**Background.** Animal communication consists of signal production and perception, which are crucial for social interactions. The main form used by anurans is auditory communication, in most cases produced as advertisement calls. Furthermore, sound perception happens mainly through an external tympanic membrane, and plays an important role in social behavior. In this study, we evaluated the influence of body and tympanic membrane sizes on call frequency across the phylogeny of anurans. **Methods.** We use data on snout-vent length, tympanic membrane diameter, and dominant frequency of the advertisement call from the literature and from natural history museum collections. We mapped these traits across the anuran phylogeny and tested different models of diversification. Our final dataset includes data on body size, tympanic membrane size, and call dominant frequency of 735 anuran species. **Results.** The best explanatory model includes body and tympanum size with no interaction term. Although our results show that call frequency is strongly constrained by body and tympanum size, we identify five evolutionary shifts in allometry from that ancestral constraint. We relate these evolutionary shifts to the background noise experienced by populations. We recognize two sources of background noise causing allometric shifts: i) environmental noise due to fast flowing water bodies and ii) biotic noise due to the sound emitted by other syntopic individuals. Body size is important for myriad ecological interactions and tympanum size is strongly associated with female call frequency preferences. Thus, allometric escape in frog calls might arise through environmental selection such as related to breeding in fast flowing or soundscape competition, as well as sexual selection linked to tympanum size.

## 30 Abstract

31 **Background.** Animal communication consists of signal production and perception, which are  
32 crucial for social interactions. The main form used by anurans is auditory communication, in  
33 most cases produced as advertisement calls. Furthermore, sound perception happens mainly  
34 through an external tympanic membrane, and plays an important role in social behavior. In this  
35 study, we evaluated the influence of body and tympanic membrane sizes on call frequency across  
36 the phylogeny of anurans.37 **Methods.** We use data on snout-vent length, tympanic membrane diameter, and dominant  
38 frequency of the advertisement call from the literature and from natural history museum  
39 collections. We mapped these traits across the anuran phylogeny and tested different models of

40 diversification. Our final dataset includes data on body size, tympanic membrane size, and call  
41 dominant frequency of 735 anuran species.

42 **Results.** The best explanatory model includes body and tympanum size with no interaction term.  
43 Although our results show that call frequency is strongly constrained by body and tympanum  
44 size, we identify five evolutionary shifts in allometry from that ancestral constraint. We relate  
45 these evolutionary shifts to the background noise experienced by populations. We recognize two  
46 sources of background noise causing allometric shifts: i) environmental noise due to fast flowing  
47 water bodies and ii) biotic noise due to the sound emitted by other syntopic individuals. Body  
48 size is important for myriad ecological interactions and tympanum size is strongly associated  
49 with female call frequency preferences. Thus, allometric escape in frog calls might arise through  
50 environmental selection such as related to breeding in fast flowing or soundscape competition, as  
51 well as sexual selection linked to tympanum size.

52

## 53 Introduction

54 Communication between animals involves signal production and perception. Signal production is  
55 a balance of energy cost and efficiency in information transmission, and it can be highly  
56 variable. Communication signal production can be visual (Osorio & Vorobyev, 2008), olfactory  
57 (Bossert & Wilson, 1963), tactile (Weber, 1973; Cerrone, 2019), electric (Bratton & Ayers,  
58 1987) or acoustic (Suthers et al., 2016). In addition, signal perception is relevant for successfully  
59 accomplishing communication, which is related to the efficiency of signal transmission, and  
60 consequently influence evolution in communication systems (Endler, 1993).

61 Among different forms of signal production, acoustic signals are one of the most widespread  
62 across animals, present in invertebrates (Wenner, 1964) and in all classes of vertebrates (Peters  
63 & Ploog, 1973; Ladich, 2019). These signals are shaped by diverse selective pressures, such as  
64 species recognition (Claridge & de Vrijer, 1994; Gerhardt & Bee, 2007), predator pressure  
65 (Cade, 1975; Tuttle & Ryan, 1981), and sexual selection (Rebouças, Augusto-Alves & Toledo,  
66 2020). Among the advantages of acoustic emission are the relatively fast signal transmission,  
67 orientation and its complexity. For instance, sounds can be subdivided into components such as  
68 frequency, amplitude, duration, and emission rate, which can be decoded into different  
69 information (Lopez & Narins, 1991; Morais et al., 2012). However, acoustic communication can  
70 be masked by the background noise, jeopardizing communication success (Duarte et al., 2019;  
71 Lima et al., 2022). Moreover, conspicuous acoustic signals can attract acoustically oriented  
72 predators (Tuttle & Ryan, 1981). In most cases, sound perception is closely related to receiver  
73 organs and structures, which are quite diverse and can improve signal sensitivity in such a  
74 context. In contrast, anurans can also perceive sounds using novel adaptations, such as in the tiny  
75 pumpkin toadlet from the Atlantic Rainforest, *Brachycephalus rotenbergae*. In this species, the  
76 inner ear (here the basilar recess) is not connected to its nervous system, suggesting that high  
77 frequency sound vibrations (as the sound of their own calls) cannot be recognized. However, low  
78 frequency vibrations can be perceived through their arms, which transmit sound to the inner ear  
79 through bone vibrations (Goutte et al., 2017).

80 Anurans present a range of communication signals (e.g., Cardoso & Heyer, 1995; Toledo et al.,  
81 2015; Narins, 2019), which can be used independently or in combination depending on the  
82 behavioral context (Hartmann et al., 2005; Lourenço-de-Moraes et al., 2016; Rebouças, Augusto-  
83 Alves & Toledo, 2020; Rebouças, 2022). However, the most used signal in anurans is  
84 vocalizations (Toledo et al., 2015; Köhler et al., 2017). Anurans present several vocalization or  
85 calls types used in social contexts, such as reproductive, defensive, and aggressive calls.  
86 Advertisement calls, one form of reproductive call, are the most widespread communication  
87 strategy in anurans, which are generally emitted to attract females and guard territories (Toledo  
88 et al., 2015; Köhler et al., 2017). The variation of these calls in both spectral and temporal  
89 parameters is also diverse. Although it is well known that temporal parameters of calls, such as  
90 call rate and duration, are influenced by the environmental temperature (Lingnau & Bastos,  
91 2007; Love & Bee, 2010; Lima et al., 2022), spectral parameters in turn are less so. Spectral  
92 parameters of anuran calls are generated by anatomical structures, and consequently constrained  
93 by the body size of the calling individual (Rebouças, Augusto-Alves & Toledo, 2020; Tonini et  
94 al., 2020). Vocalizations in anurans are produced by the contraction of trunk muscles leading the  
95 air passage from the lungs to the buccal cavity, passing through the larynx where it causes the  
96 vocal cords to vibrate and, finally, produce sounds (Colafrancesco & Gridi-Papp, 2016). These  
97 sounds are further modified by the laryngeal muscles (Gridi-Papp, 2008; Ryan & Guerra, 2014)  
98 and other related structures, such as buccal cavity and vocal sac apertures (Kime, Ryan &  
99 Wilson, 2013).

100 Besides call emission, call perception also plays a role in anuran social contexts. Anurans use  
101 calls to assess other individuals' physical condition and, consequently, respond in terms of  
102 territorial defense (Foratto et al., 2021; Rebouças, 2022). Thus, the information contained in calls  
103 determines territorial segregation, reproduction, and their fitness (e.g., Giasson & Haddad, 2006;  
104 Dautel et al., 2011). For most anurans, the tympanic membrane is the first structure to capture the  
105 external sound waves, transmitting acoustic vibrations to their inner ear. In general, it is  
106 connected to the otic capsule via extrastapes and stapes, also referred to as extracolumella and  
107 columella (Van Dijk et al., 2011; Mason et al., 2015). Some studies have reported that there is a  
108 direct relationship between size and acoustic sensitivity, which means that the larger the  
109 individuals, with larger tympanic membranes, the better the sound perception (Fox, 1995; James  
110 et al., 2022). These relations are physically constrained: larger individuals also have more  
111 massive vocals chords, which tends to result in lower call frequencies (Ryan, 1988a); and larger  
112 individuals also present larger tympanic membranes, which are more prone to vibrate with  
113 sounds with lower amplitudes, which results in a more sensitive ear (Fox, 1995). Thus, an escape  
114 from these ancestral relationships must be rare, and probably a consequence of a greater selective  
115 pressure resulting from fundamental physical constraints. Also, most studies have concentrated  
116 on a few species, and a broader overview of allometric relationships between tympanum, body  
117 size, and call frequency across anurans is still lacking.

118 There is a general understanding that the advertisement call frequency of most anuran species is  
119 correlated with individual's body size; i.e., the larger the frog, the lower its advertisement call

120 frequency (Ryan, 1988a). However, this pattern was not observed for some anuran lineages (e.g.  
121 Southeast Asian ranids, Ranid frogs, Fitzinger Neotropical tree frogs and Poison frogs) that  
122 evolved to have divergent allometric relationships (Tonini et al., 2020). Moreover, some recent  
123 evidence suggests that anatomical structures closely related to communication, such as tympanic  
124 membrane, must be a constraint in the context of the relation between call frequency and sound  
125 perception (James et al., 2022). Consequently, an analysis using a phylogenetic approach to test  
126 the relation between sound emission and perception should shed light on this relationship and  
127 improve the understanding of groups that previously presented allometric escapes. This study  
128 aims to evaluate the influence of body and tympanum sizes on advertisement call frequency  
129 across the anuran phylogeny.

130

## 131 **Materials & Methods**

132 Bioacoustic and morphometric data

133 We assembled data on mean advertisement calls dominant frequency, which is the call frequency  
134 with the higher energy, males' snout-vent length (SVL; mm; hereafter, called simply body size)  
135 and tympanum diameter (TD; mm; hereafter, called simply tympanum size; Fig. 1) of adult male  
136 frogs from literature and complemented with measurements from specimens deposited in the  
137 Museu de Diversidade Biológica (MDBio), Universidade de Campinas, Brazil (see  
138 Supplementary Material). We used dominant frequency of advertisement call because, among  
139 variables in anurans' call, this is stereotyped and not influenced by environmental conditions,  
140 such as temperature and humidity (Köhler et al., 2017), and it is commonly used in species  
141 description (e.g., Toledo, Ribeiro & Haddad, 2007; Köhler et al., 2017; de Andrade et al., 2020).  
142 Also, we only used measurements from male individuals because they are more available in  
143 literature than measurements from females, which allowed us to perform the analysis in large  
144 scale. Finally, we were not able to include those species which present no visible tympanum (or  
145 even no tympanum), since measurement in this case are only possible through anatomical  
146 desiccation, which is not commonly available in the literature.

147 Many species present a sexual size dimorphism (review in Monnet & Cherry, 2002); thus, we  
148 only considered males for the analysis from type series in species descriptions. We were not able  
149 to include the information for those species for which there are only females or juveniles in the  
150 type series. In several cases, males presented oval-shaped tympana. In these cases, we considered  
151 only tympanum length for our purposes. The dataset used here is available in supplementary  
152 material following the current nomenclature available in Frost (2023).

153

154 Phylogenetic comparative analysis

155 We trimmed the amphibian phylogeny (Jetz & Pyron, 2018) to include only species present in  
156 our dataset (See Supplementary Material). We log-transformed the data on dominant frequency,  
157 snout-vent length, and tympanum size. We estimated the phylogenetic signal of each traits using  
158 Bloomberg's K (Blomberg, Garland Jr & Ives, 2003) and Pagel's lambda (Pagel, 1999) in  
159 phytools (Revell, 2012). In addition, we tested the fit of three nested models using PGLS, 1) DF

160 ~ SVL, 2)  $DF \sim SVL + TD$  and 3)  $DF \sim SVL + TD + SVL*TD$ , and compared them using  
161 Akaike's Information Criterion (AIC) and Bayesian Information Criterion (BIC). The best fit  
162 model was implemented in the R v. 4.0.5 (R Core Team, 2022) package bayou. The bayou  
163 package fits Bayesian reversible-jump multi-optima Ornstein-Uhlenbeck (OU) models to  
164 phylogenetic comparative data (Uyeda & Harmon, 2014). We used the bayou model to identify  
165 the location across the anuran phylogeny, support, and magnitude of shifts in intercept and slope  
166 of the scaling relationship between dominant frequency, body size, and tympanum size. Our  
167 expectation is that most frog species adhere to a background allometric scaling given the strong  
168 constraint imposed by body size on functional and anatomical traits. Here, we ask whether some  
169 frog species would represent shifts in the allometric scaling of dominant frequency with body  
170 and tympanum sizes. We used as prior a half-Cauchy distribution for  $a$  and  $s^2$ , and normal  
171 distribution for  $b$  and  $\theta$ . In addition, we included 0.1 of measurement error to the data. We tuned  
172 model parameters to have acceptance ratios between 0.2-0.4. We ran the models four times, each  
173 run had 10 million generations, and we used the first 30% as burn, and filtered the results to  
174 shifts with 0.75 posterior probability or higher. We check whether all runs would result in similar  
175 anuran species identified as having distinct scaling compared to most other frog species. Shifts  
176 with less than four species were not considered. Analyses and data visualization were performed  
177 in R using packages ape (Paradis & Schliep, 2019), phytools (Revell, 2012), Geiger (Pennell et  
178 al., 2014), ggtree (Yu et al., 2017).

179

## 180 Results

181 We compiled complete information (advertisement call dominant frequency, body size,  
182 tympanum size, and phylogeny) of 735 species. Body (Fig. 2A;  $r^2 = 0.452$ ,  $p < 0.001$ ) and  
183 tympanum (Fig. 2B;  $r^2 = 0.311$ ,  $p < 0.001$ ) sizes are inversely correlated with the dominant  
184 frequency but directly correlated with each other (Fig. 2C;  $r^2 = 0.714$ ,  $p < 0.001$ ). Thus, large  
185 frogs tend to have large tympana and call at lower dominant frequency compared to smaller  
186 frogs, confirming the strong allometric relationship between these traits. After phylogeny is  
187 taken into account, the influence of tympanum size is attenuated in relation to the model with no  
188 phylogeny, which is shown by the difference in slope between regression lines, but it still shows  
189 significant correlation (Fig. 3). All three traits have significant phylogenetic signal for both  
190 Bloomberg's  $K$  ( $K_{SVL} = 0.27$ ,  $p = 0.001$ ;  $K_{TYM} = 0.28$ ,  $p = 0.001$ ;  $K_{DF} = 0.13$ ,  $p = 0.001$ ) and  
191 Pagel's lambda ( $\lambda_{SVL} = 0.85$ ,  $p < 0.001$ ;  $\lambda_{TYM} = 0.85$ ,  $p < 0.001$ ;  $\lambda_{DF} = 0.72$ ,  $p < 0.001$ ).  
192 Our model comparison results show that models 2 ( $DF \sim SVL + TD$ ) and 3 ( $DF \sim SVL + TD +$   
193  $SVL*TD$ ) presented similar marginal likelihood and BIC (Table 1). Although there is a strong  
194 allometric relationship between body size and tympanum size, we consider that the simplest  
195 model with no interaction between variables provided a better fit to the data ( $\theta DF \sim \beta SVL +$   
196  $\beta TD$ , Table 2), and used this model to test shifts in evolutionary allometry across anurans.  
197 Despite the great diversity of body and tympanum sizes and dominant frequency across frogs, we  
198 confirm the prior expectation that most frog species adhere to a single allometric scaling  
199 relationship. However, we identify five shifts from the evolutionary constraint imposed by body

200 size on tympanum size and dominant frequency (Table 2, Fig. 3). In Ranidae, we observe two  
201 embedded shifts: 1) *Rana* and *Pelophylax*, and 2) *Hylarana*, *Odorrana*, *Babina*, and *Amolops*;  
202 thus, we consider, for our purposes, as a single shift shared by their most recent common  
203 ancestral. Then, in Ranidae, we observe two regime shifts: a shift comprising *Huia* and  
204 *Meristogenys* (hereafter called Asian ranids), and another shift comprising *Rana* and *Pelophylax*,  
205 *Hylarana*, *Odorrana*, *Babina* and *Amolops* (hereafter called Ranid frogs).  
206 Among other regime shifts, in *Dendropsophus* (hereafter Fitzinger Neotropical Treefrogs) and  
207 Leiuperinae (hereafter Neotropical swamp frogs) we observe a negative slope, as most of  
208 anurans, but with a different intercept for the allometric relationship. In Fitzinger Neotropical  
209 treefrogs, sound frequency is decoupled from body size but still negatively correlated to  
210 tympanum size, while in Neotropical swamp frogs the dominant frequency is associated with  
211 body and tympanum size (Table 2). In Hylodidae (hereafter Neotropical torrent frogs), Asian  
212 ranids, and Ranid frogs, the evolution of dominant frequency is decoupled from the constraint of  
213 body and tympanum size, which is shown by the zero slope; whereas in Ranid frogs we observe  
214 the inverse situation, in which sound frequency is decoupled from tympanum size but still  
215 persists dependent on body size. In Asian ranids, sound frequency is dissociated from tympanum  
216 size and positively correlated to body size, which is unique and indicates that large species  
217 within those genera tend to call at higher frequency as opposed to what is expected for most  
218 other frog species (Fig. 4 and 5).

219

## 220 Discussion

221 Frogs have a wide range of body and tympanum size and call frequency, as well as a great  
222 diversity of reproductive behaviors (Haddad & Prado, 2005; Nunes-de-Almeida, Haddad &  
223 Toledo, 2021). In addition, frogs have colonized a variety of environments across all continents  
224 except Antarctica. Despite the vast environmental complexity in terms of biotic and abiotic  
225 factors presenting a myriad of selection pressures, the constraint of body size overcomes those  
226 selective pressures and strongly constrain the relationship between sound frequency and  
227 tympanum size. Our results show that most frog species adhere to a single allometric scaling  
228 relationship between advertisement call dominant frequency, body, and tympanum size.  
229 Although previously reported for the relationship between call dominant frequency and body size  
230 (Tonini et al., 2020; James et al., 2022), we observe here allometric escapes for the relationship  
231 between dominant frequency and tympanum size as well.  
232 In at least four groups, shifts appear to be independent, considering the great phylogenetic  
233 distance between them (Fig. 3) – out of the five shifts observed here, two of them are within  
234 ranids. Additionally, our results include allometric shifts for three of four previously reported  
235 groups (Asian ranids, Fitzinger Neotropical treefrogs, and ranid frogs) (Tonini et al., 2020). We  
236 did not observe any allometric shift including tympanum size for Neotropical poison frogs, as  
237 previously reported, and we estimate a shift for Neotropical swamp frogs and Neotropical torrent  
238 frogs, which were not observed previously (Tonini et al., 2020). Thus, considering that Tonini et  
239 al. (2020) only evaluated variables related to sound emission and James et al. (2022) evaluated

240 the tympanum size allometry (linked to sound perception) of a reduced number of species (81  
241 spp., with little overlap for all measurements), our study represents a broader estimation of  
242 allometric shifts across the anuran tree of life.

243 Our results show that call frequency is dependent on the size of individuals and correlated with  
244 tympanum size. Advertisement calls in anurans, mostly emitted by males, are used both to attract  
245 mates and to segregate calling males (Toledo et al., 2015). Accordingly, we suggest two sets of  
246 limiting factors: internal, which constrain the vocalization emission, such as body size and other  
247 physiological implications (Köhler et al., 2017); and external, which constrain the understanding  
248 of social context through the calls of other males, such as inner ear structures, amphibian papilla  
249 (for lower frequencies), and basilar papilla (for higher frequencies) (Schoffelen, Segenhout &  
250 Van Dijk, 2008). Among species groups representing allometric shifts, Fitzinger Neotropical  
251 treefrogs and Neotropical swamp frogs showed a similar negative relation between tympanum  
252 size and dominant frequency (i.e., for sound sensitivity). This relationship was distinct from all  
253 other groups (Asian ranids, Ranid frogs and Neotropical torrent frogs), which possibly indicates  
254 different selective pressures for sound perception. In relation to sound emission (i.e., size and  
255 dominant frequency), for Fitzinger Neotropical treefrogs, the sound frequency was decoupled  
256 from body size and Neotropical swamp frogs remained size dependent with species calling at  
257 lower frequency than expected. For Ranid frogs (referred as *Rana* and *Pelophylax*, *Hylarana*,  
258 *Odorrana*, *Babina*, and *Amolops* in Table 1), it is similar to Fitzinger Neotropical treefrogs and  
259 Neotropical swamp frogs, but for Neotropical torrent frogs and Asian ranids, the relation was  
260 inverse, with larger individuals presenting higher dominant frequencies.

261 Some causes of allometric shifts might be common for all groups of frogs in a certain way. For  
262 example, species of Asian ranids, ranid frogs, and Neotropical torrent frogs call near waterfalls  
263 and fast flowing water bodies. These environments are highly noisy, and consequently, over the  
264 time can limit calls to frequencies higher than the background noise (Tonini et al., 2020). In  
265 *Crossodactylus schimidti*, for example, males show a short-term adjustment for dominant  
266 frequency in face of background noise frequency (Vidigal et al., 2018). Similar results were  
267 found for other species in the genus (e.g., *C. gaudichaudii* and *C. werneri*) and for most of  
268 Hylodes species as well (e.g., *H. charadranaetes*, *H. glaber*, and *H. malhagaesi*) (Augusto-  
269 Alves, Dena & Toledo, 2021). Among species of the other two groups recovered as a shifts, *Huia*  
270 *cavitympanum* for example present most of their communication through ultrasonic calls,  
271 ranging from 5 to 25 kHz (Arch, Grafe & Narins, 2008), as do *Wijayarana masonii* (formerly *H.*  
272 *masonii*) (Boonman & Kurniati, 2011). Similar results were also found for *Amolops tormotus*  
273 (Feng et al., 2006) and *Odorrana graminea* (Shen et al., 2011).

274 The Fitzinger Neotropical treefrogs and Neotropical swamp frogs are not known to call in fast  
275 flowing water environments, but our results also indicate them as an allometric scape from the  
276 ancestral body size constraint. Species of these two groups use ponds and swamps as  
277 reproductive sites. Species in both groups reproduce year around, frequently with hundreds of  
278 individuals calling at the same time very closely from each other in lek (Barreto & Andrade,  
279 1995; Camargo et al., 2005; Abrunhosa, Wogel & Pombal, 2006; Curi et al., 2014; Pompeu, de

280 Sa & Haddad, 2020). In this case, the selective force causing is not fast flowing water but  
281 hypothesized to be the noise of other organisms that produce sounds, including vertebrates and  
282 invertebrates, that may impose similar selective pressure to individuals as fast flowing streams  
283 (e.g., Both & Grant, 2012; Lima et al., 2022). The environment in which these species tend to  
284 live might also influence the optimal call frequency (Marten, Quine & Marler, 1977; Fricke,  
285 1984). For a given body size, individuals of Fitzinger Neotropical treefrogs and Neotropical  
286 swamps frogs call at a lower frequency than expected, which might represent an advantage in  
287 territorial dispute and female attraction. The fitness of males is commonly evaluated through call  
288 for both males and females (Rebouças, Augusto-Alves & Toledo, 2020; Rebouças, 2022), since  
289 lower-frequency calls indicate larger males (Tonini et al., 2020), which may present an  
290 advantage in disputes (Ryan, 1988b). Consequently, larger males, which spend less energy  
291 calling in lower frequencies, present a higher probability to win disputes, and consequently better  
292 protect the reproductive territory. In this scenario, females tend to be more attracted by those  
293 males through lower-frequency calls (Ryan, 1988b). In some cases, males could even present a  
294 call with a frequency lower than predicted by its size, which effort the sexual selection role of  
295 calls (Rebouças, Augusto-Alves & Toledo, 2020). In these two groups, the selective constraint of  
296 body size on sound frequency and tympanum size is weaker compared to other frogs, which is  
297 shown by the lower slope value relative to the background regime. Once sound frequency and  
298 tympanum size are less constrained by body size, call frequency not necessarily would indicate  
299 larger sizes. Therefore, selection on tympanum size and male sound frequency could result from  
300 other parts of the male advertisement call, such as temporal parameters or behavioral interactions  
301 that include territorial or mating displays. However, an intraspecific relationship between call  
302 frequency / body size / tympanum size could still be present, and further analysis should evaluate  
303 it considering an within species variation, mainly in these groups that presented allometric  
304 escapes.

305

## 306 **Conclusions**

307 This study evaluated allometric escape across the anuran phylogeny using parameters of call  
308 emission (i.e., males' call frequency) and parameters of call sensitivity (i.e., tympanum size). We  
309 showed that the inclusion of tympanum size allows the identification of new acoustic allometric  
310 shifts across anurans. Also, we hypothesize that shifts might result from selective pressure of  
311 background noise and those that reproduce in high species-rich or overpopulated ponds. Finally,  
312 our observations provide insights for future studies which aim to evaluate sound communication  
313 in anurans, and additional conclusions could be reached with measurements of females in the  
314 analysis.

315

## 316 **Acknowledgements**

317 We thank to Victor Fávoro, Isabel Máximo, and João Pedro Bovolon Thomaz for their help in  
318 accessing individuals in museum; Ulmar Grafe, Carlos Henrique Luz Nunes-de-Almeida, Václav  
319 Gvoždík, and João Luiz Gasparini by kindly allow us to use their photos, and Alexander Pyron

320 by its review on the manuscript. We also thank to Museu de Diversidade Biológica for allow us  
321 to access the specimens.

# Figure 1

## Diversity of tympana in Anura

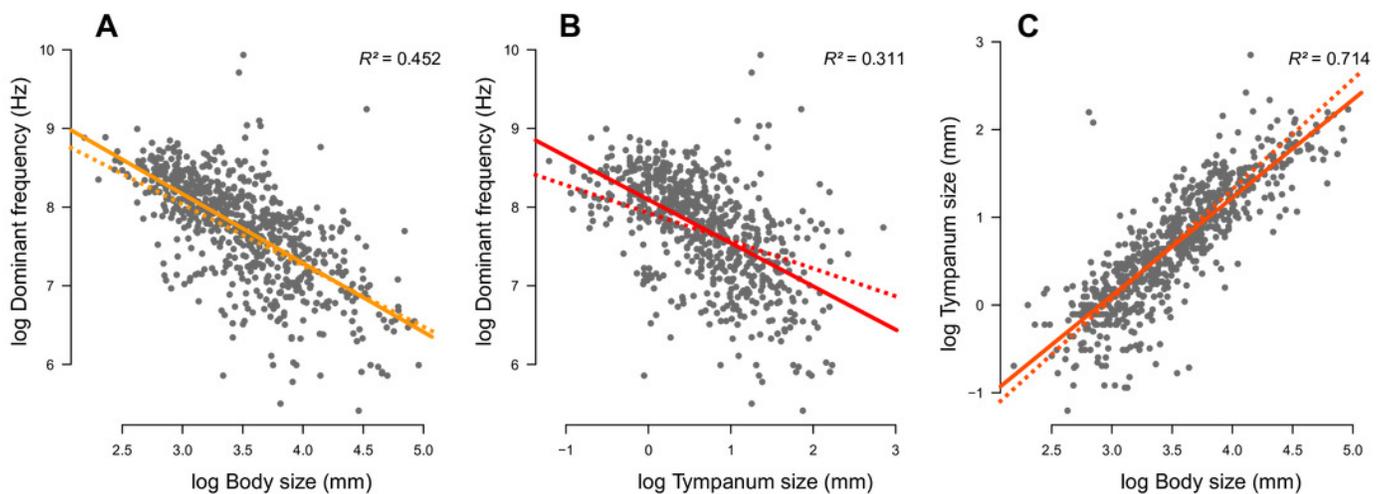

Concave tympanum of *Huia cavitympanum* (photo by Ulmar Grafe) (A); enlarged tympanum in *Thoropa megatympanum* (photo by Carlos Henrique Luz Nunes-de-Almeida) (B); regular tympanum in *Hylodes cardosoi* (photo by Luís Felipe Toledo) (C); tympanum with external apparatus in *Petropedetes vulpiae* (photo by Václav Gvoždík) (D); reduced tympanum in *Megaelosia apuana* (photo by João Luiz Gasparini) (E); and tympanum not externally visible in *Cycloramphus rhyakonastes* (photo by Luís Felipe Toledo) (F) (individuals present different sizes).

## Figure 2

Linear regression (solid line) and phylogenetic generalized linear squared models (dotted line).

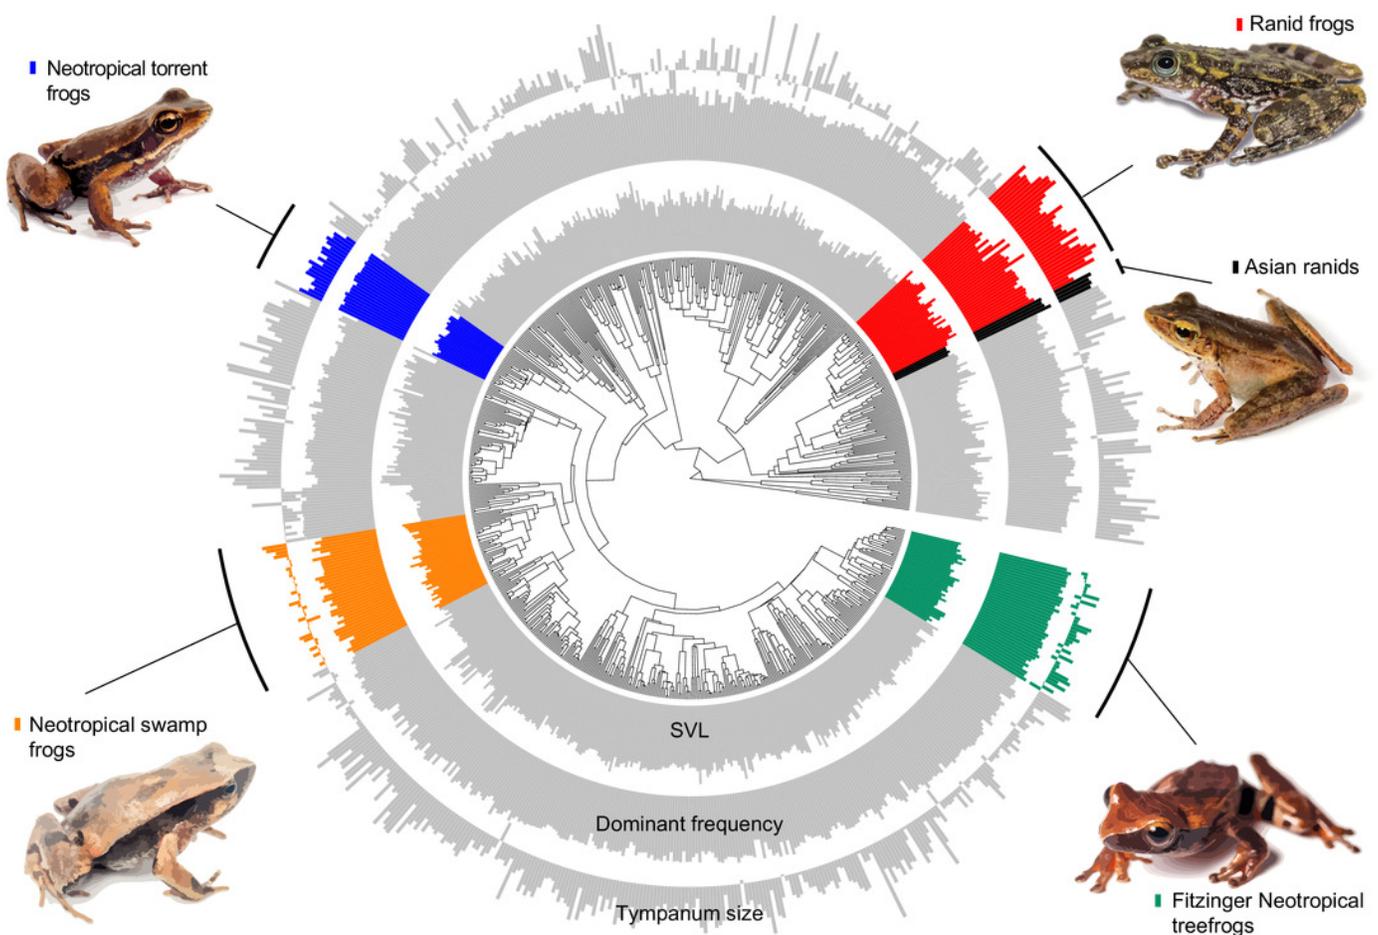

body and tympanum sizes explain 45% and 31% of the diversity of dominant frequency, respectively. Moreover, body size explains 71% of the variation in tympanum size.

## Figure 3

### Measured variables on the phylogeny

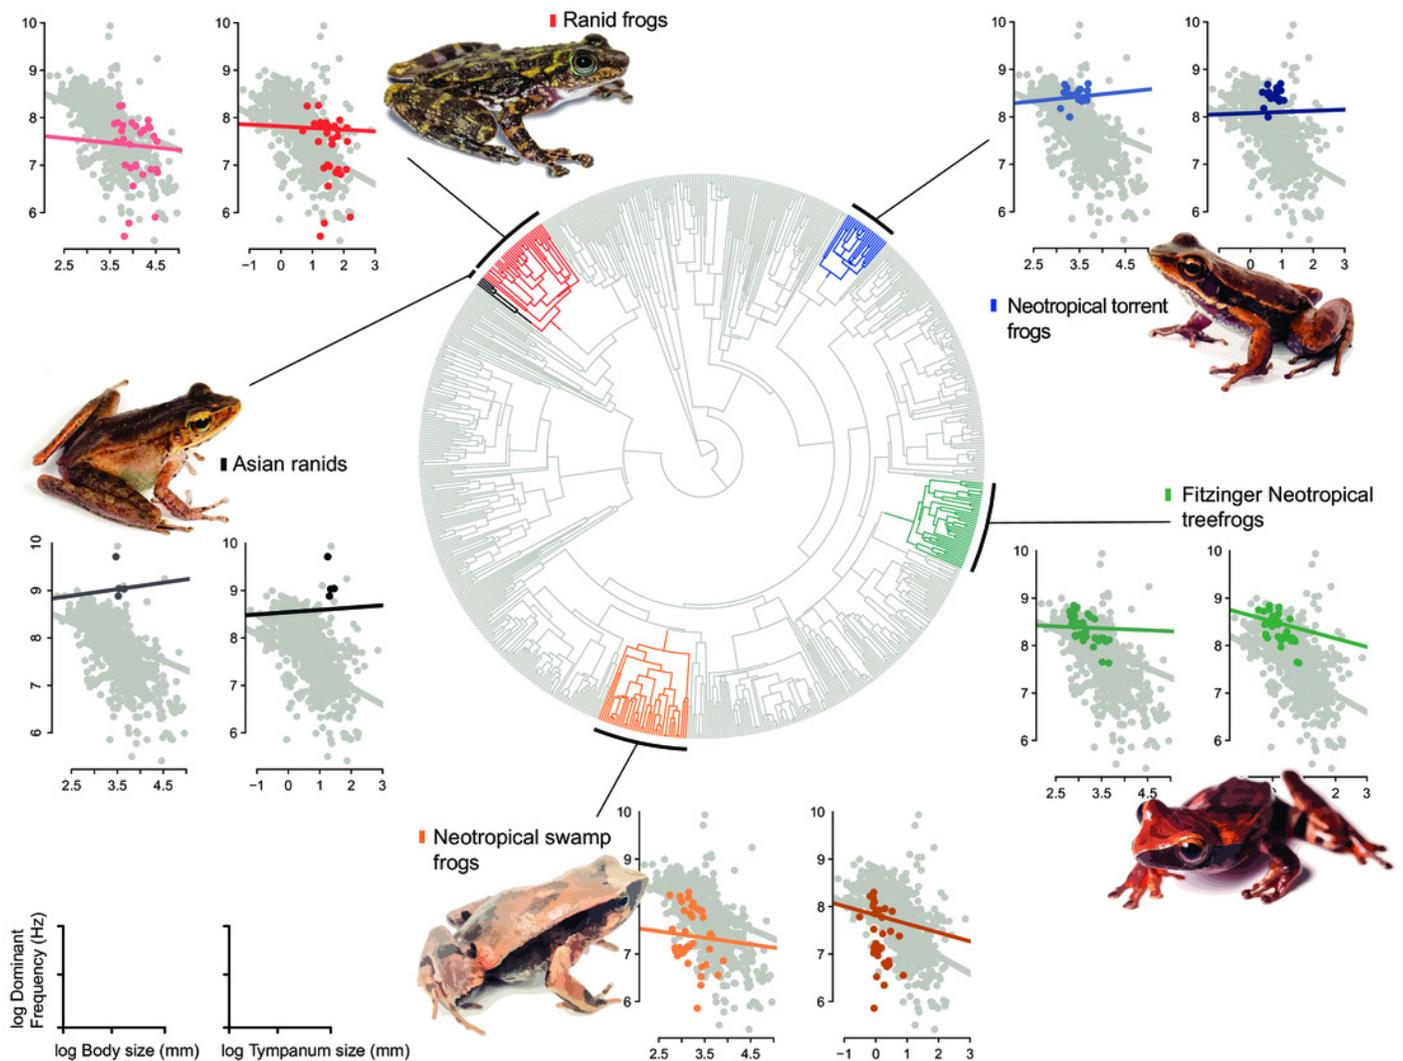

Barplot of measured variables of the 735 species included in our estimatives. Inner circle represent the Snout-vent length (SVL), mid circle represent dominant frequency and outer circle represent tympanum size. Values are log-transformed.

## Figure 4

### Allometric shifts across anuran phylogeny

Relation between dominant frequency and body size (left chart) and between advertisement call dominant frequency and tympanum size (right chart). The general relationship for all sampled species is in grey, and specific relation are coloured as follows: Asian ranids (black), Ranid frogs (red), Neotropical torrent frogs (blue), Fitzinger Neotropical treefrogs (green) and Neotropical swamp frogs (orange).

## Figure 5

Estimates of intercept and slopes of model

Density plots showing the uncertainty in model parameter estimates of intercept ( $\theta_{\text{Dominant frequency}}$ ) and slopes ( $\beta_{\text{Snout-vent length}}$  and  $\beta_{\text{Tympanum size}}$ ) for each escaped lineage: Hylodidae (blue), *Dendropsophus* (green), Leiuperinae (orange), other ranids (red) and *Huia* + *Meristogenys* (black).
