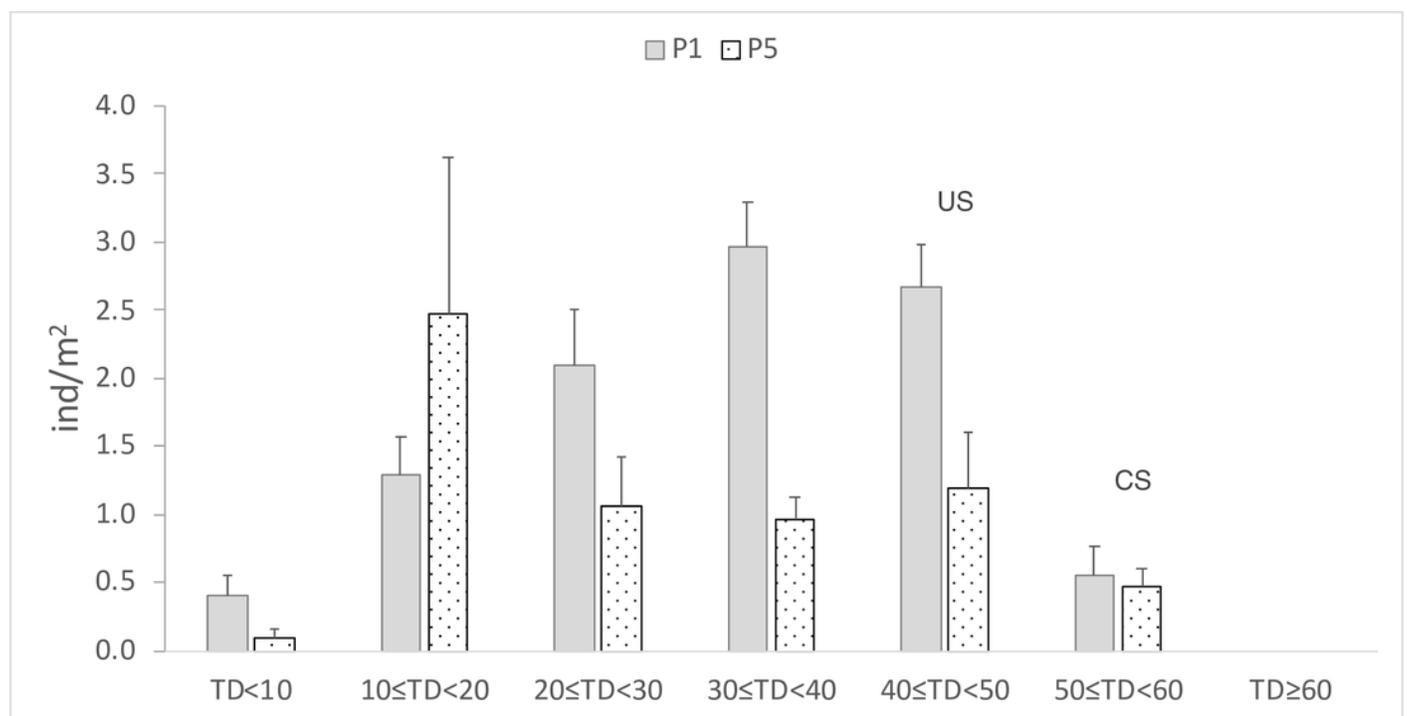

Trend across the five sampling periods of a) Annual mean GonadoSomatic Index ( $R^2=0.36$ ) and b) Annual Gamete Output ( $R^2=0.27$ ) of the H population and of the C population in the last sampling period.

## Figure 4

### Sea urchin population structure

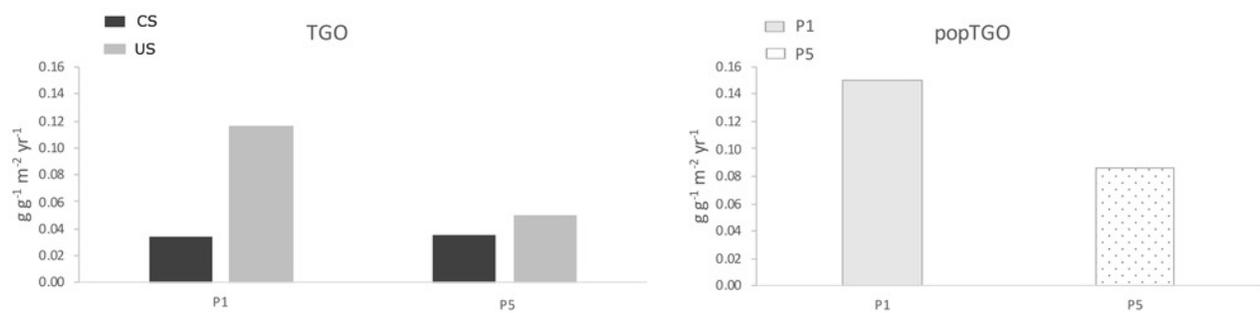

Size-density distribution of the sea urchin population at H locality in P1(full bars) and P5 (spotted bars) sampling periods. The range of the size classes is 10 mm of test diameter without spines (TD). Under Commercial (US) and Commercial size classes (CS) are indicated.

## Figure 5

### Population reproductive potential

Total Gamete Output (TGO) of the CS and US size-classes, and the reproductive potential of the whole population (popTGO) during P1 and P5 sampling periods.

**Table 1** (on next page)

GLMM results for GonadoSomatic Index in function of a) “period” and “size” across the five-year period and, b) “locality” and “size” during the last sampling period P5

The “temp”, “wave” and “site” are set as random effects. Estimate coefficient, Standard Error, z-value and significance level (p-value) are provided for fixed effects.

1

<b>a</b>	<b>Fixed effects</b>	<b>Estimate coeff</b>	<b>Std. error</b>	<b>z-value</b>	<b>p-value</b>

**Table 3** (on next page)

Summary table of GonadoSomatic Index, Individual Gamete Output and Annual Gamete Output

Table shows mean monthly GSI, IGO and AGO of H and C populations during the sampled periods (P1-P5). In the table are also reported the sea urchin density and the related reproductive potential of the H population in P1 and P5 and the C population in P5.

	Size-class	P1	P2	P3	P4	P5	Control (P5)
Avg. GSI (%)	CS	3.66±0.19	3.69±0.43	3.98±0.96	2.90±0.40	2.78±0.37	3.63±0.42
