**Background.** Southeast Asia has experienced widespread deforestation and change in land use. Consequently, many reforestation projects have been initiated in this region. However, it is imperative to carefully choose the tree species for planting, especially in light of the increasing climate variability and the potential alteration of plantation on the watershed water balance. Thus, the information regarding water-use characteristics of various tree species and sizes is critical in the tree species selection for reforestation.

**Methods.** We estimated tree water use ( $T$ ) of dominant species including *Syzygium antisepticum* and *Adinandra integerrima*, hereafter  $Sa$  and  $Ai$ , respectively, in a secondary tropical forest in Khao Yai National Park, Thailand, using sap flow data, and compared  $T$  between species and size classes. Additionally, we evaluated the responses of  $T$  of both species in each size class to environmental factors including soil moisture and vapor pressure deficit (VPD).

**Results.** Results showed consistently higher  $T$  in  $Sa$  compared to  $Ai$  across ranges of VPD and soil moisture. Under low soil moisture,  $T$  of  $Sa$  responded to VPD, following a saturating exponential pattern while  $Ai$  maintained  $T$  across different VPD levels, irrespective of tree size. No responses of  $T$  to VPD were observed in either species when soil water was moderate. When soil moisture was high,  $T$  of both species significantly increased and saturated at high VPD, albeit the responses were less sensitive in large trees. Our results imply that  $Ai$  may be suitable for reforestation in water-limited areas where droughts frequently occur to minimize reforestation impact on water availability to downstream ecosystems. In contrast,  $Sa$  should be planted in regions with abundant and reliable water resources. However, a mixed species plantation should be generally considered to increase forest resilience to increasing climate variation.

27 **Abstract**

28 **Background.** Southeast Asia has experienced widespread deforestation and change in land use.  
29 Consequently, many reforestation projects have been initiated in this region. However, it is  
30 imperative to carefully choose the tree species for planting, especially in light of the increasing  
31 climate variability and the potential alteration of plantation on the watershed water balance.  
32 Thus, the information regarding water-use characteristics of various tree species and sizes is  
33 critical in the tree species selection for reforestation.

34 **Methods.** We estimated tree water use ( $T$ ) of dominant species including *Syzygium antisepticum*  
35 and *Adinandra integerrima*, hereafter  $Sa$  and  $Ai$ , respectively, in a secondary tropical forest in  
36 Khao Yai National Park, Thailand, using sap flow data, and compared  $T$  between species and  
37 size classes. Additionally, we evaluated the responses of  $T$  of both species in each size class to  
38 environmental factors including soil moisture and vapor pressure deficit (VPD).

39 **Results.** Results showed consistently higher  $T$  in *Sa* compared to *Ai* across ranges of VPD and  
40 soil moisture. Under low soil moisture,  $T$  of *Sa* responded to VPD, following a saturating  
41 exponential pattern while *Ai* maintained  $T$  across different VPD levels, irrespective of tree size.  
42 No responses of  $T$  to VPD were observed in either species when soil water was moderate. When  
43 soil moisture was high,  $T$  of both species significantly increased and saturated at high VPD,  
44 albeit the responses were less sensitive in large trees. Our results imply that *Ai* may be suitable  
45 for reforestation in water-limited areas where droughts frequently occur to minimize  
46 reforestation impact on water availability to downstream ecosystems. In contrast, *Sa* should be  
47 planted in regions with abundant and reliable water resources. However, a mixed species  
48 plantation should be generally considered to increase forest resilience to increasing climate  
49 variation.

50

## 51 Introduction

52 Over an annual timescale with negligible change in total water storage, precipitation is coarsely  
53 partitioned into evapotranspiration and runoff in the forest water cycle (Wang and Tang 2014).  
54 Because tree water use ( $T$ ) constitutes 40–90% of evapotranspiration (Jasechko et al. 2013; Deb  
55 Burman et al. 2019), the quantity of  $T$  affects the amount of precipitation that ultimately  
56 contributes to runoff, impacting the downstream ecosystems. With the projected increases of  
57 global climate change impacts,  $T$  may be altered through changes in environmental conditions  
58 including temperature and precipitation regimes, severity of weather and climate extremes such  
59 as droughts and floods (Menezes-Silva et al. 2019). Such changes will certainly affect the  
60 responses of  $T$  to environmental factors, therefore governing the outflow from forests. Thus,  
61 evaluating such responses would provide insights into environmental management that involves  
62 water cycling, such as predicting runoff from forests which may result in floods or droughts in  
63 the downstream ecosystems.

64 The variations of  $T$  are mainly related to tree size (Meinzer et al. 2005; Jung et al. 2011)  
65 and environmental factors including soil water availability, solar radiation, and vapor pressure  
66 deficit (VPD) which represents atmospheric humidity (Xu et al. 2020; Gutierrez Lopez et al.  
67 2021). Several previous studies reported significant variations of  $T$  with tree size. The  
68 relationship between tree diameter and  $T$  was found among several species of angiosperms  
69 (*Meinzer et al. 2005*), *Eucalyptus crebra* and *Callitris glaucophylla* in evergreen woodland in  
70 Australia (Zeppel and Eamus 2008), and trees in a temperate mixed-deciduous forest in South  
71 Korea (Jung et al. 2011). Additionally, different tree sizes have been linked to different  
72 responses to droughts with large trees being more vulnerable than small trees to drought because  
73 of greater exposure to atmospheric demand (Bennett et al. 2015; Stovall et al. 2019). However,  
74 information of the effects of tree size on  $T$  is still lacking in secondary tropical forests. The  
75 effects of environmental factors on  $T$  vary in different forest types and regions. For example,  
76 when soil moisture is not limited,  $T$  strongly responds to VPD, which increases when the air  
77 humidity decreases, and solar radiation in an old-growth spruce forest in the Ore Mountains,  
78 Germany (Clausnitzer et al. 2011). Under soil water stress, Brum et al. (2018) found that  $T$  could

79 decrease with increasing VPD during an extreme drought in an Amazonian tropical rainforest.  
80 On the other hand, Spanner et al. (2022) found that the sensitivity of  $T$  to soil moisture varied  
81 with species, with some increasing and some decreasing during the dry period in an old-growth  
82 upland forest in the central Amazon. Thus, changing environmental conditions can alter the  
83 response patterns of  $T$ .

84 Forests in Southeast Asia provide a wide range of important ecosystem services to many  
85 people and communities. Unfortunately, these forests have been disrupted by widespread  
86 deforestation and land use change (Stibig et al., 2014; Zeng et al. 2018), resulting in various  
87 stages of forests in the same area (Curtis et al. 2018). In particular, the areas that were previously  
88 used for agricultural purposes have been abandoned for several years, and naturally or artificially  
89 transformed into secondary forests. Consequently, many of the degraded forests may not  
90 contribute much to improving biodiversity and mitigating climate change through carbon dioxide  
91 removal from the atmosphere. Therefore, reforestation projects have emerged in many countries  
92 in the tropics, highlighting the use of native species to avoid competition with other native trees,  
93 which can help restore biodiversity and sequester carbon (Hooper et al. 2002). However, planting  
94 more trees in existing secondary forests may raise some concerns because trees are potentially  
95 heavy water users and might deplete water resources (Jackson et al. 2005). Also, reforestation  
96 may not be desirable in certain areas because it may reduce water availability for the existing  
97 trees and increase the evapotranspiration rate (Van Kantén and Vaast 2006) and thus leading to  
98 reductions in runoff (Li et al. 2014). With these regards, an appropriate selection of tree species  
99 for planting is among the priority tasks for forest restoration since species-specific water-use  
100 characteristics play an important role in changing the components of the forest hydrologic cycle  
101 (van Dijk and Keenan 2007). However, the availability of such information is still limited in  
102 tropical forests, especially in secondary ones. Hence, it is imperative to evaluate the response  
103 patterns of  $T$  to environmental factors in secondary tropical forests that would offer necessary  
104 information on species-specific water-use characteristics.

105 Khao Yai National Park (KYNP) is a UNESCO world heritage site. Most of the areas of  
106 KYNP consist of a mosaic of different stages of vegetation succession with more than 60% of  
107 the forests undergoing different stages of regeneration while the remainder are old-growth  
108 forests. Thus, secondary forests in KYNP are important to biodiversity conservation and climate  
109 change mitigation through the regulation of atmospheric carbon. With these regards, this study  
110 was performed in a secondary tropical forest at KYNP, representing a young forest aged ~10  
111 years. In this study site, the dominant tree species include *Syzygium antisepticum* and *Adinandra*  
112 *integerrima*. *Syzygium antisepticum* can be found as the dominant species in other tropical  
113 forests such as tropical evergreen swamp forests in Cambodia (Theilade et al. 2011), dry  
114 evergreen forests in northeastern Thailand (Bunyavejchewin 1999) and tropical coastal sand  
115 dune in southern Thailand (Marod et al. 2020). *Adinandra integerrima* can be found in other  
116 parts of Thailand, such as Doi Inthanon National Park in the northern region (Georgiadis 2022)  
117 and other countries in the tropics, such as Cambodia, China, Laos, and Vietnam (Tagane et al.  
118 2020). Despite the widespread presence of these species in Thailand and neighboring countries

119 of Southeast Asia, the information on the water-use characteristics of both species is still lacking.  
120 Therefore, this study aims to (1) estimate  $T$  of *Syzygium antisepticum* and *Adinandra integerrima*  
121 in a secondary tropical forest in KYNP, and (2) evaluate the responses of  $T$  to environmental  
122 factors of both species in different tree size classes. The collected data covered a period from 18  
123 September 2020 to 26 November 2022, including a wide range of environmental conditions. The  
124 outcome of this study would improve the understanding of species-specific water-use  
125 characteristics in secondary forests which can support policy design on the management of  
126 tropical forests and water resources. In addition, findings from this study may provide a  
127 recommendation for selecting appropriate tree species for forest restoration in the tropical region.  
128

## 129 **Materials & Methods**

### 130 *Study site and measurements of the environmental variables*

131 The study was conducted in Khao Yai National Park, Thailand (14°26'31" N, 101°22'55" E).  
132 Khao Yai National Park covers an area of about 200 km<sup>2</sup> in Nakhon Ratchasima, Saraburi,  
133 Prachinburi and Nakhon Nayok Provinces in Thailand. This region is dominated by monsoon  
134 climate, where the dry season usually lasts from November to April and from May to October for  
135 the wet season (Brockelman et al. 2017). Based on recorded data between 1994-2018, the overall  
136 mean annual temperature was 22.4 °C. The mean annual rainfall was 2,100 mm. Khao Yai  
137 National Park is characterized by different stages of forest succession comprising primary forests  
138 and various stages of secondary forests. In this study, we performed the study in a secondary  
139 forest representing a young forest in Nakhon Nayok Province. The study site has an area of 2 ha  
140 and an age of approximately 10 years (Chanthorn et al. 2017). Its mean canopy height is 15 m  
141 and its tree density of 1,226 trees ha<sup>-1</sup>. The soil is gray-brown ultisol which was degraded by  
142 shifting agriculture by burning before regeneration (Chanthorn et al., 2016, 2017). The bulk  
143 density was 1.24 g cm<sup>-3</sup> and soil texture was sandy clay-loam with the sand contents of 64.4%  
144 and 56.4% as measured in September 2020 and February 2021, respectively (Rodtassana et al.  
145 2021). In 2020, a 20 m tall tower was constructed for installing weather sensors above the forest  
146 canopy in the plot. Environmental conditions that influence  $T$  including atmospheric humidity,  
147 solar radiation, and soil moisture have been continuously monitored since then. Air temperature  
148 ( $T$ , °C), relative humidity (RH, %), and photosynthetically active radiation (PAR,  $\mu\text{mol m}^{-2} \text{s}^{-1}$ )  
149 were measured by a temperature and relative humidity probe (EE181-PT, Campbell Scientific)  
150 and a quantum sensor (LI190R-PT, Campbell Scientific), respectively. Soil moisture sensors  
151 (Water content reflectometer, CS616-PT-U, Campbell Scientific) were installed to monitor  
152 volumetric soil moisture at 5, 10, 15, and 30 cm depth because tree roots may access water from  
153 multiple depths in the soil (Wang et al. 2019). We randomized the points to install soil moisture  
154 sensors around the tower. Two soil moisture sensors were installed at each depth of 5, 10, and 15  
155 cm. However, soil moisture at 30 cm depth was monitored by one soil moisture sensor because  
156 soil moisture in subsoil was less sensitive to changing environmental conditions than topsoil  
157 (Rong et al. 2017). Rainfall (mm) was measured by tipping rain gauge bucket (TE525MM-PT,  
158 Campbell Scientific). All sensors were connected to a datalogger (CR1000 series; Campbell

159 Scientific, Logan, UT) which recorded data every 30 minutes. Air temperature and relative  
 160 humidity are used to calculate vapor pressure deficit (VPD, kPa), which is the difference  
 161 between actual vapor pressure and saturated vapor pressure (SVP), from the following equations  
 162 (Monteith and Unsworth 1990)

$$163 \quad \text{SVP} = 610.7 \times 10^{\frac{7.5T}{237.5 + T}} \quad (1)$$

$$164 \quad \text{VPD} = \left(1 - \frac{RH}{100}\right) \times \text{SVP} \quad (2)$$

165 Because we did not have any information regarding rooting depth, which determines the depth of  
 166 soil moisture data to be used in the analysis, we used the average of soil moisture data from all  
 167 soil water probes, covering soil depth up to 30 cm, as the soil moisture data ( $\theta$ ,  $\text{m}^3\text{m}^{-3}$ ) for further  
 168 analysis. Based on previous studies in the central Amazon which reported the most fine root  
 169 distribution within 20 cm soil depth (Noguchi et al. 2014), we assumed that the average soil  
 170 moisture across 30 cm depth represents the soil water that largely influences tree water use. To  
 171 facilitate the cross-site comparison with other or future studies, Relative Extractable Water  
 172 (REW) was used in the analysis and was calculated according to Granier et al. (2000)

$$173 \quad \text{REW} = \frac{\theta - \theta_m}{\theta_{FC} - \theta_m} \quad (3)$$

174 where  $\theta$  is the average soil moisture of all sensors across 30-cm soil depth,  $\theta_m$  is minimum  
 175 volumetric soil moisture and  $\theta_{FC}$  is the soil water at field capacity. In the plot where soil water at  
 176 field capacity has not been measured, maximum volumetric soil moisture during the study period  
 177 can be used as  $\theta_{FC}$  for the REW calculation (Tor-ngern et al. 2018). Accordingly, we used the  
 178 maximum and minimum  $\theta_{\text{average}}$  that were determined from our data during the study period to  
 179 represent  $\theta_{FC}$  and  $\theta_m$ , respectively.

### 180 ***Species selection and tree sampling***

181 The tree species were chosen based on the relative abundance of basal area in this plot, which  
 182 was calculated from the basal area of one species relative to total basal area of all species within  
 183 the site. To examine the difference in tree water use, two dominant tree species with similar leaf  
 184 phenology were selected for this study. As a result, *Syzygium antisepticum* and *Adinandra*  
 185 *integerrima*, hereafter *Sa* and *Ai*, respectively, which have evergreen leaf habit, were chosen to  
 186 measure water flow rate. We attempted to select trees to cover the range of size distribution  
 187 within the plot, based on the inventory data from the site (unpublished data, personal  
 188 communication with Dr. Wirong Chanthorn), by partitioning the tree size classes into 10-cm  
 189 intervals and sampled 3 trees from each size class. However, due to the requirement of trees  
 190 being within 25 m radius from the data logger, 4 trees of *Sa* and 5 trees of *Ai* were selected for  
 191 the measurement (Table 1).

### 192 ***Sap flux measurement and scaling up from the point measurement to whole-tree water use***

193 Sap flux density ( $J_s$ ), which represents water mass flowing through a unit area per time in trees,  
 194 was measured using self-constructed thermal dissipation probes (TDPs) (Granier 1985). Each  
 195 TDP set contains one non-heated and one heated probe being supplied with a constant  $\sim 0.2$  W  
 196 electrical power. Before inserting TDPs into the stems, debarking around the drilling point was  
 197 done before drilling the holes for TDP installation. Two holes were drilled with approximately

198 10-15 cm spacing between two probes. Based on previous studies in pine trees, the patterns of  
 199 radial variation in  $J_s$  along the sapwood depth were observed with higher  $J_s$  in the outer sapwood  
 200 layers than in the inner sapwood layers (Ford et al. 2004; Oishi et al. 2008). Therefore, ignoring  
 201 the radial variation of  $J_s$  may produce an error when scaling up from  $J_s$  to  $T$ . However, previous  
 202 studies in tropical forests that use similar sap flow sensors only measured  $J_s$  at the outer sapwood  
 203 because of the unknown pattern of sapwood area in tropical tree species (Horna et al. 2011;  
 204 Raquel Salas-Acosta et al. 2022). In addition, most tropical trees have diffuse-porous wood  
 205 without distinct annual rings and tend to have a sap flow rate that is similar along the radial  
 206 sapwood depth (Lu et al. 2004). Therefore, we assumed that  $J_s$  was uniform along the sapwood  
 207 depth of the selected trees when scaling from single-point measurements to the whole-tree level,  
 208 and only measured  $J_s$  at the outer 2-cm sapwood at breast height (~1.3 m above ground). In  
 209 addition, azimuthal variation of  $J_s$  may produce variation when scaling up from  $J_s$  to  $T$  (Lu et al.  
 210 2000; James et al. 2002; Tateishi et al. 2008). This variation depends on the effect of forest  
 211 canopy shading by neighboring trees. In other words, trees may be obstructed from sunlight by  
 212 canopy shading from surrounding trees leading to varying  $J_s$  along the circumference. In this  
 213 study, the surrounding trees were equally distributed around the measured trees. Nevertheless,  
 214 we installed two sensors in the north and the south directions in some trees which may be  
 215 influenced by canopy shading at certain times during the day. Data from TDPs were recorded as  
 216 30-minute means of voltage difference between the probes ( $\Delta V$ , mV) by the same data logger  
 217 (CR1000, Campbell Scientific, Logan, UT, USA) that recorded environmental data. For the  
 218 analysis, the voltage difference was converted to  $J_s$  ( $\text{g m}^{-2} \text{s}^{-1}$ ) using an empirical equation  
 219 (Granier 1987)

$$220 \quad J_s = 118.99 \times 10^{-6} \times \left( \frac{\Delta V_m - \Delta V}{\Delta V} \right)^{1.231} \quad (4)$$

221 where  $\Delta V_m$  is the maximum voltage difference under no flow conditions which usually occurs at  
 222 night and when VPD is low. The Baseline program version 4.0 was used to select  $\Delta V_m$  to  
 223 calculate  $J_s$  (Oishi et al. 2016). The program automatically determines the maximum daily  $\Delta V$  to  
 224 represent  $\Delta V_m$ . Maximum voltage difference may occur every night if air humidity is very high,  
 225 or VPD reaches 0 kPa, resulting in potentially zero water flow. However, this assumption is not  
 226 valid for many ecosystems due to nighttime transpiration (e.g. Caird et al. 2007; Forster 2014;  
 227 Dayer et al. 2020) or recharge of stem water (Phillips and Oren 1998). For these reasons, no  
 228 universal rule exists for identifying  $\Delta V_m$ . The Baseline software takes an approach to  $\Delta V_m$   
 229 estimation by first identifying points in time where flow is likely zero and allowing the user to  
 230 visually inspect and modify those points.

231 To scale up from  $J_s$  to  $T$ , we employed the following approach. Daily sum  $J_s$  ( $\text{g m}^{-2} \text{day}^{-1}$ )  
 232 was considered in the analysis to avoid issues related to the nighttime recharge of stem water that  
 233 may increase as soil moisture becomes more depleted (Phillips and Oren 1998). When nighttime  
 234 recharge increases with decreasing soil moisture, the proportions of sap flux at night relative to  
 235 sap flux during the day become larger. This problem can be avoided when calculating  $T$  as a  
 236 daily sum (Phillips and Oren 1998). For trees with sensors in the north and the south direction,

237 daily sum  $J_s$  from both sensors were averaged to a mean daily  $J_s$  ( $J_{\text{mean}}$ ) for each of them (Kunert  
238 et al. 2012). The following equation was used to estimate  $T$

$$239 \quad T = 1800 \times 10^{-7} \times J_{\text{mean}} \times A_S \quad (5)$$

240 where  $T$  is daily tree water use ( $\text{L d}^{-1}$ ),  $J_{\text{mean}}$  is mean daily sum  $J_s$  ( $\text{g m}^{-2} \text{ day}^{-1}$ ) and  $A_S$  is  
241 sapwood area ( $\text{cm}^2$ ). In both species,  $A_S$  was estimated based on an allometric equation which  
242 was derived from 13 dominant species in an old growth and a secondary forest (the same plot as  
243 this study site) at Khao Yai National Park as follows (Yaemphum et al. 2022)

$$244 \quad y = 0.728x^{1.998} \quad (6)$$

245 where  $y$  is sapwood area ( $\text{cm}^2$ ),  $x$  is diameter at breast height (cm).

### 246 **Data analysis**

247 For the analysis, we used the environmental data and  $T$  between 18 September 2020 to 26  
248 November 2022. The data covered two years which represents a wide range of environmental  
249 conditions. To avoid the potential effects of wet canopy conditions that may inhibit  $T$  when the  
250 leaf surface is covered with water droplets (Aparecido et al. 2016), we selected the days under  
251 rain-free conditions to perform the analysis.

252 To evaluate the responses of  $T$  to environmental factors including VPD and REW, we  
253 performed a boundary line analysis (Schäfer et al. 2000) to obtain the response of  $T$  to  
254 environmental factors under non-limiting conditions. Trees were categorized based on the size  
255 distribution of each species as presented in Table 1 into large trees ( $\text{DBH} \geq 10$  cm for *Ai* and  
256  $\text{DBH} \geq 20$  cm for *Sa*) and small trees ( $\text{DBH} < 10$  cm for *Ai* and  $\text{DBH} < 20$  cm for *Sa*). This  
257 results in 2 trees for both species in the small class, and 3 *Ai* trees and 2 *Sa* trees in the large  
258 class. After that,  $T$  from all trees in the same category was averaged to mean  $T$  ( $T_{\text{mean}}$ ) for each  
259 day. Tree water use varies with VPD, REW and PAR (Phillips and Oren 2001). Based on our  
260 data during the study period, VPD and PAR were highly correlated ( $r = 0.79$ ,  $p = <0.001$ ),  
261 therefore we focused on VPD and REW as environmental driving variables. We performed  
262 boundary line analysis after partitioning data into three REW classes based on the REW  
263 distribution including low soil moisture ( $\text{REW} < 0.1$ ), intermediate soil moisture ( $\text{REW} 0.1-0.4$ ),  
264 and high soil moisture ( $\text{REW} > 0.4$ ). With two classes of tree size (large and small), we had six  
265 subsets of data in both species. Each subset was subjected to the boundary line, designed to  
266 select data representing the maximum  $T_{\text{mean}}$  for each tree size in each REW class along the range  
267 of VPD. The upper boundary line was derived by (1) partitioning  $T_{\text{mean}}$  data of each REW class  
268 into at least five VPD intervals for appropriate number of data points in regression analysis (at  
269 least five data points per analysis), (2) calculating the mean and standard deviation of  $T_{\text{mean}}$  in  
270 each interval, (3) removing outliers using Dixon's test, (4) selecting the data falling above the  
271 mean plus one standard deviation and (5) averaging the selected data for each VPD interval. For  
272 each tree size and REW class, the mean  $T_{\text{mean}}$  values of all VPD intervals obtained in step (5)  
273 were analyzed by regression analysis. All regression analyses were performed in SigmaPlot  
274 version 12.0 (Systat Software, Inc., San Jose, CA USA). Data management and analysis were  
275 performed with Rstudio, version 1.3.1073 (The R Foundation for Statistical Computing,  
276 <http://www.R-project.org>).

277

## 278 **Results**

### 279 *Environmental conditions in the study site*

280 During the study period, there were 52% rainy and 48% rain-free days. The average daily VPD  
281 and PAR inversely corresponded with rainfall, being low when rainfall occurred and vice versa.  
282 The maximum and minimum values of PAR during the study period were 575 and 57.3  $\mu\text{mol m}^{-2}$   
283  $\text{s}^{-1}$ , respectively, with an average of  $345.76 \pm 103.47 \mu\text{mol m}^{-2} \text{s}^{-1}$ . The average daily VPD was  
284  $0.34 \pm 0.23 \text{ kPa}$ . Volumetric soil moisture of all depths was averaged into  $\theta_{\text{average}}$ . The maximum  
285 and minimum  $\theta_{\text{average}}$  during the study period were 0.2 and 0.04  $\text{m}^3 \text{m}^{-3}$ , respectively. The  $\theta_{\text{average}}$   
286 was then used to calculate REW with an average value of  $0.44 \pm 0.25$ . Figure 1 summarizes the  
287 environmental conditions during the study period.

### 288 *Tree water use of *Syzygium antisepticum* and *Adinandra integerrima**

289 Tree water uses of both species during the study period are shown in Figure 2. The average  $T$   
290 values with one standard deviation of  $Sa$  and  $Ai$  were  $21.48 \pm 7.73$  and  $10.01 \pm 4.04 \text{ L d}^{-1}$ ,  
291 respectively. Comparing  $T$  between both species, we found that the  $T$  of  $Sa$  was significantly  
292 higher than that of  $Ai$  under high soil moisture and high light conditions ( $p < 0.0001$ ).

### 293 *Responses of tree water use to environmental factors in different tree size classes*

294 Figure 3 summarizes the results of the responses of  $T$  to VPD under various REW ranges, with  
295 the regression statistics in Table 2. At low soil moisture ( $\text{REW} < 0.1$ , black circles),  $T$  of  $Sa$   
296 increased with increasing VPD and gradually saturated at high VPD while that of  $Ai$  did not  
297 respond to the changing VPD, regardless of tree size. Under intermediate soil moisture  
298 conditions ( $\text{REW} 0.1-0.4$ , gray squares), the  $T$  of both species in both sizes did not respond to  
299 VPD. Under high soil moisture ( $\text{REW} > 0.4$ , red triangles), the  $T$  of both species in both sizes  
300 followed the saturating exponential pattern as previously described in the case of low soil  
301 moisture. However, the sensitivity of increasing  $T$  at low VPD was different between the species  
302 and size class. In both species,  $T$  of large trees was less sensitive to rising VPD than small ones  
303 (Table 2).

304

## 305 **Discussion**

306 Overall, the environmental data during the study period represent a wide range of environmental  
307 conditions which facilitates the analysis of  $T$  responses to the environments. The maximum  $T$  of  
308  $Sa$  in our data ( $47.54 \text{ L d}^{-1}$ ) was higher than the values that were found in  $T$  of *Syzygium*  
309 *cordatum* in a peat swamp forest in South Africa (Clulow et al. 2013), ranging from  $30 \text{ L d}^{-1}$  in  
310 the winter to  $45 \text{ L d}^{-1}$  in the summer. Moreover, our average  $T$  of  $Sa$  was within the range of  $T$   
311 found in *Eugenia natalitia* ( $2$  to  $28 \text{ L d}^{-1}$ ), which is the same family as  $Sa$ , as reported by the  
312 same study. Although we did not find studies that reported  $T$  values of  $Ai$  or similar genus,  $T$  of  
313  $Ai$  was within the range of  $T$  ( $10$  to  $1,180 \text{ L d}^{-1}$ ) found in 93 tree species from 52 reviewed  
314 publications that estimated whole-plant water use for trees growing in worldwide natural forests  
315 or plantations (Wullschleger et al. 1998). The study reported that the rates of water use ranged  
316 from  $10 \text{ L d}^{-1}$  for trees in a 32-year-old plantation of *Quercus petraea* L. ex Liebl. in eastern

317 France to  $1,180 \text{ L d}^{-1}$  for an overstory tree, *Euperua purpurea* Bth., growing in the Amazonian  
318 rainforest. Overall, the  $T$  values of both species in this study were within the wide ranges found  
319 in previous studies in tropical settings (Table 3).

320 Previous studies showed that the variation of  $J_s$  among trees of different ages and sizes is  
321 relatively low (Kumagai et al. 2007; Jaskierniak et al. 2016); thus, sapwood area may be a major  
322 determinant of  $T$  in this study. Based on our data,  $J_s$  of trees was similar between both species ( $p$   
323 = 0.278), suggesting the greater contribution of sapwood area or tree size to the significant  
324 difference in  $T$ . Additionally, higher water use in large trees may imply their deeper access to  
325 groundwater whereas small trees may only consume water from shallow soil as previously  
326 shown in a study investigating water use by *Acer saccharum* Marsh. in different sizes (Dawson  
327 1996). Moreover, other research in tropical forests reported that large trees consume much more  
328 water relative to small trees as indicated by the positive relationship between water consumption  
329 and tree size (O'Grady et al. 1999; Meinzer et al. 2001; Horna et al. 2011; Aparecido et al.  
330 2016).

331 The response pattern of saturating exponential function of  $T$  with VPD found in this study  
332 is similar to the one observed in various tree species in a wide range of tropical forests, including  
333 a lowland tropical forest of Central and northern South America (Meinzer et al. 1993), a primary  
334 lowland tropical forest in eastern Amazon (Brum et al. 2018) and a per-humid tropical forest of  
335 Central Sulawesi in Indonesia (Horna et al. 2011). A previous study showed that tree  
336 transpiration strongly increases with rising VPD under high soil water availability; however,  
337 such response may become weaker or disappear when soil moisture is lower, depending on tree  
338 species (Butz et al. 2018). In general, we observed similar responses of  $T$  to VPD under wet and  
339 dry conditions with stronger responses in the former; whereas no responses were detected when  
340 trees experienced moderate soil moisture. Under dry conditions, our results indicate that  $Sa$  was  
341 sensitive to increasing VPD while  $Ai$  can maintain their water use rate regardless of changes in  
342 VPD, regardless of tree size. This implies that  $Ai$  may be more tolerant to drought than  $Sa$  and  
343 may have strong control over their water use under low soil moisture, regardless of tree size,  
344 which can prevent it from negative effects from droughts. This result agreed with a previous  
345 study that investigated the drought tolerance of both species in this site (Unawong et al. 2022).  
346 Based on tree hydraulic measurement, the study reported that xylem pressure at 50% loss of  
347 hydraulic conductivity ( $P_{50}$ ) of  $Ai$  and  $Sa$  were  $-5.97$  and  $-4.71$  MPa, respectively. It is implied  
348 that species with lower  $P_{50}$  have greater resistance to embolisms, thus allowing better adaptation  
349 to environments where water stress frequently occurs (Maherali et al. 2004). When comparing  $T$   
350 in different size classes of  $Sa$ , large trees were less sensitive to rising VPD at lower VPD ranges.  
351 The less sensitivity of large trees to rising VPD leads to a slower decrease in water consumption  
352 rate to save water than small trees, resulting in potentially greater vulnerability to hydraulic  
353 failure during drought in large trees. Previous studies have shown size-dependent sensitivity to  
354 droughts in many ecosystems. A synthetic study using data on tree growth and mortality, which  
355 were collected during 40 drought events in forests worldwide, showed that droughts consistently  
356 exerted negative impacts on the growth and mortality rates of larger trees (Bennett et al. 2015).

357 Greater vulnerability of large trees to drought could be affected by the higher exposure to  
358 radiation and atmospheric demand because of increasing tree height (Roberts et al. 1990;  
359 Nepstad et al. 2007). Moreover, large trees have to transport water to greater heights, which is  
360 against the effects of gravity, thus facing greater hydraulic failure (Ryan et al. 2006; Zhang et al.  
361 2009). Thus, large *Sa* may be at higher risk of hydraulic failure when drought is more  
362 pronounced, plausibly leading to increasing mortality rates (Choat et al. 2018). At moderate soil  
363 water, the results indicated that both species could maintain their tree water use, regardless of  
364 tree size. Under high soil moisture conditions, the *T* of both species in both sizes also followed  
365 the saturating exponential pattern as in the case of low soil moisture conditions. However, the  
366 sensitivity of increasing *T* at low VPD was different between sizes. In both species, *T* of large  
367 sizes was less sensitive to rising VPD than small ones. In other words, when the air becomes dry,  
368 small trees may decrease water consumption rate faster to save water than large trees. This may  
369 be partly because small trees mainly use shallow soil water whereas large trees can access water  
370 from deeper soil (Brum et al. 2018), allowing less sensitivity to droughts in large trees.  
371 Nevertheless, further studies that investigate water-source partitioning of different tree species in  
372 the same forest (e.g., Hasselquist et al. 2010; Wang et al. 2020), tracing isotopic signals of water  
373 from various soil layers to the stems, may be performed to confirm these results.

374

### 375 ***Implications for environmental management***

376 The results from this study imply that *Sa* may provide ecosystem disservice in dry areas due to  
377 its high water consumption which results in low water supply for the downstream community,  
378 but it may slow down runoff in the region that experiences heavy precipitation. In contrast, *Ai*  
379 may provide ecosystem benefits by conservatively using water, even under drought conditions,  
380 but may increase runoff when storms come with high rainfall. Another implication is that *Ai* may  
381 be suitable for reforestation in the area where droughts frequently occur in downstream  
382 ecosystems through its conservative water-use behavior, thus maintaining runoff from the forests  
383 during drought. Moreover, because *Ai* showed relatively constant water use regardless of tree  
384 size, the species would still provide such benefits to the ecosystems even when it grows larger in  
385 the future. In contrast, *Sa* may be appropriate for reforestation in the area with frequent floods  
386 because it has high water consumption during high water availability which may decelerate  
387 runoff from forests into downstream ecosystems. This would benefit the downstream ecosystems  
388 when storms occur. Regardless, mixed planting species seem to be suitable for reforestation in  
389 the areas where extreme events do not frequently occur because both species can maintain their  
390 water use at moderate soil moisture regardless of tree size, therefore preventing the depletion of  
391 soil water availability. In addition, mixed planting species could reduce the competition for  
392 limited water resources because the differences in root structures of different tree species lead to  
393 less competition for water (Schwendenmann et al. 2015). Nevertheless, reforestation projects  
394 should emphasize the use of native species to avoid competition with other native trees on the  
395 site (Hooper et al. 2002).

396

## 397 **Conclusions**

398 We estimated tree water use ( $T$ ) of dominant tree species including *Syzygium antisepticum* ( $Sa$ )  
399 and *Adinandra integerrima* ( $Ai$ ) in a secondary tropical forest in Khao Yai National Park from  
400 sap flux density ( $J_s$ ) which was continuously monitored with custom-made thermal dissipation  
401 probes and compared  $T$  of both species in different tree size classes. In addition, we evaluated the  
402 responses of  $T$  to environmental factors of both species in different tree size classes. The results  
403 showed that  $T$  of  $Sa$  was significantly higher than  $Ai$  and that large trees had higher  $T$  than small  
404 ones which was related to relatively lower sapwood area in the small trees. Further analysis of  
405 the response patterns of  $T$  showed that  $Sa$  was more sensitive to increasing VPD than  $Ai$  while  $Ai$   
406 can maintain their water use regardless of tree size under low soil moisture. This implies that  $Ai$   
407 may be able to cope with the negative effects of droughts and retain such capacity when they  
408 grow. With ample soil moisture, both species can maintain their tree water use regardless of tree  
409 size. When soil moisture becomes high, the  $T$  of both species in both sizes increases with rising  
410 VPD and then saturated at high VPD. Nevertheless,  $T$  of both species in large size was less  
411 sensitive to rising VPD than in small size which may be explained by the deeper access to  
412 groundwater in large trees. For the implications for management, our results suggest that  $Ai$  may  
413 be suitable for reforestation in the area where droughts frequently occur in the downstream  
414 ecosystem through its conservative water-use behavior and may benefit downstream ecosystems  
415 with continuous runoff from the forest despite droughts. Moreover,  $Ai$  has conservative water-  
416 use behavior regardless of tree size. Thus,  $Ai$  would still provide these benefits to ecosystems  
417 when they grow larger in the future. In contrast,  $Sa$  seems suitable for reforestation in the area  
418 with frequent floods because it has high water consumption during high water availability which  
419 may slow down runoff from forest into downstream ecosystems when storms come. However,  
420 mixed planting species may be suitable for reforestation in areas where extreme events do not  
421 frequently occur because both species can maintain their water use at moderate soil moisture  
422 regardless of tree size which prevents the depletion of soil water availability. In this case,  
423 depending on the purposes of reforestation,  $Sa$  and  $Ai$  may provide either benefits or negative  
424 effects to the ecosystems. In conclusion, this study highlights the dependency of responses of  $T$   
425 to environmental conditions on tree species and size. Such information would benefit the  
426 selection of tree species for reforestation that could adapt well to certain environments and  
427 support policy design on the management of tropical forests and water resources. Nevertheless, a  
428 further study involving additional field measurements of the physiological parameters of trees,  
429 such as root depth, is needed to support the proposed findings.

430

# Figure 1

Figure 1 Environmental conditions during the study period.

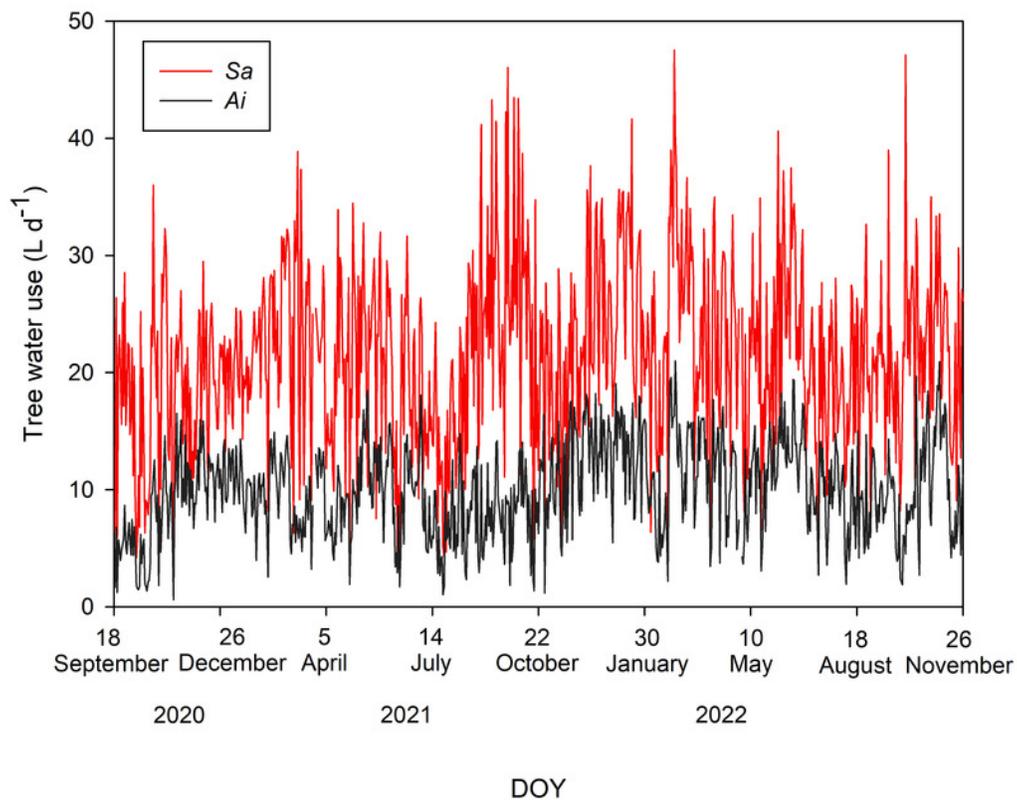

Daily values of **(A)** vapor pressure deficit (VPD in kPa; black line) and photosynthetically active radiation (PAR in  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ; red line) and **(B)** rainfall (mm; gray bar) and relative extractable water (REW; red line).

## Figure 2

Figure 2 Daily tree water use.

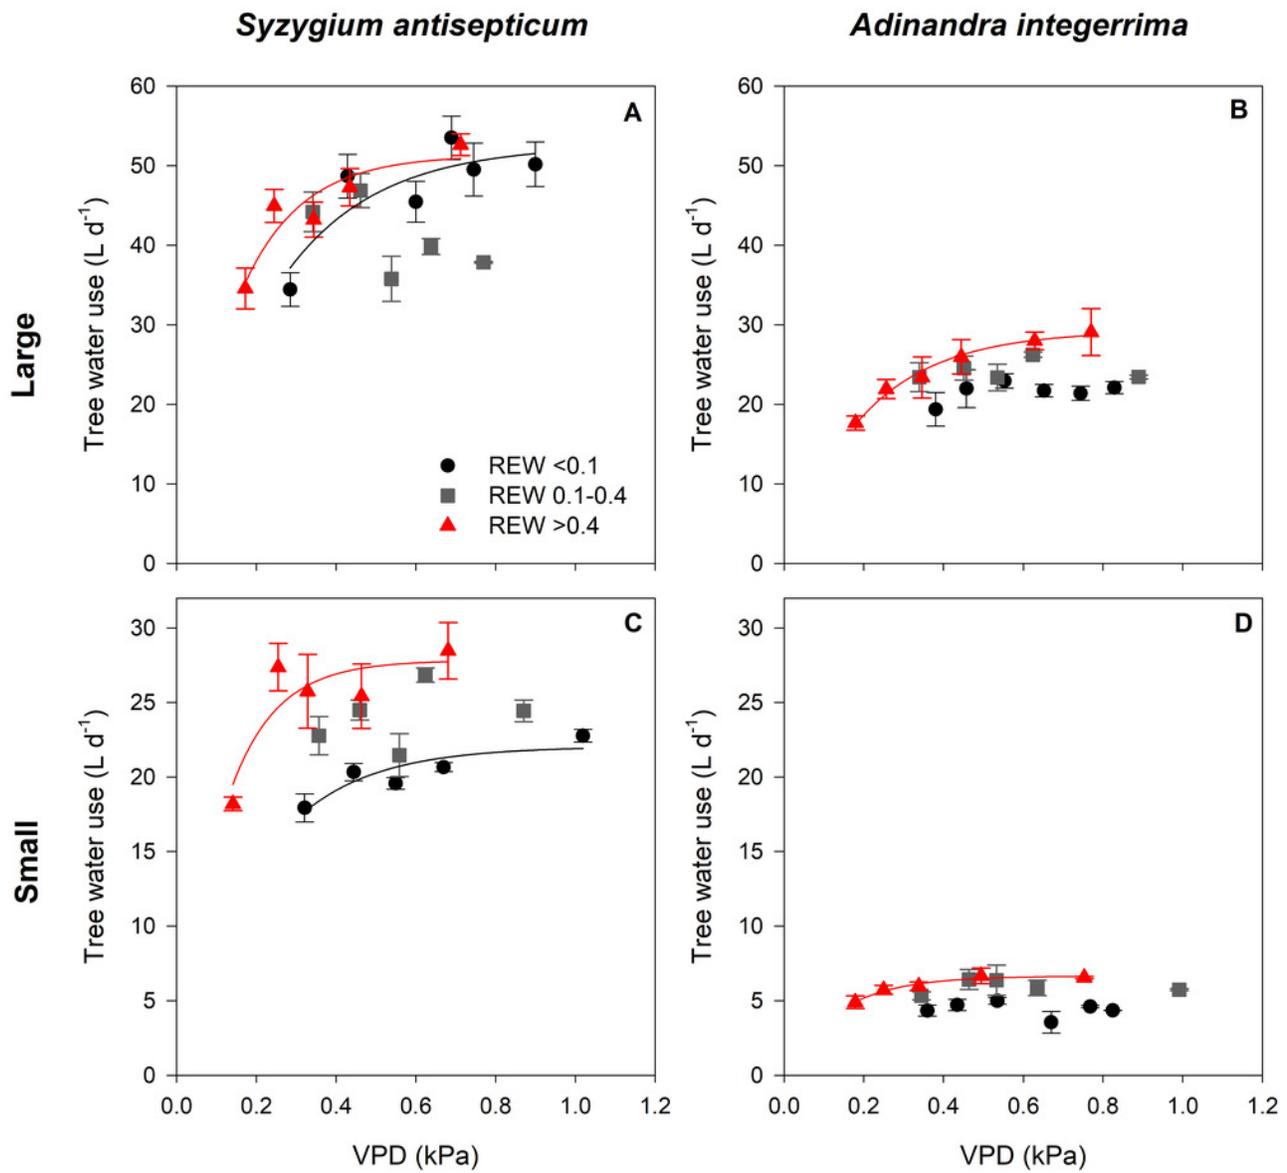

Daily sum of tree water use ( $L d^{-1}$ ) of *Syzygium antisepticum* (red line) and *Adinandra integerrima* (black line), averaged across all trees for each species, throughout the study period from 18 September 2020 to 26 November 2022.

## Figure 3

Figure 3 Relationship between tree water use and vapor pressure deficit under different soil moisture conditions.

Relationship between tree water use ( $T$ ;  $L\ d^{-1}$ ) and vapor pressure deficit (VPD; kPa) of *Syzygium antisepticum* in **(A)** large and **(C)** small size classes and *Adinandra integerrima* in **(B)** large and **(D)** small size classes under low soil moisture condition (REW <0.1, circles), under intermediate soil moisture condition (REW 0.1-0.4, squares), and under high soil moisture condition (REW >0.4, triangles).

**Table 1** (on next page)

Table 1 Information of the selected study trees. DBH refers to the diameter at breast height in cm. Sapwood area (in  $\text{cm}^2$ ) was estimated using an allometric equation derived from dominant species in the study site (Yaemphum et al. 2022).

1

<b>Species</b>	<b>DBH (cm)</b>	<b>Sapwood area (cm<sup>2</sup>)</b>
<i>Adinandra integerrima</i>	13.7	135.92
<i>Adinandra integerrima</i>	6.5	30.64
<i>Adinandra integerrima</i>	11	87.67
<i>Adinandra integerrima</i>	5.3	20.38
<i>Adinandra integerrima</i>	11.3	92.51
<i>Syzygium antisepticum</i>	24.8	444.88
<i>Syzygium antisepticum</i>	22.4	363.02
<i>Syzygium antisepticum</i>	18.7	253.09
<i>Syzygium antisepticum</i>	17.8	229.34

2

**Table 2** (on next page)

Table 2 Summary of regression statistics.

$T$  is tree water use ( $L d^{-1}$ ), VPD is vapor pressure deficit (kPa) and  $r^2$  is the coefficient of determination and  $p$  value for each regression result. The analyses were based on significance level of 0.05. n/a indicates no significant relationship was found.

1

Species	Size classes	REW classes	Relationships	r <sup>2</sup>	p
<i>Syzygium antisepticum</i> (Sa)	Small (DBH < 20 cm)	< 0.1	$T = 22.04 \times (1 - e^{-5.03 \times VPD})$	0.77	0.049
		0.1 – 0.4	n/a	0.14	0.538
		> 0.4	$T = 27.82 \times (1 - e^{-8.55 \times VPD})$	0.80	0.042
	Large (DBH ≥ 20 cm)	< 0.1	$T = 56.63 \times (1 - e^{-4.30 \times VPD})$	0.76	0.023
		0.1 – 0.4	n/a	0.44	0.56
		> 0.4	$T = 51.34 \times (1 - e^{-6.75 \times VPD})$	0.85	0.027
<i>Adinandra integerrima</i> (Ai)	Small (DBH < 10 cm)	< 0.1	n/a	0.13	0.868
		0.1 – 0.4	n/a	0.21	0.440
		> 0.4	$T = 6.65 \times (1 - e^{-7.53 \times VPD})$	0.96	0.003
	Large (DBH ≥ 10 cm)	< 0.1	n/a	0.45	0.143
		0.1 - 0.4	n/a	0.11	0.589
		> 0.4	$T = 29.25 \times (1 - e^{-5.08 \times VPD})$	0.99	<0.0001

**Table 3** (on next page)

Table 3 Summary of water use of tropical forest trees reviewed in this study.

Mean values ( $\pm$  SD if available) are presented. The abbreviations are DBH, diameter at breast height ( $\sim$ 1.3 m above ground);  $T$ , tree water use ( $L\ d^{-1}$ ); TDP, thermal dissipation probes; HPM, heat pulse method. NA indicates not available data.

1

Reference	Location		Species	Method	DBH (cm)	Tree height (m)	$T$ (L d <sup>-1</sup> )	Period
