

# Decadal comparison of a diminishing coral community: a case study using demographics to advance inferences of community status

Margaret Miller, Dana E Williams, Brittany E Huntington, Gregory A Piniak, Mark JA Vermeij

The most common coral monitoring methods estimate coral abundance as percent cover, either via *in situ* observations or derived from images. In recent years, growing interest and effort has focused on colony-based (demographic) data to assess the status of coral populations and communities. In this study, we infer changes in coral communities from two separate data sets (photo-derived percent cover estimates, 2002-12, and opportunistic *in situ* demographic sampling, 2004 and 2012) in order to more fully understand the decade-scale changes observed at a small, uninhabited Caribbean island. Photo-derived percent cover documented drastic declines in coral abundance including disproportionate declines in *Orbicella* spp. While overall *in situ* estimates of total coral density were not different between years, densities of several rarer taxa were. *Meandrina meandrites* and *Stephanocoenia intersepta* increased while *Leptoseris cucullata* decreased significantly, changes that were not discernable from the photo-derived cover estimates. Demographic data also showed significant shifts to larger colony sizes (both increased mean colony sizes and increased negative skewness of size frequency distributions, but similar maximum colony sizes) for most taxa likely indicating reduced recruitment. *Orbicella* spp. differed from this general pattern, significantly shifting to smaller colony sizes due to partial mortality. Both approaches detected significant decadal changes in coral community structure at Navassa, though the demographic sampling provided better resolution of more subtle, taxon-specific changes.

3 advance inferences of community status

4

5 ABSTRACT: The most common coral monitoring methods estimate coral abundance as percent  
6 cover, either via *in situ* observations or derived from images. In recent years, growing interest  
7 and effort has focused on colony-based (demographic) data to assess the status of coral  
8 populations and communities. In this study, we relied on two separate data sets (photo-derived  
9 percent cover estimates, 2002-12, and opportunistic *in situ* demographic sampling, 2004 and  
10 2012) to more fully infer decadal changes in coral communities at a small, uninhabited  
11 Caribbean island. Photo-derived percent cover documented drastic declines in coral abundance  
12 including disproportionate declines in *Orbicella* spp. While overall *in situ* estimates of total  
13 coral density were not different between years, densities of several rarer taxa were. *Meandrina*  
14 *meandrites* and *Stephanocoenia intersepta* increased while *Leptoseris cucullata* decreased  
15 significantly, changes that were not discernable from the photo-derived cover estimates.  
16 Demographic data also showed significant shifts to larger colony sizes (both increased mean  
17 colony sizes and increased negative skewness of size frequency distributions, but similar  
18 maximum colony sizes) for most taxa likely indicating reduced recruitment. *Orbicella* spp.  
19 differed from this general pattern, significantly shifting to smaller colony sizes due to partial  
20 mortality. Both approaches detected significant decadal changes in coral community structure at  
21 Navassa, though the demographic sampling provided better resolution of more subtle, taxon-  
22 specific changes.

## 34 INTRODUCTION:

35 Coral cover and community composition have been established as the standard metrics  
36 for reef monitoring programs. Visual census techniques have been around for decades (Stoddart  
37 & Johannes 1978), and gained early recognition for their utility in understanding population  
38 dynamics (Hughes 1984) and disturbance/recovery dynamics (e.g., Done 1985). These  
39 techniques provide a valuable, albeit general, overview of the status of reef communities, but  
40 offer little insight on the processes that drive the observed patterns. Coral cover also carries  
41 relatively low signal:noise ratio in depauperate reef areas (e.g. <10% or even 1-2% cover) as is  
42 characteristic of many modern Atlantic/Caribbean reefs (Jackson et al. 2014), making change  
43 detection difficult without substantive (and perhaps unrealistic) increase in sample size (Molloy  
44 et al. 2013). As a result, there has been increasing interest (and implementation) in expanding  
45 from simple percent cover to more refined, process-based measures.

46 Coral demographic parameters have only recently been included in comprehensive coral  
47 monitoring programs but may be a valuable supplement to percent cover data, as a demographic  
48 approach offers species-specific and mechanistic insights into observed changes in percent cover.  
49 Regional programs in south Florida (e.g., Smith et al. 2011; and Florida Reef Resilience  
50 Program, [frp.org/coral-monitoring](http://frp.org/coral-monitoring)) and internationally (e.g., Atlantic and Gulf Rapid Reef  
51 Assessment: Lang & Ginsburg 2006; IUCN: Obura & Grimsditch 2009) began implementing  
52 colony based size and density measures in the early-mid 2000s. There is a wealth of ecological  
53 theory to support analysis and interpretation of coral colony-based demographic data (Bak &  
54 Meesters 1998; Vermeij & Bak 2002) whereby changes in the size structure of a population is  
55 used to infer underlying ecological processes. Meanwhile, the collection of such data over large  
56 programs and time frames carries some potential challenges such as inter-observer variation in

57 detection (especially of small corals), uncertainty in species identification (especially of small  
58 colonies), and consistently delineating colony boundaries in populations with large amounts of  
59 partial mortality.

60 In this study, we analyze coral information derived from both percent cover data and  
61 from demographic data collected at haphazardly selected reef sites to examine temporal change  
62 in coral status at Navassa, a small, uninhabited Caribbean island. Reefs in this area have suffered  
63 severe disturbances, including hurricane impacts, severe disease outbreaks, and mass bleaching  
64 over the past decade resulting in a drastic loss of live coral cover (Miller et al. 2008a). We  
65 present coral percent cover data using standard photo-quadrat techniques (collected in 2002,  
66 2004, 2006, 2009, 2012) in parallel with a separate coral demographic data set collected in 2004  
67 and 2012. Our purpose is not to compare between these sampling methods per se, as choice of  
68 method is influenced not only by practical considerations (level of effort, etc) but also the type of  
69 information desired and applicability within a habitat type. Rather, we examine these data sets  
70 (the only *in situ* data available from reefs of this uninhabited island) in parallel to address two  
71 questions: 1) Are observed changes in coral community status consistent between these two data  
72 sets (i.e. cover versus colony density and size structure); and 2) Does the demographic data  
73 provide insights on processes underlying observed changes that are not evident from the cover  
74 data alone?

## 75 METHODS:

76 The small oceanic island of Navassa (18.40°N, -75.01°W) is a component of the United  
77 States National Wildlife Refuge system located approximately 55 km off the southwest tip of  
78 Haiti. Though uninhabited, it is frequently visited by Haitian subsistence fishers. Reef  
79 development mostly occurs on the narrow shelf along the leeward southwest coast of the

80 somewhat triangular island, whereas low-relief reef communities are found along the exposed  
81 north coast (Fig 1). Benthic habitats along the windward east coast mainly consist of rubble  
82 bottom. Due to its remoteness, there has been no structured monitoring program at Navassa.  
83 Instead, episodic, opportunistic cruises have gathered both demographic and photoquadrat/cover  
84 data. The opportunistic cruises were not intentionally designed to provide a rigorous comparison  
85 across methodologies. Thus, here we leverage the only available data for a remote Caribbean  
86 reef system starting from a relatively unimpacted baseline (Miller & Gerstner 2002) by laying  
87 out parallel observations derived from two separate coral sampling schemes, collected within  
88 coherent time and habitat strata, to examine the observed differences to determine what  
89 meaningful and complementary inferences can be discerned.

#### 90 *Photoquadrat data*

91 A set of sites along the southwest shelf of Navassa (depth 18-34m), was sampled with  
92 haphazardly-placed, photoquadrats in 2002, 2004, 2006, 2009, and 2012. In 2002 and 2004 the  
93 sites were haphazardly selected (but always targeting reef habitats along the southwest coast) by  
94 necessity, as no habitat maps were available. Within the logistic constraints of working from a  
95 single large ship with multiple cruise objectives, effort was made to disperse these sites  
96 throughout the southwest shelf reef habitats. Later, the development of habitat maps from efforts  
97 on the 2004 cruise (Miller et al. 2008b) enabled the stratified-random selection of sampling sites  
98 in 2006, 2009, and 2012, similarly restricted to patch- and slope- reef habitats along the  
99 southwest coast in order to be comparable to sets of sites sampled in earlier years. Although the  
100 means of site selection varied between sample years, a relatively high sampling intensity (hence  
101 a representative sample given the restriction of habitat strata) was accomplished in each year  
102 (e.g., >2 sites km<sup>-2</sup> shelf area in 2004, >4 sites km<sup>-2</sup> shelf area in the other years, e.g., Fig 1b).

103 Photoquadrats were placed by taking five fin kicks in a haphazard direction from the  
104 prior quadrat and then tossing the quadrat forward while the diver's eyes were closed, yielding  
105 approximately 6-8 m distance between quadrats. Each photoquadrat was comprised of a 1m<sup>2</sup>  
106 image and a close-up of each quadrant of the quadrat (to provide a clearer image for reference to  
107 aid in coral identification), for a total of five images per quadrat. Benthic community structure  
108 was analyzed by overlaying each 1m<sup>2</sup> picture with 100 (2002-4) or 50 (2006-12) random point  
109 counts (reduced over time because large numbers of points per frame do not contribute to  
110 improved power; Aronson et al. 1994; Houk & Van Woesik 2006) using CPCe software (Kohler  
111 & Gill 2006). Corals were identified to species when possible, genus if not. Eight to ten quadrats  
112 were analyzed per site.

113 Variation over time in percent live coral cover was analyzed for the community as a  
114 whole (all species summed) as well as for the most common individual taxa (*Orbicella* spp.  
115 [primarily *O. faveolata*], *Agaricia* spp. [primarily *A. agaricites*], and branching *Porites*) via  
116 separate one-way ANOVAs on ranks followed by Dunn's post-hoc tests for differences among  
117 individual years. To make parallel, taxa-specific comparisons in percent cover as for the density  
118 data (described below), we additionally performed separate Mann-Whitney rank sum tests to test  
119 for differences in cover for each of three rarer taxa (*Siderastrea siderea*, *Meandrina meandrites*,  
120 and *Stephanocoenia intersepta*) between 2004 and 2012.

#### 121 *Coral demographic data*

122 In 2004 and 2012, coral colonies were surveyed at a separate set of haphazardly selected  
123 reef sites (Table 1; including a subset of the stratified-random photoquadrat sites in 2012), with  
124 effort to disperse these sites among the patch reef and slope reef habitats of the southwest and  
125 north coasts (Fig 1). This demographic sampling was accomplished via belt transects (15m x

126 0.5m [2004] or 10m x 1m [2012]), with short dive times due to deep depths sometimes dictating  
127 a smaller sample area. The actual area sampled was recorded for each transect and used to  
128 standardize colony density (as # colonies m<sup>-2</sup>). Within each belt transect, every colony (defined  
129 as all tissue sharing a single skeletal unit, even if multiple live tissue isolates were divided by  
130 areas of dead skeleton) was identified to species, and size was recorded for most colonies  
131 (*Porites astreoides*, was tallied for density but not sized in 2012 due to dive time constraints). In  
132 2004, a clear acetate grid was overlaid the colony and used to estimate projected live colony area  
133 directly. In 2012, the dimensions of each colony (maximum diameter and the diameter  
134 perpendicular to the maximum) and a visual estimate of its projected % live area were recorded  
135 *in situ* as was deemed more consistent to apply among multiple observers and to conform to  
136 regionally established protocols (AGRRA; <http://www.agrra.org/method/methodhome.html>). To  
137 compare colony areas with those measured in 2004, a circular area (2-dimensional, projected) was  
138 estimated with a diameter that was the average of the two diameters measured, and adjusted for  
139 the estimated % live area of the colony (adjusted circular area). While the adjusted circular area  
140 and acetate grid are different means to estimate area, all field methods represent approximations  
141 and these are both reasonable, comparable methods. Other efforts specifically aimed and  
142 comparing different geometric approximations for coral colony size/area have shown negligible  
143 differences (e.g., between using a circular versus elliptical approximation for 2d colony area; Van  
144 Woesik et al. 2011). Colonies of less than 2 cm diameter (3.14 cm<sup>2</sup> area) were excluded from  
145 subsequent analyses to account for potential observer bias in the detection of small colonies and  
146 inherent difference in detectability between years or transects due to variable cover of the  
147 macroalga, *Lobophora variegata*. Identification uncertainties for the smaller juveniles also

148 dictated pooling of certain taxa (mostly to genus, though *Porites* was delineated into branching  
149 and mounding morphologies; see list in Fig 3).

150 For both coral density and multivariate community structure analyses, only transects  
151 located along the southwest (leeward) coast of the island between 18 – 34 m depth were included  
152 to standardize the sampled habitat in these analyses where including replicates in different  
153 habitats would increase variance and decrease power. A smaller sampling effort did occur along  
154 the north coast in each year (Table 1), but the reef habitats and benthic assemblage found here  
155 are substantively distinct (Miller et al. 2008b) relative to the more-developed southwest reefs. ).  
156 However, since the colonies along the north and southwest coasts clearly do not represent  
157 distinct populations (being separated by < 1 km distance) and sampling effort was similar  
158 between years (Table 1), all colonies available (including the north coast) were pooled for the  
159 within-taxa size frequency analyses (described below) where pooling habitats helped boost  
160 sample size.

161 Coral density was tallied for each transect (n=17 for 2004, 18 for 2012) along the  
162 southwest coast for 15 taxa in each year to generate mean abundance estimates of coral species  
163 found in Navassa's high relief reef habitat. Univariate Mann-Whitney rank sum tests (or t-tests)  
164 were used to test for univariate differences in density between years for each taxon and for total  
165 coral density using transects as replicates. To characterize potential differences in coral  
166 assemblage structure between 2004 and 2012, we calculated Bray-Curtis similarities on species  
167 density estimates among all transects after square-root transforming the data to reduce the  
168 influence of highly dominant taxa (Clarke & Warwick 2001). A non-metric Multi-Dimensional  
169 Scaling (nMDS) plot was created to visualize differences in coral composition of transects  
170 between years while Analysis of Similarity (ANOSIM) was used to determine significance of

171 these differences. Similarity Percentage (SIMPER) analysis was applied to identify which taxa  
172 were most influential in determining significant difference between years (PRIMER v. 6.0).

173 In analyzing potential differences in size structure of coral populations, we focussed on  
174 taxa with  $n > 30$  colonies sized in each year. Colony areas were ln-transformed (Vermeij and  
175 Bak 2002) and histograms constructed for each sampled year (2004 and 2012). Descriptive  
176 statistics were calculated and the distribution of colonies among size classes was compared  
177 between years via Kolmogorov-Smirnov tests for each taxa. Taxa not consistently measured in  
178 2012 (due to dive time constraints [i.e. *Porites astreoides*]) are not included in analyses of size  
179 frequency.

180 Lastly, the individual colony areas (measured taxa only) for each transect were summed  
181 by taxa and divided by the transect area. This yields a demographically-derived estimate of coral  
182 cover (as coral area) to provide an integration of the (potentially contrasting) density and size  
183 differences among taxa. This allows visualization of contrasts in assemblage composition  
184 according to different ‘currencies’ (density versus area occupied) within the same demographic  
185 data set.

186 This research was conducted under Navassa National Wildlife Refuge Special Use  
187 Permits #41529-2002-10, #41529-2004-12 and #41529-2006-03, #41529-2009-01, and #41529-  
188 2012-001 from the US Fish and Wildlife Service.

189 RESULTS:

190 *Photoquadrat data*

191 The average photo-derived coral cover along the southwest coast of Navassa declined  
192 from 34% in 2002 to 9.6% in 2012. 2002 and 2004 do not differ significantly from each other,

193 but they both are significantly higher than the subsequent three survey years (Fig 2, Dunn's post-  
194 hoc pairwise comparisons). *Orbicella* spp. (predominantly *O. faveolata*) constituted about three-  
195 quarters (0.76) of total coral cover in 2002, but only one fifth (0.20) of coral cover in 2012 with  
196 the steepest (and statistically significant) decline between 2002 and 2004, prior to the  
197 demographic sampling (Fig 2). In contrast, the other two taxa with the highest cover showed  
198 more gradual declines and retained similar proportional representation of total cover over the  
199 same time frame (0.20 to 0.23 for *Agaricia* spp. and 0.19-0.23 for branching *Porites*) (Fig 2).

#### 200 *Coral demographic data*

201 In contrast to total photo-derived coral cover, total coral density along the southwest  
202 coast did not differ between 2004 and 2012 (Table 1, t-test  $p=0.33$ ). However, significant  
203 differences in species composition did occur (Global  $R=0.308$ ; significance level of 0.1%; Fig 3)  
204 with *S. siderea*, *A. agaracites*, branching *Porites*, *Leptoseris cucullata*, and *Orbicella* spp. being  
205 the taxa contributing foremost to the dissimilarity between the two years, cumulatively  
206 contributing 45% of the total dissimilarity (SIMPER analysis). When analyzed separately  
207 (univariate Mann-Whitney rank sums tests), *A. agaracites*, *L. cucullata*, and *Orbicella* spp. all  
208 showed significant univariate decreases in density whereas branching *Porites* did not show any  
209 significant difference between 2004 and 2012 (Fig 4). Coral species exhibiting significantly  
210 higher colony density in 2012 included one common species, *S. siderea*, and two rarer species,  
211 *Stephanocoenia intersepta* (formerly *S. michelini*) and *Meandina meandrites* (Fig 4). In  
212 comparison, the photo-derived coral cover similarly captured a significant increase between 2004  
213 and 2012 in *S. siderea* (from 0.41 to 0.97% cover;  $U=57$ ,  $p=0.039$ ), but no significant change  
214 was detected for *M. meandrites* (0.10 to 0.20%;  $U=100$ ,  $p=0.864$ ) nor *S. intersepta* which was

215 not identified in any of the photoquadrats in 2012, though it was detected at low abundance (a  
216 mean of .013%) in 2004.

217 Robust coral size frequency distribution comparisons ( $n \geq 100$  colonies) were obtained for  
218 four taxa and for another four taxa based on smaller sample sizes ( $n=30-99$ ) (Table 2; three  
219 additional taxa were recorded but lacked sufficient sample size for comparisons between years).  
220 All four of the taxa with larger sample sizes show significant changes in size frequency  
221 distributions between 2004 and 2012 (Fig 5a-d, Table 2). *Orbicella* spp. populations showed  
222 smaller mean colony size (985 cm<sup>2</sup> in 2004 to 347 cm<sup>2</sup> in 2012), while branched *Porites* spp., *S.*  
223 *siderea*, and *A. agaracites* had larger mean colony sizes. Of the four taxa with lower sample  
224 size, only *L. cucullata* showed a significant difference (Fig 5e, Table 2), in this case shifting to a  
225 larger mean colony size. Skewness shifted from positive to negative for four of the taxa (*A.*  
226 *agaracites*, branched *Porites*, *L. cucullata*, and *S. intersepta*) indicating increased under-  
227 representation of small (or over-representation of large) colonies in these populations (Table 2;  
228 Vermeij et al. 2007).

229 Pooling the area occupied by measured corals, juxtaposed with their cumulative density  
230 (Fig 6) aids in integrating the contrasting patterns of decreased cover, stable density, and  
231 contrasting size changes among taxa. The calculated area occupied by these corals in 2012 is  
232 less than half of that in 2004, despite only small (insignificant) change in colony density.  
233 Additionally, individual taxa show contrasting patterns between area and density units, due to the  
234 influence of different size structure. While *Orbicella* spp. showed small losses (a factor of 0.36)  
235 in density between 2004 and 2012, its losses in calculated area were extreme (less than one tenth  
236 remained due to loss of large colonies). In contrast, *S. siderea* showed much greater increases in  
237 density (tripled) than in area occupied (due to increased abundance constituted by small colonies

238 occupying little area). Meanwhile, some taxa (e.g., *A. agaricites*) showed approximately  
239 proportional changes in both units (Fig 6).

#### 240 DISCUSSION:

241         The overall decline in coral cover and lack of resilience displayed among Caribbean reefs  
242 over the past decades is well described in the literature. A large meta-analysis covering sites  
243 throughout the Caribbean from 1970-2012 (Jackson et al. 2014) provides context for the changes  
244 described here in Navassa reefs in the later portion of this interval. This meta-analysis indicates  
245 the mean corrected coral cover for deeper reefs (5-20m depth, 88 locations) over three time  
246 periods declined from 32.6% (1970-1983) to 19.4% (1984-1998) to 16.5 (1999-2012)(Jackson et  
247 al. 2014, Part 1, Table 3, p.67). Though most of our Navassa sampling sites in all years were  
248 deeper than 20m, the initial coral cover documented at Navassa's southwest reefs in this study  
249 was 34% in 2002, corresponding with the Caribbean-wide average several decades earlier.  
250 Subsequently, a 20% absolute decline in Navassa coral cover occurred over a period of just four  
251 years, whereas the Caribbean- wide mean decline of only 16% absolute took two decades. While  
252 coral cover at Navassa does appear to have remained robust for a longer duration in the absence  
253 of local development and human habitation, acute disturbance events of global stressors such as  
254 thermally-induced coral bleaching (Miller et al. 2011) and coral disease (Miller & Williams  
255 2006) have coincided at Navassa with at least as great a magnitude of decline at a much more  
256 rapid pace than the regional average.

257         We acknowledge several caveats to the data presented here when interpreting our  
258 findings. The sites sampled in most cases were haphazardly chosen. However, all sites sampled  
259 in both data sets were constrained by habitat type for each temporal comparison (e.g., to deep  
260 patch and bank reefs on the southwest coasts for coral density). The total shelf area at Navassa is

261 small and the relative density of sampled sites was adequate to detect differences between years  
262 in both cover and demographic parameters. The demographic data were collected  
263 opportunistically to supplement % cover monitoring data, not as planned repeat monitoring or a  
264 methods comparison. Furthermore, our sampling in both years was constrained by a limited  
265 number of dives per cruise to survey the coral community, not shaped by an objective power  
266 analysis nor optimal spatial allocation of samples (e.g., Smith et al. 2011). The sampling effort  
267 (i.e. person dives and area covered) was fairly similar between both data sets in 2004, but  
268 somewhat higher for the demographic data in 2012 (Table 1). Given this non-homogenous field  
269 sampling, we took a conservative approach to our analyses. Our analytical approach has been to  
270 filter the demographic data in conservative ways to avoid potential bias in the primary  
271 comparison between years i.e., excluding (e.g. small sizes) or pooling (e.g. nominal spp  
272 identifications into higher taxa groups) data whenever there was uncertainty in comparability.  
273 Given this sub-optimal data set, interesting and significant differences between years are evident  
274 from the demographic data (Fig 4, Table 2) that are not resolvable from the more traditional and  
275 more frequent coral cover data.

276         Significant loss in coral cover occurred while total coral density remained unchanged, as  
277 substantially lower colony abundance of some taxa (mainly *Orbicella* spp) was offset by  
278 significantly higher density of other, typically smaller taxa. These taxa with higher density  
279 include both the common *S. siderea* (for which increase was also apparent from the more  
280 frequent photo-derived cover data), as well as two rare species for which changes in photo-  
281 derived cover were not discernable (*M. meandites* and *S. intercepta*). High recruitment rates  
282 have similarly been reported for these three species in other studies (e.g., Huntington & Lirman  
283 2012; Vermeij et al. 2011). Historic studies of juvenile coral assemblages in Curaçao indicate *M.*

284 *meandrites* ranking 4<sup>th</sup> and *S. intersepta* 7<sup>th</sup> in terms of relative abundance within the total  
285 juvenile population (Bak & Engel 1979). For *M. meandrites*, our 2004 mean density of 0.09  
286 colonies m<sup>2</sup> is congruent with that reported by Pinzon and Weil (2011) measured in southwest  
287 Puerto Rico in 2002-3, as is a negative skewness of its size distribution. However, this species  
288 showed a decrease in juvenile density in Curaçao between 1979 and 2005 (Vermeij et al. 2011),  
289 and we are unaware of other published reports of significant increasing abundance trends for this  
290 species as observed at Navassa (Fig 4). Interestingly, *L. cucullata*, a significant ‘loser’ in colony  
291 abundance in the current study, has showed a similar drastic decrease in juvenile density in both  
292 Curaçao (as *Helioseris cucullata*; (Vermeij et al. 2011) and Jamaica (Hughes & Tanner 2000).

293         The size frequency data showed that some species shifted significantly toward larger  
294 colonies, and others toward smaller size. The loss of very large *Orbicella* spp. colonies is most  
295 likely attributable to substantial mortality associated with disease and bleaching events between  
296 2004 and 2006 (Miller et al. 2011; Miller & Williams 2006 ). The most drastic difference in size  
297 distribution among the taxa examined was a strong shift to larger colonies in branching *Porites*.  
298 The reason for this remains unclear, but a reduction in recruitment combined with growth of  
299 colonies through time (from a modal diameter of 3 cm to a modal diameter of 14 cm in eight  
300 years, Fig 5B) seems plausible, given no significant change in density (Fig 4). Alternatively, it is  
301 possible that a substantial shift in species representation within this morphological group may  
302 have occurred (e.g., more *P. porites* and less of the small *P. furcata* and/or *P. divaricata*). We  
303 do not think this explanation likely due to substantial representation by both small and larger  
304 morphs in both sampling years, and recent genetic evidence has failed to support these three as  
305 distinct species (Prada et al. 2014).

306 We considered the sampling efficiency of collecting both percent cover and demographic  
307 data in deep water reefs where bottom time is limiting. The present data sets were collected with  
308 roughly comparable levels of in-water effort per unit sample (at the depths and dive times  
309 available for these deep reefs, a single diver was able to complete either one demography  
310 transect or a set of photoquads, each method surveying  $\sim 10 \text{ m}^2$  of the seafloor, Table 1),  
311 though there are clear tradeoffs in both the amount of post-processing effort required and aspects  
312 of statistical power related to ten replicate photoquads versus a single transect that yields data on  
313 a large but variable number of coral colonies. The consequences of these replication differences  
314 will depend on the types of analyses attempted. Fundamentally, the methods pose different  
315 questions-- % cover provides a picture of the overall coral community composition and enables  
316 comparison across other competing benthic taxa (algae, sponges, etc), whereas demographic  
317 surveys are necessarily species inventories aimed at characterizing populations. For sampling of  
318 deep water reefs, the decision to use photoquads, demography transects, or both methods should  
319 be based on the underlying questions motivating the survey.

320 Demographic and percent cover approaches can both pose pitfalls. For example,  
321 increasing frequencies of small colonies can result from beneficial processes such as recruitment  
322 of new colonies or undesirable processes such as partial mortality resulting in small remnant  
323 colonies. Meanwhile, a single massive colony is not functionally equivalent (in terms of habitat  
324 value, susceptibility to various threats, nor fecundity) to many small colonies but might be  
325 represented as equal in terms of percent cover. Photoquadrats do not necessarily sample every  
326 coral in the area surveyed, and can have poorer resolution or detectability for rare, small, or  
327 similar-appearing species. For example, we were not able to quantify *L. cucullata* abundance  
328 reliably from our photos (likely mis-identified as *Agaricia* spp., or present in cryptic locations

329 not visible in top-down photographs) whereas it was easily distinguishable in the field. Hence,  
330 the significant loss of this species (sixth most common taxon in 2004) would not have been  
331 detected from photoquadrat sampling alone. The decline of *L. culcullata*, also reported in  
332 Curacao (Vermeij et al. 2011) and Jamaica (Hughes & Tanner 2000), is likely the most  
333 substantial collapse of a Caribbean coral species since *Acropora* spp. but has largely gone  
334 unnoticed due to predominance of photographic monitoring approaches.

335         Most long-term coral monitoring efforts have relied solely on percent cover to quantify  
336 abundance, community structure, and changes through time. This approach has been sufficient  
337 to detect changes over long time frames (De'ath et al. 2012) and the drastic losses over short time  
338 frames due to recent acute disturbances on Atlantic/Caribbean reefs (e.g., Coelho & Manfrino  
339 2007; Miller et al. 2009). Significant declines are relatively easy to detect from a baseline of  
340 50% cover, but change detection likely requires much greater sampling effort from a baseline  
341 signal of 10%, or even much lower for individual coral species, as characterizes most modern  
342 Caribbean reefs (e.g., Gardner et al. 2003; Ruzicka et al. 2013). Within the photoquadrat data set  
343 reported here, significant change is detectable over less than a decade in coral percent cover and  
344 even in the few dominant individual coral taxa (Fig 2). However, given the low percent coral  
345 cover in Navassa by the end of the study period, it seems highly unlikely that future changes in  
346 total coral cover (either continued decline from a low baseline or, hopefully, recovery), let alone  
347 individual taxa, will be detectable over the next decade without substantially greater sampling  
348 effort if relying on photoquadrat sampling alone. For example, Molloy et al. (2013) performed  
349 intensive power analyses to determine the number of photoquadrats/points required to detect 1%  
350 per annum recovery in coral cover and concluded this scale of recovery was essentially  
351 impossible to detect with their most intensive photoquadrat protocols (250 quadrats per site, 50

352 points per quadrat). While traditional percent cover data such as from photoquadrats provides  
353 crucial information on the status of the ‘other 90%’ of the reef that is not hard coral, it may  
354 provide relatively less information for corals, especially when they are at low abundance. By  
355 supplementing photoquadrat data with minimal demographic sampling we were able to detect  
356 increased densities of several species over eight years. The collection of colony-based (i.e.  
357 demographic) data provide additional metrics, greater resolution and analytical power (e.g.,  
358 hundreds of colonies for many taxa in an effort such as this, rather than a cover estimate of, e.g.,  
359 <1%), and a valuable mechanistic insight as to the population dynamics driving coral population  
360 changes. Hence, a combined approach employing both photoquadrat data with demographic data  
361 may be the most informative to track changes in benthic reef communities at low coral  
362 abundances.

363

364 ACKNOWLEDGEMENTS: This work was made possible by the excellent logistic support  
365 provided by D McClellan, J Javech, the John G. Shedd Aquarium’s R/V Coral Reef II, the  
366 NOAA Ship Nancy Foster, and the LOF’s M/Y Golden Shadow. Special thanks to A Bruckner  
367 (LOF) for enabling 2012 data collection.

## Summary effort and density

In-water effort for 2004 and 2012 demographic ('Demo') and photoquadrat (PQ) sampling including number of sites, transects or photoquadrats and person-dives. Area (m<sup>2</sup>) indicates the cumulative area of transects (demo) or quadrats sampled. The total number of colonies sampled and the colony density (# colonies/m<sup>2</sup>) are also given under the demographic section.

1 Table 1. In-water effort for 2004 and 2012 demographic ('Demo') and photoquadrat (PQ)  
 2 sampling including number of sites, transects or photoquadrats and person-dives. Area (m<sup>2</sup>)  
 3 indicates the cumulative area of transects (demo) or quadrats sampled. The total number of  
 4 colonies sampled and the colony density (# colonies/m<sup>2</sup>) are also given under the demographic  
 5 section.  
 6

Year	Location	PQ # sites	PQ area	PQ person - dives	Demo # sites	Demo # transects	Demo person -dives	Demo area	# col	Overall Density (SE)
2004	SW	14	149	16	13	17	13	111.5	1227	11.48 (1.06)
	N*				6	7	6	50.5	351	7.07 (0.56)
2012	SW	12	125	13	8	18	20	166.5	1711	10.17 (0.80)
	N*				4	6	5	51	316	6.18 (0.46)

7 \*Transects from the north coast are included only in the size frequency analyses (Table 2, Fig 4)  
 8

**Table 2** (on next page)

## Size frequency data

Coral colony size frequency summary statistics from Navassa demographic sampling in 2004 and 2012, based on  $\ln(\text{colony area [cm}^2\text{]})$ . P-values are given for Kolmogorov-Smirnov tests comparing distributions between the two years. Three sections indicate groups of taxa with progressively lesser N's. Histograms for taxa that are significantly different are shown in Fig 5. Taxa as in Fig 4.

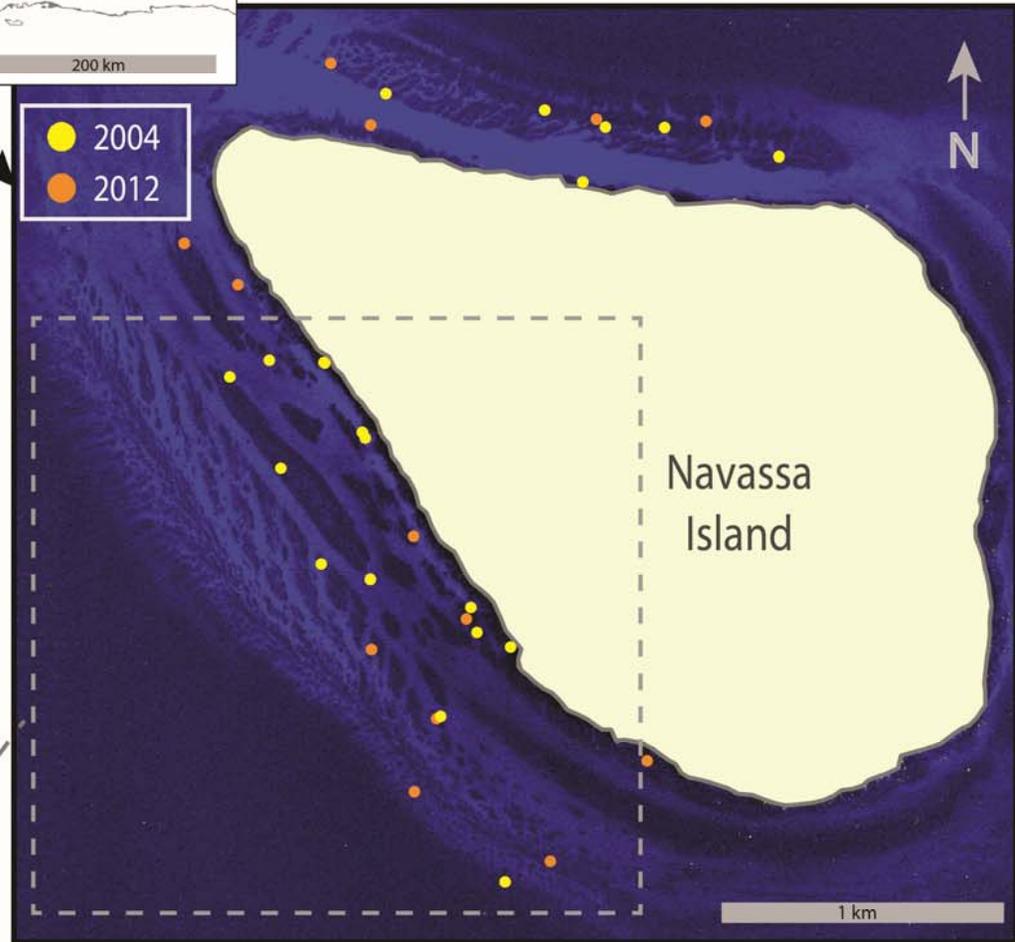

**Figure 1**(on next page)

## Sample Location

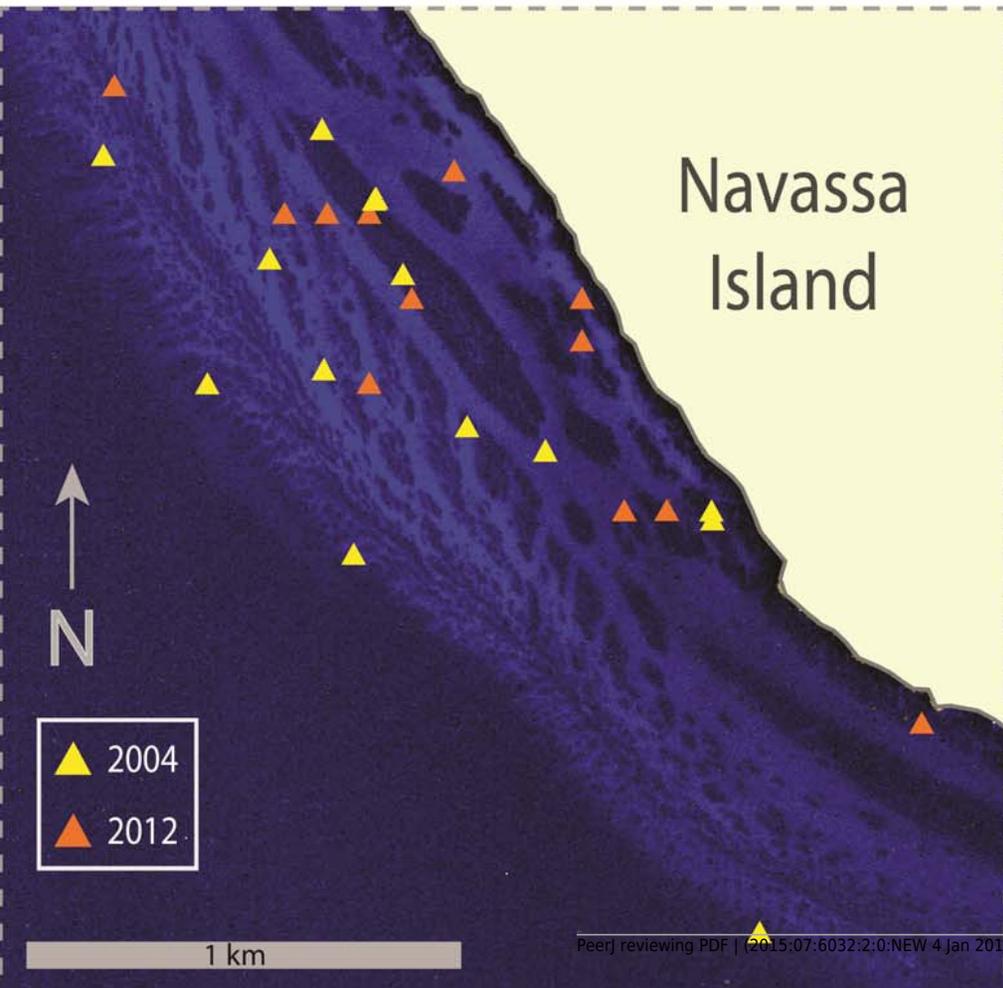

Map showing location of Navassa Island in the greater Antilles. Insets show the specific location of demographic sites (a) and photoquadrat sites (b) that were sampled in 2004 and 2012. Photoquadrat sites sampled in the other years were similarly dispersed among reef habitats of the southwest coast (i.e., 2004 and 2012 are shown as representative examples). Site locations are superimposed on satellite imagery showing reef distribution along the Navassa shelf (IKONOS image provided by DigitalGlobe).

a) Demographic sites

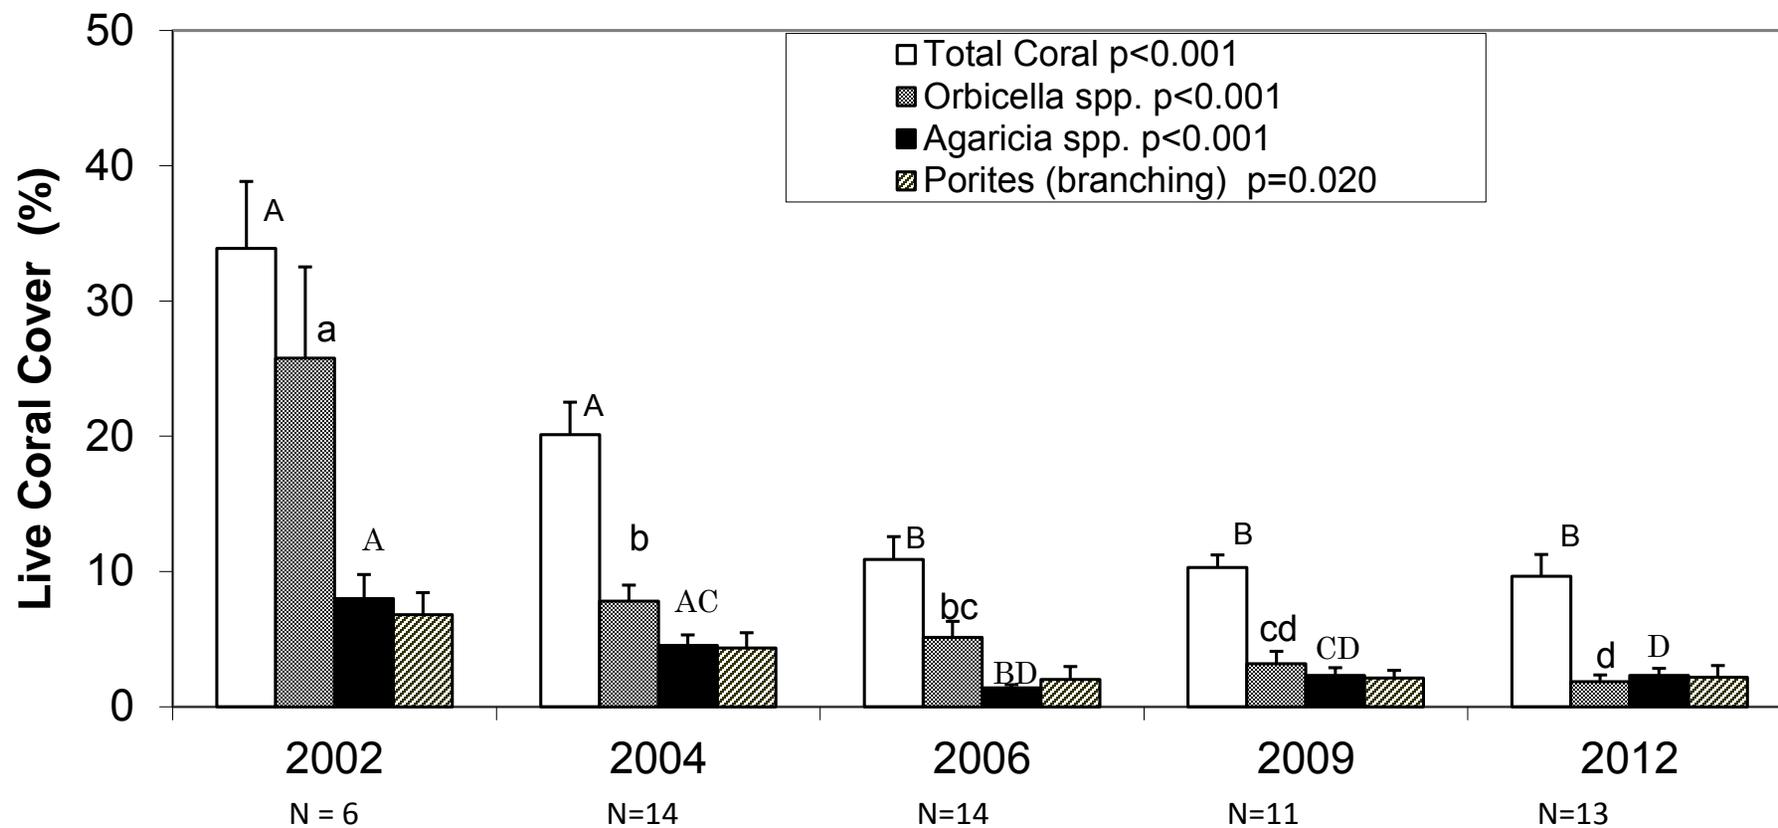

b) Photoquadrat sites

**Figure 2**(on next page)

Photo-derived percent cover

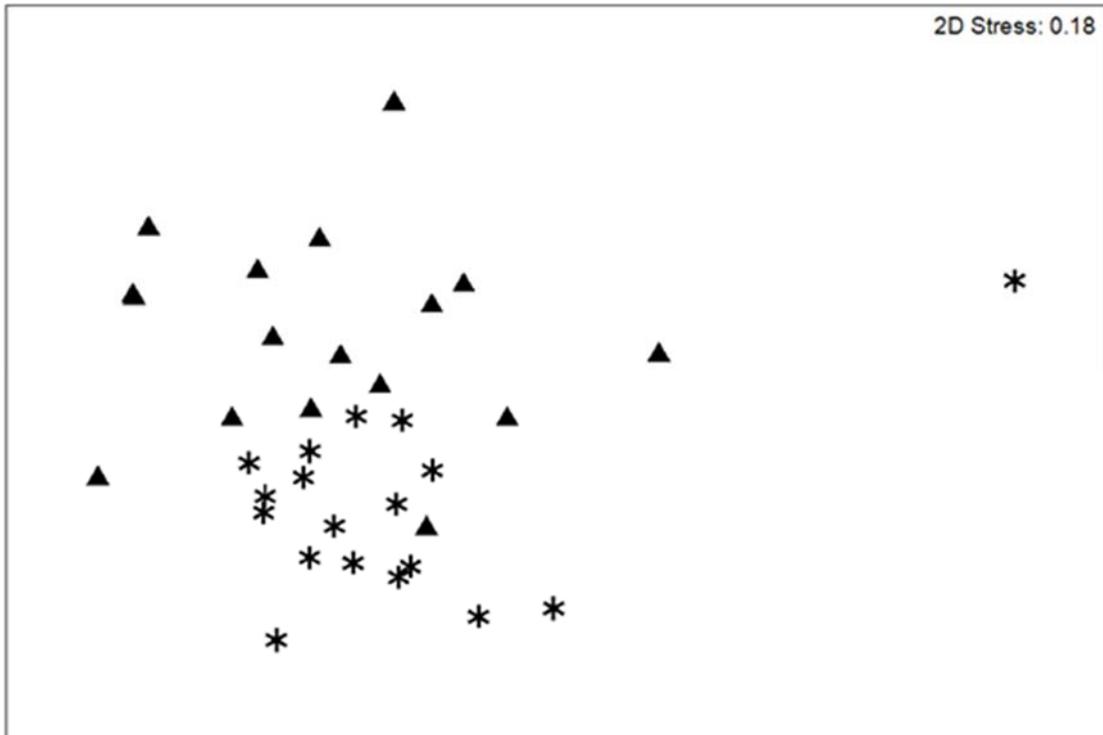

Percent cover (+ 1SE) for total scleractinian corals and for the three most abundant coral taxa in Navassa photoquadrats over time. The three most abundant taxa are *Orbicella* spp. (predominantly *O. faveolata*), *Agaricia* spp. (dominated by *A. agaricites*), and branching *Porites* (*P. porites*, *P. furcata*, and *P. divaricata*). P-values in legend from separate one-way ANOVA on ranks for each taxa across time. N (number of sites) is given for each year under the axis. Similar letters over each set of bars indicate no statistical difference in post-hoc comparisons for a given taxa across time. Note that *Orbicella* spp. cover had declined most before 2004, whereas the other two taxa (and total coral cover) continued declining through 2006.

**Figure 3**(on next page)

## Community change

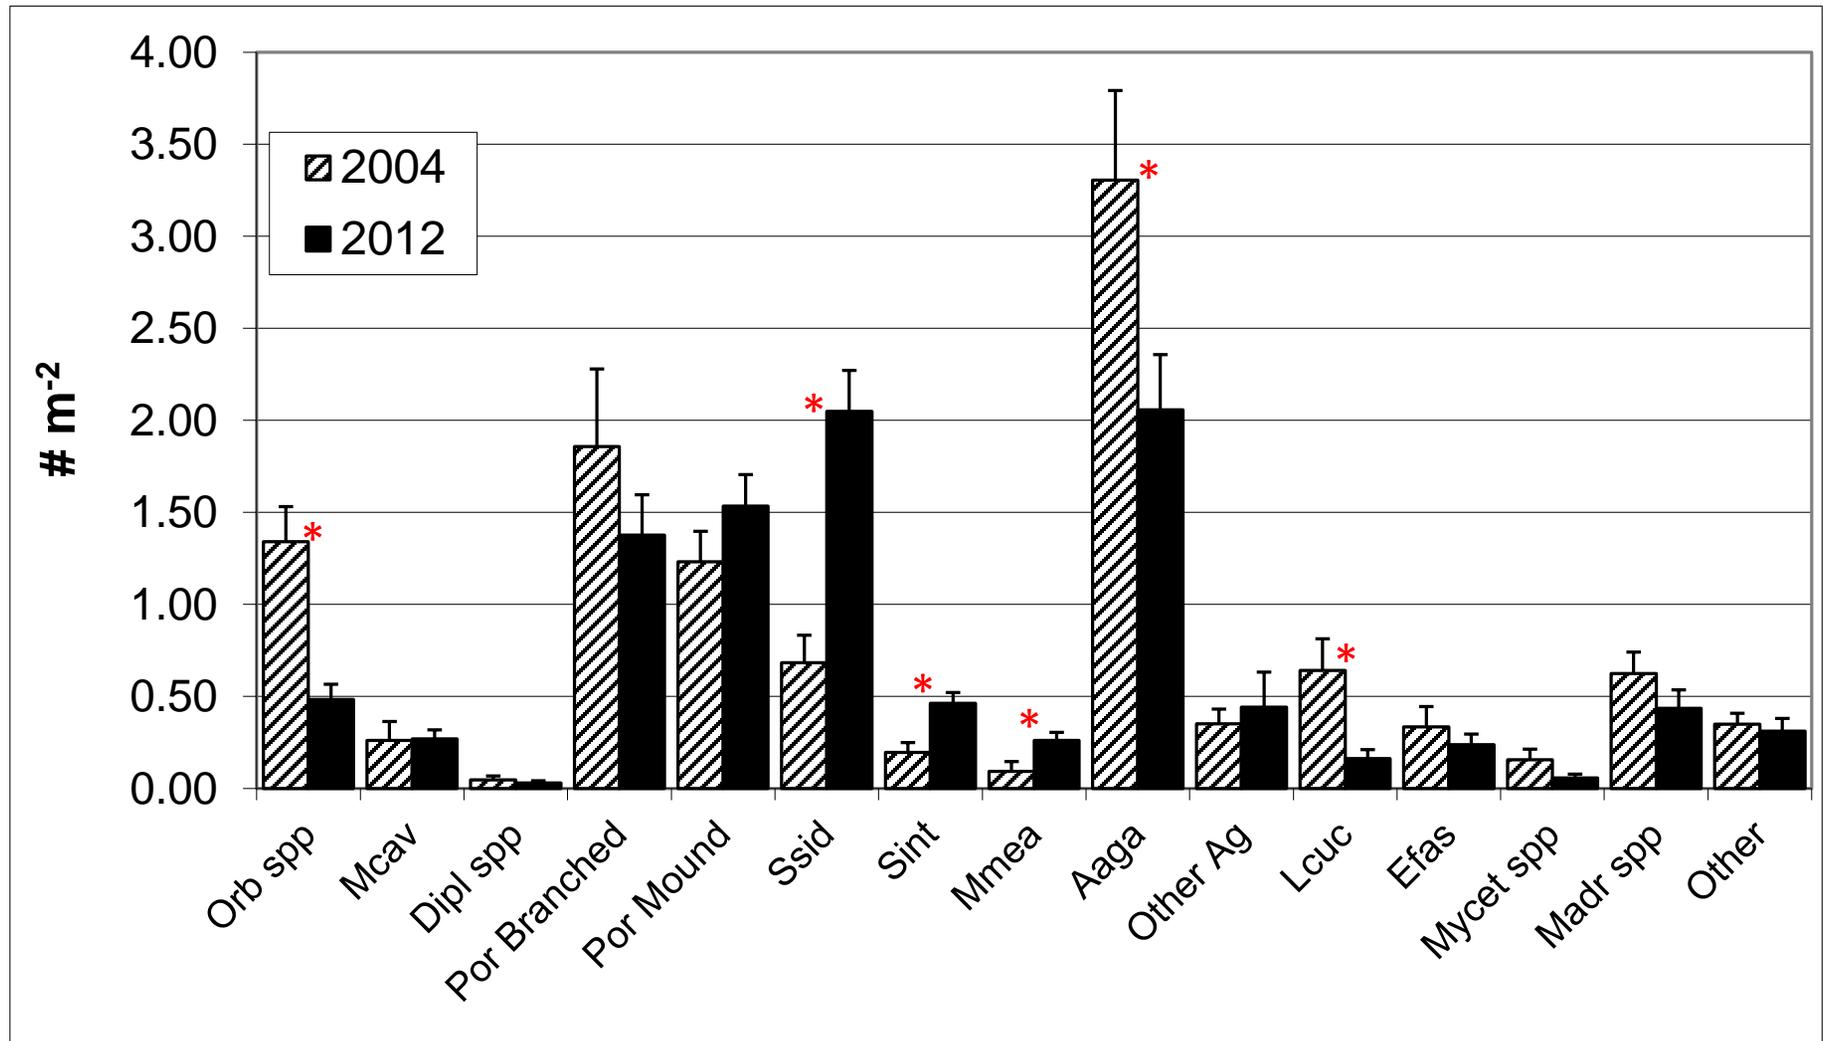

nMDS scaling plot for coral demographic transects sampled on the southwest coast of Navassa in 2004 (triangles) and 2012 (asterisks). Although the somewhat high stress level indicates that this 2-dimensional rendering is not a perfect representation of the similarity among samples, ANOSIM indicates significant change in coral community structure (based on square-root transformed colony density) between the two years (Global  $R=0.308$ ; significance level of 0.1%).

**Figure 4**(on next page)

## Colony density by taxa

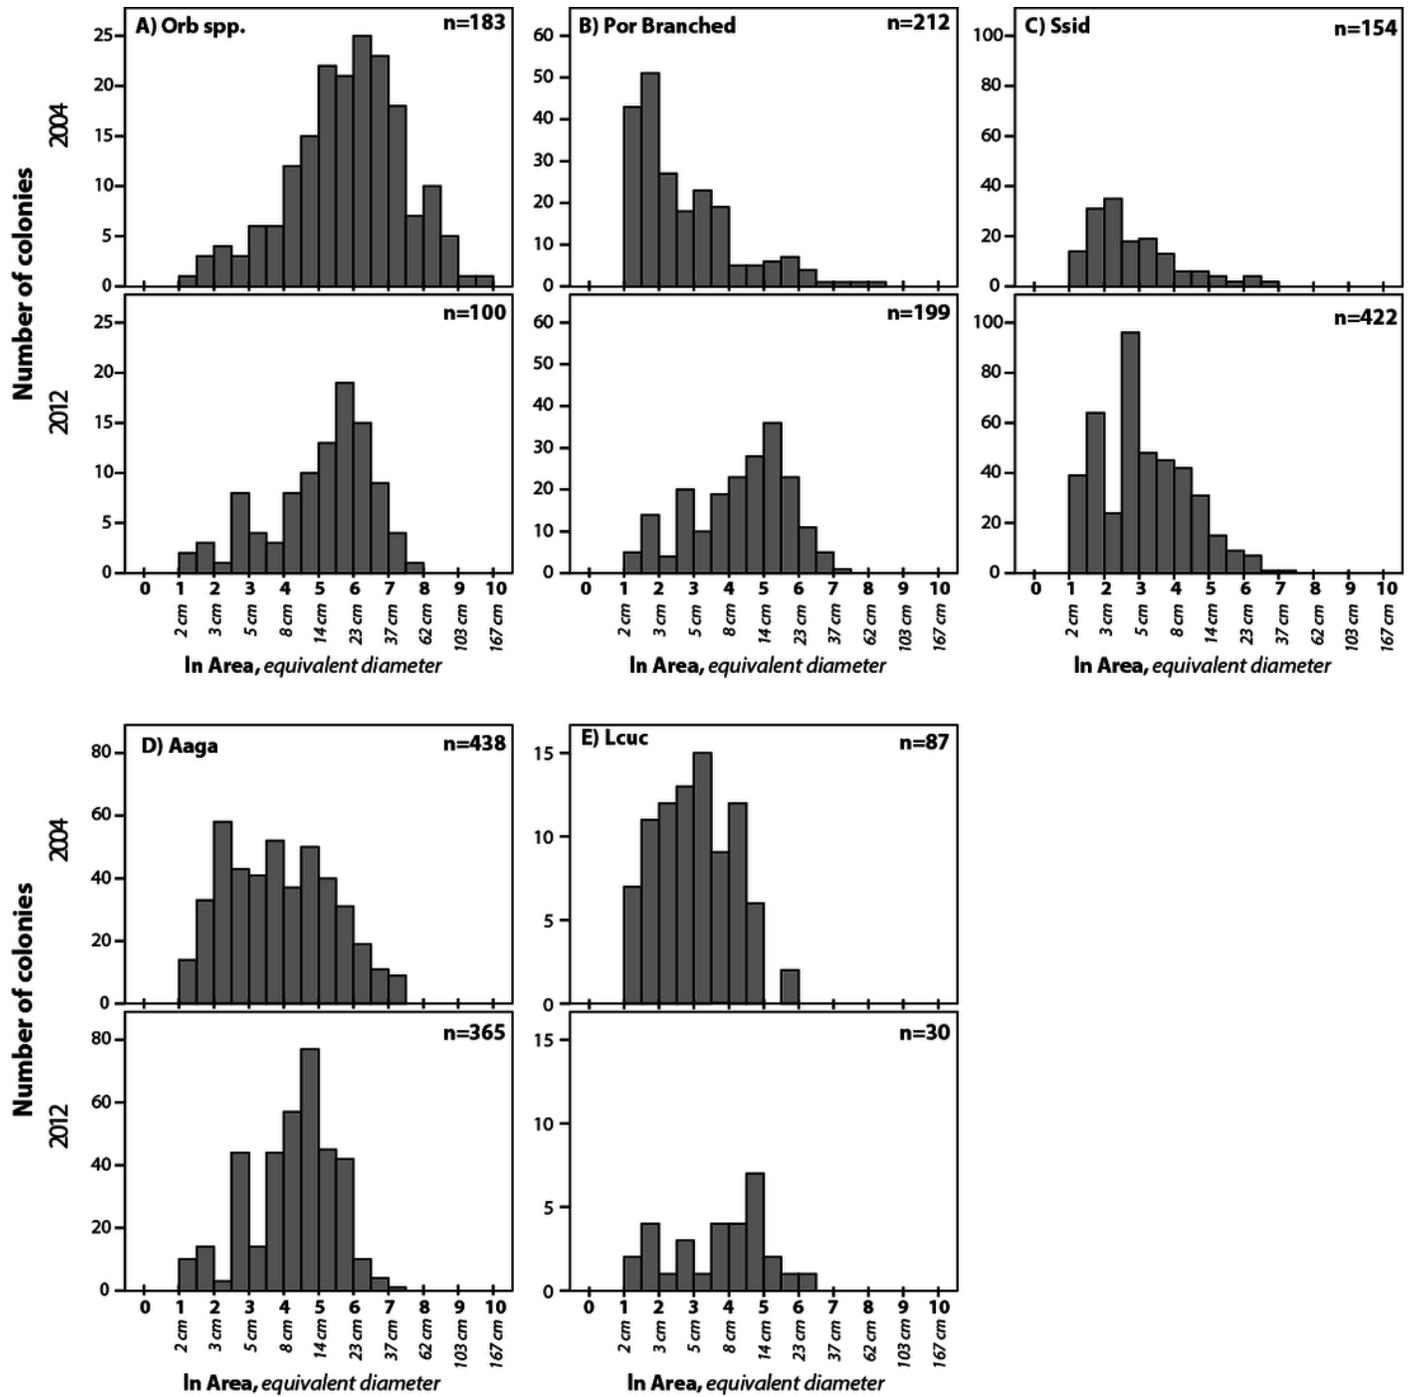

Colony density for coral taxa (mean + 1SE; n=17, transects in 2004 and 18 in 2012) in the demographic sampling of sites along the southwest coast of Navassa. \*indicates significant difference between the two years as determined by Mann-Whitney rank sum test ( $p < 0.05$ ). Orb spp = *Orbicella* spp. (predominantly *O. faveolata*); Mcav = *Montastraea cavernosa*; Dipl spp = *Diploria* (includes recently reclassified *Pseudodiploria strigosa*, ( Budd et al. 2012 ) ) species; Por branched = branched *Porites* spp (*P.porites*, *P.furcata*, *P.divaricata*); Por Mound = mounding *Porites* species (predominantly *P.astreoides*); Ssid=*Siderastrea siderea*; Sint = *Stephanocoenia intersepta*; Mmea = *Meandrina meandrites*; Aaga=*Agaricia agaricites*; Other Ag= *Agaricia* species other than *A.agaricites*; Lcuc = *Leptoseris cucullata*; Efas = *Eusmilia fastigiada*; Mycet spp= *Mycetophyllia* species; Madr = *Madracis* species; Other = other scleractinians.

# 5

## Size frequency distributions

Fig 5. Size frequency distributions for five taxa that showed significant difference between 2004 and 2012. Size bins are expressed as  $\ln$  (colony area in  $\text{cm}^2$ ). Corresponding colony diameters (for calculated circular area) are shown below the x-axis for scale. Summary statistics given in Table 2. Taxa as in Fig 4.

**Figure 6**(on next page)

Area occupied by taxa

A comparison of coral composition (sized taxa only) for southwest sites based on demographic data expressed as density (A) and as area back-calculated by summing the area occupied by each of these sized colonies (B). Taxa abbreviations as in Fig 4.
