Paired petrography and acid maceration has shown that preferential silicification of shelly faunas can bias recovery based on taxon and body size. Here, silicified fossils from the Upper Ordovician Edinburg Formation, Strasburg Junction, Virginia, USA, were analyzed using X-ray tomographic microscopy ( $\mu$ CT) in conjunction with recovered residues from acid maceration of the same materials to further examine sources of potential bias. Results reveal that very small ( $< \sim 1$  mm) fossils are poorly resolved in  $\mu$ CT when scanning at lower resolutions ( $\sim 30\mu\text{m}$ ), underestimating abundance of taxa including ostracods and bryozoans. Acid maceration, meanwhile, fails to recover poorly silicified fossils prone to disarticulation and/or fragmentation during digestion. Tests for patterns of breakage, however, indicate no significant size or taxonomic bias during extraction. Comparisons of individual fossils from 3-D fossil renders and maceration residues reveal patterns of fragmentation that are taxon-specific and allow the differentiation of biostratigraphic and preparational breakage. Multivariate ordinations and cluster analyses of  $\mu$ CT and residue data in general produce concordant results but indicate that the variation in taxonomic composition of our samples is compromised by the resolvability of small size classes in  $\mu$ CT imaging, limiting the utility of this method for addressing paleoecological questions in these specific samples. We suggest that comparability of results will depend strongly on the sample size, taphonomic history, textural, and compositional characteristics of the samples in question, as well as  $\mu$ CT scan parameters. Additionally, applying these methods to different deposits will test the general applicability of the conclusions drawn on the relative strengths and weaknesses of the methods.

**40 Abstract**

41 Paired petrography and acid maceration has shown that preferential silicification of  
42 shelly faunas can bias recovery based on taxon and body size. Here, silicified fossils  
43 from the Upper Ordovician Edinburg Formation, Strasburg Junction, Virginia, USA, were  
44 analyzed using X-ray tomographic microscopy ( $\mu$ CT) in conjunction with recovered  
45 residues from acid maceration of the same materials to further examine sources of  
46 potential bias. Results reveal that very small ( $< \sim 1$  mm) fossils are poorly resolved in  $\mu$ CT  
47 when scanning at lower resolutions ( $\sim 30\mu\text{m}$ ), underestimating abundance of taxa  
48 including ostracods and bryozoans. Acid maceration, meanwhile, fails to recover poorly  
49 silicified fossils prone to disarticulation and/or fragmentation during digestion. Tests for  
50 patterns of breakage, however, indicate no significant size or taxonomic bias during  
51 extraction. Comparisons of individual fossils from 3-D fossil renders and maceration  
52 residues reveal patterns of fragmentation that are taxon-specific and allow the  
53 differentiation of biostratinomic and preparational breakage. Multivariate ordinations and  
54 cluster analyses of  $\mu$ CT and residue data in general produce concordant results but  
55 indicate that the variation in taxonomic composition of our samples is compromised by  
56 the resolvability of small size classes in  $\mu$ CT imaging, limiting the utility of this method  
57 for addressing paleoecological questions in these specific samples. We suggest that  
58 comparability of results will depend strongly on the sample size, taphonomic history,  
59 textural, and compositional characteristics of the samples in question, as well as  $\mu$ CT  
60 scan parameters. Additionally, applying these methods to different deposits will test the  
61 general applicability of the conclusions drawn on the relative strengths and weaknesses  
62 of the methods.

## 79 **Introduction**

80 Silicification is a common preservational mode in the fossil record, especially in the  
81 early Paleozoic (Butts, 2007; Butts & Briggs, 2010), involving the fabric-specific  
82 replacement of calcareous biota (calcite and aragonite) with silica, typically as  
83 chalcedony (fine-grained fibrous quartz), opaline silica, or sometimes as sparry  
84 (macrocrystalline) quartz cement. While the fine-scale mechanisms of silicification in  
85 limestone remain unclear, the overall process is simple: pore fluids containing dissolved  
86 silica (whether volcanic, hydrothermal, or biogenic in origin) undergo transport and react  
87 with the host rock, causing contemporaneous dissolution of calcite and/or aragonite and  
88 the precipitation of silica through mechanisms involving pH change, increased  
89 temperature due to burial depth, and pressure dissolution (Kastner, Keene & Gieskes,  
90 1977; Maliva & Siever, 1988).

91         Due to their enhanced resistance to other fabric-destructive diagenetic process  
92 (Schubert, Kidder & Erwin, 1997), silicified fossils are typically preserved in great fidelity  
93 and abundance. Moreover, the replacement process frequently replicates fine  
94 morphological details if not internal microstructure, and the insolubility of silica to  
95 dissolution by acid allows such material to be prepared chemically rather than  
96 mechanically (Baars, 2008; Butts, 2014). Acid maceration is a broadly employed  
97 technique used to extract silicified fossils from limestone, relying on the high solubility of  
98 calcite in acidic solution and the comparatively low resistance of micritic matrix to  
99 alteration or dissolution (St. Clair, 1935; Grant, 1989). However, such extraction  
100 methods can introduce potential biases that might skew perceptions of paleoecological  
101 studies investigating silicified specimens (Pruss, Payne & Westacott, 2015). Two  
102 primary sources of bias that can readily be identified include the differential likelihood

103 that a given specimen will (1) silicify during diagenesis, and (2) once silicified, survive  
104 preparation and be recovered.

105         If biases in differential preservation and recovery methods go unaccounted for,  
106 certain types of analyses can be more severely affected. Systematic descriptions of  
107 organisms may be only mildly affected by the underrepresentation of some ontogenetic  
108 stages relative to others, but studies specific to the paleoecology or biofacies of an  
109 assemblage can suffer in quality due to their reliance on an accurate assessment of  
110 which biota are present in the deposit. For example, the near absence of a guild of  
111 predators or the preferential breakage of certain types of shell ornamentation might  
112 drastically alter the interpretation of trophic relationships and biotic interactions.  
113 Similarly, the loss of fossils in a certain size range during preparation can affect  
114 interpretations of biostratigraphic processes. Because these biases may skew  
115 paleoecological interpretations of fossil assemblages, quantifying or at least  
116 constraining them can improve confidence in the results of research relying on this  
117 common preparatory method.

118         Previous research has attempted to account for preservational and preparation  
119 bias in acid maceration of silicified fossils. Pruss et al. (2015) compared the relative  
120 abundances of fossil taxa in 11 hand samples of the Triassic Virgin Limestone Member  
121 of the Moenkopi Formation, from which the authors made a petrographic thin section  
122 and extracted fossil specimens via buffered acetic acid maceration. In general,  
123 echinoderms and gastropods were disproportionately over-represented in residues while  
124 bivalves were more likely to be identified in thin-section point counts (Pruss, Payne &  
125 Westacott, 2015).

126 Two questions not addressed by the aforementioned study are those of body  
127 size bias and breakage patterns. Since analysis of petrographic thin sections can  
128 identify fossils by their taxonomic group but offers minimal useful information with  
129 respect to their dimensions, detecting differences in body size distribution between thin  
130 section grains and fossils recovered in residues is not feasible. Similarly, it is impossible  
131 to tell by extraction methods whether fossils in residues suffered damage during  
132 digestion and washing or whether the breakage occurred prior to burial. Because thin  
133 sections and residues do not record the same fossils but rather disjoint subsets of the  
134 total fossils within the hand sample, no true pre and post comparison can be made.  
135 Indeed, since both methods applied in the Pruss et al. (2015) study are destructive, a  
136 single fossil cannot be recorded by both. This inherent limitation can be avoided,  
137 however, by pairing a non-destructive whole-rock analytical method with acid  
138 maceration. X-ray tomographic microscopy ( $\mu$ CT) is well-suited to such an approach,  
139 allowing compositional and textural differences within a sample to be imaged as a  
140 grayscale representation of density variation in three dimensions, revealing fossil  
141 material within. By then subjecting the sample to acid maceration, individual fossils can  
142 be resolved and measured before and after chemical preparation, and any breakage or  
143 loss documented and quantified.

144 Herein, we employ a paired approach combining  $\mu$ CT-generated three-  
145 dimensional volume data of bulk rock samples with investigation of subsequently acid-  
146 extracted insoluble residues from the same scanned samples to test the hypothesis that  
147 smaller fossils would be disproportionately less likely to survive preparation and be  
148 recovered from acid-digested residues and to further assess and quantify introduced

149 biases and their implications for paleoecological studies. For this study, we used  
150 prepared cores of carbonate bulk rock samples from the Edinburg Formation of Virginia,  
151 USA, which is well-known to host abundant and diverse silicified Ordovician marine  
152 fossils (Whittington & Evitt, 1953; Kraft, 1962). The pervasive silicification of the fossils  
153 within this unit makes it amenable to delivering sufficient contrast between the skeletal  
154 material and the host matrix using  $\mu$ CT.

155

## 156 **Materials & Methods**

### 157 **Geological Setting**

158 The Edinburg Formation is an Upper Ordovician unit of massively bedded black  
159 limestone with occasional shale interbeds, representing deep ramp to basinal deposition  
160 at the northwest of the Taconic foreland basin system after drowning of shallower ramp  
161 carbonate facies including the underlying Lincolnshire Limestone (Holland &  
162 Patzkowsky, 1996). K-bentonites derived from Taconic volcanism are sporadically  
163 present in the sediments of the foreland basin and have been sampled for radiometric  
164 ages, most notably the Millbrig bed, which lies up section of the Edinburg in the  
165 Martinsburg Formation and has a U-Pb date of 452.86 Ma (Mitchell et al., 2004; Sell,  
166 Ainsaar & Leslie, 2013).

167 All samples in this study were collected from the Liberty Hall facies of the  
168 Edinburg Formation exposed at Strasburg Junction rail cut, a well-studied site in the  
169 Shenandoah Valley of Virginia (Fig. 1, Table 1; Cooper & Cooper, 1946; Whittington &  
170 Evitt, 1953; Read, 1980; Jacobs & Carlucci, 2019). Hand sample observations revealed  
171 two starkly different lithologies (Table 1). Rocks from Horizon 1, approximately 0.5 m  
172 above the contact between the Lincolnshire Limestone and Edinburg Formation, were

173 coarse-grained, with a sparry or dismicritic texture likely indicative of recrystallization  
174 during early diagenesis. Sparse fossils and possible intraclasts visible on fresh surfaces  
175 were weakly aligned with the direction of original bedding, suggesting directional sorting  
176 during deposition. Horizons 3, 4, 5, and 6 cropped out over 30 m up section (Table 1)  
177 and were finely grained with only occasional sparry or hematitic grains. Fossils, where  
178 visible on fresh or weathered surfaces, were oriented randomly to original bedding and  
179 comprised arthropods, brachiopods, and occasional crinoid ossicles. Rocks from these  
180 horizons also displayed heavy rinds on weathered surfaces, frequently stained rusty  
181 orange to pale yellow with iron oxides/oxyhydroxides.

## 182 **Fossil Extraction**

183 From five horizons with fossils visible on weathered surfaces, 15 samples were  
184 prepared as cylindrical cores (Table 1), approximately 2 cm in diameter and ranging  
185 from 1 to 4 cm in height, normal to bedding. Each core was imaged via X-ray  
186 tomographic microscopy ( $\mu$ CT) using a Zeiss Xradia 510 Versa X-ray microscope with  
187 an isotropic voxel size of approximately 30  $\mu$ m, producing three-dimensional renders of  
188 the core interiors. All  $\mu$ CT scans were processed using Dragonfly software Build 941–  
189 v.4.2.2 for Windows, Object Research Systems (ORS) Inc, Montreal, Canada, 2018  
190 (<http://www.theobjects.com/dragonfly>). Post-image processing within the software was  
191 conducted to reduce imaging artifacts using the Ring Removal and Median filters.  
192 Regions of high brightness (corresponding to high-density ferrous material) and low  
193 brightness (corresponding to low-density siliceous material) relative to the local  
194 background were thresholded and manually segmented, excluding regions at the very  
195 top and bottom of cores due to persistent boundary artifacts. Due to radial and

196 longitudinal variation in background brightness across the cores, multiple brightness  
197 thresholds were used to segment siliceous material in some cores; in such cases, the  
198 total siliceous volume is the union of the volumes from segmentation by the various  
199 thresholds. Segmented volumes for ferrous and siliceous material were refined by  
200 removing small (<100 voxel total volume) islands and were then partitioned into distinct  
201 regions-of-interest (ROIs), using 6-connectivity (voxels considered to be connected if  
202 sharing faces rather than only edges or vertices) for both purposes. Individual fossils  
203 and other objects were identified among these ROIs by visual inspection in 3-D  
204 representations of voxels and against individual 2-D projections of  $\mu$ CT imagery. In  
205 cases where a fragmentary or incompletely resolved fossil fell into multiple non-  
206 connected ROIs, those ROIs were merged into one; in cases where a single ROI  
207 contained multiple contiguous objects, it was manually partitioned.

208         After each core had been imaged with  $\mu$ CT, they were macerated in 10% acetic  
209 acid to dissolve calcareous material until fully disaggregated and no longer visibly  
210 evolving gas bubbles. Acetic acid was chosen over alternatives such as hydrochloric  
211 acid or formic acid to allow for slow dissolution and avoidance of fossil damage.  
212 Insoluble residues were washed with water and sonicated in 30-second intervals,  
213 iterating until the supernatant ran clear. This washing process was then repeated using  
214 Calgon solution (0.052 M  $\text{Na}_6(\text{PO}_3)_6$ , 0.286 M  $\text{NaHCO}_3$ ) as a deflocculant, sonicating as  
215 before, until all loose clay was removed. Cleaned residues were then washed over a  
216 250- $\mu\text{m}$  sieve, oven dried, and picked for identifiable fossils.

## 217 **Statistical Analyses**

218 Following scanning and segmentation, each object resolved in the  $\mu$ CT data was  
219 measured for minimum, maximum, and mean three-dimensional Feret diameter. Fossils  
220 that could be confidently identified to at least the phylum level were scored for additional  
221 taxon-specific features and anatomical measurements (Table 2).

222 Fossils recovered from residues were photographed using a GIGAmacro  
223 Magnify2 Robotic Imaging System with Canon EOS Rebel T8i DSLR and Nikon T1 1 $\times$   
224 and 3 $\times$  objectives. For large specimens, additional photographs were taken under a  
225 reflected light microscope (Nikon SMZ1500 tethered to a Nikon D600 DSLR) to record  
226 features not visible in top-down view. Photographs were processed and analyzed with  
227 FIJI/ImageJ software, using the Trainable Weka Segmentation plugin to isolate fossils  
228 against the image background (Andreola et al., 2004a, b; Schindelin et al., 2012). Each  
229 fossil was measured for minimum and maximum two-dimensional Feret diameter as  
230 well as taxon-specific measurements corresponding to those taken from  $\mu$ CT data  
231 (Table 2).

232 For each core, both the segmented  $\mu$ CT render and acid residues were counted  
233 for the total abundance of fossil specimens. Trilobites were identified to the family level  
234 based on their general geometry, furrow pattern, and, in residues, their prosopon.  
235 Trilobite material not reliably assignable to a single family was treated as a separate  
236 category. Prosopon and other textural features were not easily resolvable in the  $\mu$ CT  
237 dataset, and so were not generally considered for taxonomic assignment in counts  
238 based on  $\mu$ CT results. Bryozoans were morphologically classified by growth form either  
239 as thin-branching, thick-branching, or fenestrate. Ostracods, gastropods, and bivalves

240 were not further classified due their generally small sample size and coarse silicification,  
241 precluding the reliable identification of taxonomically relevant features.

242 Using R statistical software, datasets were subjected to NMDS in three  
243 dimensions based on the Bray-Curtis dissimilarity index, using the *metaMDS* function  
244 provided in the *vegan* package (Dixon, 2003; R Core Team, 2021). Sites with no  
245 counted fossils were excluded from the analysis. Further paleoecological analysis of  
246 taxon abundances within and between samples was performed using PAST statistical  
247 software, calculating ecological dominance within samples (Simpson's *D*) and  
248 assessing compositional similarity between samples using the Bray-Curtis index  
249 (Hammer & Harper, 2001, 2022).

250

## 251 **Results**

252 A total of 582 distinct objects were resolved via  $\mu$ CT, 460 as a low-opacity siliceous  
253 phase and 122 as a high-opacity ferrous phase. Of these, 241 siliceous objects and 14  
254 ferrous objects were identifiable to at least a coarse taxonomic level, with the remaining  
255 219 and 108 respectively left unidentified (Fig. 2). Siliceous fossils were dominated by  
256 trilobites ( $n = 225$ ), of which slightly less than half ( $n = 99$ ) could be confidently assigned  
257 to a family classification; including Asaphidae (c.f. *Isotelus*), Cheiruridae (*Ceraurus*),  
258 Metagnostidae (*Trinodus*), Pterygometopidae (*Calyptaulax*), Raphiophoridae (*Ampyx*,  
259 *Lonchodomas*), and Remopleurididae (*Remopleurides*), all of which are previously  
260 known from this site (Whittington & Evitt, 1953; Evitt, 1961). Non-trilobite siliceous  
261 material consisted of thin-branching and fenestrate bryozoans and a single valve from  
262 an ostracod. Ferrous fossils were mostly gastropods, with two bivalves, one possible  
263 thin-branching bryozoan, and one infilling of a raphiophorid cranidium (Table 3). This

264 cranidium was counted towards siliceous and ferrous  $\mu$ CT object totals due to being  
265 preserved as silicified cuticle filled in by moldic pyrite but was counted as one individual  
266 in taxon totals (Fig. 2D).

267 Residues yielded 1,349 recognizable objects, 1,222 preserved as silica, 125 as  
268 ferrous minerals (pyrite, hematite, and/or limonite), and the remaining two as other  
269 indeterminate materials (neither were identifiable as a fossil) (Fig. 3). Nearly all siliceous  
270 fossils were attributed to at least a coarse taxonomic level, with only 48 unidentifiable.  
271 Conversely, 113 of the ferrous objects could not be identified. Siliceous objects in  
272 residue were made up largely of trilobites, fragments of thin-branching bryozoans, and  
273 ostracods. All trilobite genera represented in  $\mu$ CT were found also in residues, along  
274 with trilobites from the family Odontopleuridae (c.f. *Ceratocephala*). The remainder  
275 consisted of thick-branching and fenestrate bryozoans along with occasional brachiopod  
276 fragments. Ferrous fossils were exclusively represented by gastropods, except for a  
277 single bivalve (Table 3).

### 278 **Tests of Preparation Bias**

279 A contingency table was constructed containing  $\mu$ CT identified specimens  
280 counts, broken down by taxonomic grouping and by presence or absence in residues.  
281 The relationship between taxon and recovery was investigated using Pearson's  $\chi^2$  test  
282 (Table 4). The only taxonomic group which deviated significantly ( $p = 0.04$ ) from overall  
283 likelihood of recovery was Unidentified Trilobita—material clearly from trilobites but  
284 lacking anatomical features in  $\mu$ CT sufficient to assign it to a family—which, despite  
285 being identified in  $\mu$ CT, are disproportionately unlikely to be recovered in residues.

286 Application of Pearson's  $\chi^2$  test to total counts of taxa identified in  $\mu$ CT and in  
287 residue found strong support ( $p = 1.89 \times 10^{-35}$ ) for different proportional abundances in  
288 the two preparation types (Table 5). Raphiophorids ( $p = 1.99 \times 10^{-5}$ ), remopleuridids ( $p$   
289  $= 0.02$ ), unidentified trilobites ( $p = 9.92 \times 10^{-17}$ ), bivalves ( $p = 0.02$ ), and gastropods ( $p =$   
290  $2.08 \times 10^{-4}$ ) are significantly more abundant in  $\mu$ CT, while thin-branching bryozoans ( $p =$   
291  $3.26 \times 10^{-14}$ ), thick-branching bryozoans ( $p = 1.15 \times 10^{-3}$ ), and ostracods ( $p = 1.27 \times 10^{-$   
292  $13$ ) are significantly more abundant in residues.

293 The presence of size bias in the likelihood of recovery was evaluated using the  
294 Mann-Whitney U-test with a null hypothesis of no difference in medians and a standard  
295 threshold of significance of  $\alpha = 0.05$  (Mann & Whitney, 1947). In comparisons between  
296 fossils identified in both  $\mu$ CT and residue and those identified in  $\mu$ CT but *not* in residue,  
297 there was no statistically significant difference of maximum ( $p = 0.54$ ), minimum ( $p =$   
298  $0.09$ ), or mean ( $p = 0.24$ ) Feret diameters, nor of elongation factor ( $p = 0.16$ ) defined as  
299 the ratio of maximum to minimum Feret diameters. However, when testing overall  
300 distributions of size between all fossils identified in  $\mu$ CT and all those found in residue,  
301 the U-test found a dramatic difference in maximum Feret diameter ( $p = 1.75 \times 10^{-79}$ )  
302 between the medians of the two groups (3.98 mm for CT, 1.41 mm for residue).

### 303 **Exploratory Paleoecological Ordinations**

304 NMDS performed separately on the  $\mu$ CT (Table 6) and residue (Table 7)  
305 datasets resulted in ordinations with stress scores of 0.06 and 0.08, respectively (Fig.  
306 4). Taxon loadings in both ordinations consistently grouped bivalves and gastropods  
307 nearby each other. Ordinations of both  $\mu$ CT and residues tended to group medium-  
308 sized benthic trilobites (raphiophorids, pterygometopids, and cheirurids) together along

309 with unidentified trilobite material (most of which likely derived from one of those  
310 families), with pelagic trilobites (remopleuridids) plotting closer to gastropods and  
311 bivalves. Asaphids, likely represented here by the extremely large benthic trilobite  
312 *Isotelus*, consistently fall near the latter cluster but are represented only by fragments of  
313 cuticle. The ordination position of agnostids, whose life habit remains controversial  
314 (Fortey & Owens, 1999), is inconsistent between  $\mu$ CT and residues, falling near the  
315 benthic and pelagic trilobite clusters in those analyses, respectively. In both cases, they  
316 are closely accompanied by ostracods (which can occupy pelagic or benthic niches and  
317 whose life habit was not interpreted in this study). Due to the extreme disparity between  
318 identification in  $\mu$ CT and recovery in residues of ostracods, their location within the  
319 ordination for  $\mu$ CT data is likely not informative.

320         Thin-branching and fenestrate bryozoans plotted relatively close together,  
321 forming an isolated cluster. Thick-branching bryozoans were not closely associated with  
322 the other two morphotypes in the residue ordination and were not detected in  $\mu$ CT.

323         Samples from individual horizons tended to fall near each other in loose  
324 association. Two main clusters are apparent in both residue and  $\mu$ CT ordinations: one  
325 characterized by low NMDS1 scores and dominated by bryozoans, and one with higher  
326 NMDS1 scores and dominated by arthropods (trilobites and ostracods).

327 For each sample, dominance was computed for both  $\mu$ CT (Table 6) and residue (Table  
328 7) taxon totals, with 95% confidence intervals based on 9999 bootstrap replicates (Fig.  
329 5). The results of this analysis differed notably between the two;  $\mu$ CT dominance values  
330 fell in a tight band between 0.25 and 0.40 (excepting two outliers with  $n < 3$ ), while  
331 residue dominance values had a bimodal distribution with one group of values between

332 0.40 and 0.65 and another falling between 0.15 and 0.30. (Fig. 5) Rarefaction curves  
333 were calculated for both  $\mu$ CT (Table 6) and residue (Table 7) counts of each sample  
334 using PAST (Hammer & Harper, 2022; Fig. 6). Curves were visually inspected for the  
335 presence of an inflection point as a rough qualitative assessment of sampling  
336 completeness; a sample's curve "leveling off" (sudden decrease in slope) is considered  
337 informal evidence that taxa in the true population are well-represented in the sample  
338 (Sanders, 1968; Raup, 1975). This inflection point was observed in residue counts from  
339 most samples (prominently in 03-C1, 03-C3, 04-C1, and 06-C3), but not in  $\mu$ CT counts.  
340 This suggests that the smaller total counts of individuals in  $\mu$ CT data are leading to the  
341 non-recovery of rarer taxa. Such under-sampling is a liability of ecological analyses  
342 based on those samples.

### 343 **Cluster Analysis**

344 Multivariate cluster analyses were performed in PAST to provide alternate  
345 metrics of similarity in the paleoecological composition of the samples, using the Bray-  
346 Curtis index as before (Bray & Curtis, 1957; Hammer & Harper, 2022). Dendrograms  
347 with branch length scaled to similarity were constructed for  $\mu$ CT counts, residue counts,  
348 and a combined dataset treating  $\mu$ CT and residue counts for each sample as two  
349 separate sites (Figs. 7 and 8). Cluster analysis of  $\mu$ CT counts grouped samples from  
350 Horizon 04, and treated Horizon 05 similarly, but scattered samples from Horizons 03  
351 and 06 across the tree. Using residue data, Horizon 05 formed a cluster as before but  
352 Horizon 04 split, with cores 04-C2 and 04-C3 remaining close but 04-C1 further  
353 removed; Horizons 03 and 06 were dispersed as in the  $\mu$ CT tree. In both trees, samples

354 from Horizon 01 were far removed from other samples, tending to form a cluster basal  
355 to the rest of the samples.

356         The combined tree retains the general close groupings of the two individual trees  
357 due to sharing the same dissimilarity metric (Fig. 8). Notably, even for Horizons 01, 04,  
358 and 05 whose samples tended to cluster in both the  $\mu$ CT and residue trees, those  
359 clusters are not closely related in the overall analysis; there are few clear patterns in this  
360 tree, but  $\mu$ CT samples tend to cluster more closely with other  $\mu$ CT samples, and residue  
361 samples with residue samples, than do  $\mu$ CT and residue counts of the same sample or  
362 even of samples from the same horizon.

363

## 364 **Discussion**

### 365 **Size and Taxon Effects on Recovery**

366 We hypothesized at the outset of this study that body size would be negatively  
367 associated with likelihood of recovery in residues; larger fossils may be more  
368 susceptible to breakage, and larger organisms with thicker skeletal elements may not  
369 fully silicify, producing a brittle outer husk. However, the results of our analysis do not  
370 support this possible effect. While fossils recovered in residue have a smaller median  
371 body size than those resolved in  $\mu$ CT, this appears to be due not to preferential  
372 breakage of larger fossils during washing but rather disproportionate non-resolution of  
373 smaller fossils in  $\mu$ CT datasets. Rather than  $\mu$ CT acting as a baseline to test the biases  
374 of acid maceration based on body size, the results of this study suggest the opposite.

375         Overrepresentation with respect to the abundance of pyritized taxa (gastropods  
376 and bivalves) in  $\mu$ CT may be the result of the high contrast between iron-bearing  
377 phases and the matrix, making such fossils easier to resolve in  $\mu$ CT than otherwise-

378 comparable siliceous fossils. Alternatively, because most of the pyritized fossil materials  
379 represent internal molds, they may be harder to identify outside of the 3D context  
380 provided in  $\mu$ CT, where they remain within their shell. If the latter is the case, this likely  
381 reflects lower fidelity of moldic pyrite preservation than that of the replacive silicification.  
382 Results of the NMDS ordinations consistently plotted molluscan taxa nearby one  
383 another, which may reflect either a shared infaunal environment or instead early burial  
384 conditions conducive to pyritization in those deposits. However, the low abundance of  
385 bivalves (2 in  $\mu$ CT, 1 recovered from residues, always alongside multiple gastropods)  
386 makes this apparent association tenuous. It is noteworthy that disseminated pyritization  
387 in the form of non-fossil granules was present in several samples (e.g., 05-C4) that  
388 contained no mollusks, suggesting that the presence or absence of mollusks in a  
389 sample may reflect their abundance in the paleoenvironment and is not solely controlled  
390 by whether early burial chemistry allowed pyritization to proceed. Ostracods,  
391 meanwhile, are disproportionately overrepresented in residue due to their small size  
392 making them difficult to resolve in  $\mu$ CT at the resolution used in this study. Branching  
393 bryozoans also suffer from this, but their numbers in residue are likely inflated by  
394 fragmentation of large individuals into many smaller ones.

### 395 **Nonrecovery Bias and Potential Causes**

396 Revealing that the number of unidentified trilobite fossils recognized in  $\mu$ CT is  
397 significantly less likely to be recovered in residue is to be expected. Fragmentation and  
398 incomplete preservation are common causes for trilobite material to lack identifying  
399 characteristics, and both are likely to promote further breakage and degradation during  
400 washing by compromising the structural integrity of the sclerite. This may also influence

401 likelihood of recovery by impeding identification of the fossil in residue; a fragment of  
402 cuticle lacking identifying characteristics is less likely to be recognized as corresponding  
403 to an object observed in  $\mu$ CT, and minor breakage is likely to disrupt recognizable  
404 aspects of its outline and other key features.

405         Diagenetic biases arise from a variety of sources and are heavily dependent on  
406 shell microstructure, organic matter, and availability of reactive and replacive ions to the  
407 shell. It is well-documented that certain taxa are more susceptible to silicification than  
408 others, and, even within taxa, textural differences can make certain skeletal elements  
409 more likely to be preserved than others (Daley & Boyd, 1996; Cherns et al., 2011; Butts,  
410 2014). Organic matter content within a shell also influences the likelihood of silicification  
411 by providing nucleation sites for the deposition of silica, though the chemistry of this is  
412 complex (Wallace, DeYoreo & Dove, 2009; Butts, 2014). Similarly, replacement via  
413 pyrite tends to initiate at sites of organic matrix in the shell but is also dependent upon  
414 reducing microenvironments and/or microbial zonation within the sediment (Fisher,  
415 1986; Canfield & Raiswell, 1991; Schiffbauer et al., 2014).

416         Further biases can arise from the sample extraction and preparation process  
417 itself. During washing, larger fossils may be tumbled against other grains or container  
418 walls, leading to abrasion or breakage, while smaller fossils may be crushed beneath  
419 larger objects as grains settle. Elongated grains may be more prone to breakage than  
420 spheroidal grains of the same volume due to a lower minimum cross-sectional area,  
421 which can lead to taxon or sclerite bias against fossils with rod-like geometry, such as  
422 branching bryozoans and the spines of some trilobites. Breakage during preparation  
423 can cause taxa to be undercounted due to indiscriminate destruction of individuals or

424 damage sufficient to remove recognizable features. Paradoxically, it can also inflate  
425 taxon counts by turning one fossil into many still-recognizable fragments. These  
426 overlapping effects can produce a wide variety of biases in size and shape, and the  
427 cumulative effect on measurements of abundance cannot reasonably be predicted *a*  
428 *priori*.

429         The composition of the host rock can further impose preparation-related biases.  
430 For instance, well-cemented rocks frequently require longer maceration periods than  
431 poorly consolidated ones, while argillaceous rocks may need more thorough washing to  
432 drive off insoluble clays, often including sonication. The longer sediment is washed and  
433 manipulated, the more breakage tends to occur, making matrix texture an important  
434 factor of preparation bias. While the acid maceration processes can be accelerated by  
435 using alternative acids, such as hydrochloric, the violent effervescence caused by the  
436 intensity of the reaction can also have a deleterious effect on the extraction of delicate  
437 forms.

#### 438 **Artifacts and Limitations of $\mu$ CT**

439 While a powerful tool for visualization,  $\mu$ CT does present some unavoidable sources of  
440 potential error: artifacts arising from specimen capture and processing, particularly the  
441 “hardening” of the X-ray beam through preferential absorption of lower-energy photons  
442 by the sample. Beam hardening is a ubiquitous issue in  $\mu$ CT, but not all hardening  
443 artifacts are of equal impact. Since the beam is slightly hardened by passing through  
444 the outer surface of the sample, the interior is always slightly darkened relative to the  
445 outermost layer; these “cupping artifacts” are produced predictably based on sample

446 geometry and can be corrected relatively easily (Schladitz, 2011; Jung et al., 2011;  
447 Abel, Laurini & Richter, 2012).

448 Heterogeneous samples may experience additional artifacts. Regions of higher-  
449 density material (e.g., iron minerals in sediments, bones in biological samples) can  
450 drastically harden beams passing through them, causing dark blotches to appear  
451 around bright features within a sample and especially in the spaces between multiple  
452 bright features. These artifacts are far more difficult to correct due to their irregular  
453 shape and remain the subject of ongoing research in economic geology and other  
454 materials science fields (Remeysen & Swennen, 2006; Park, Chung & Seo, 2015; Bam  
455 et al., 2019). Given the abundant pyrite in the material examined in this study, this  
456 stands as a caveat to the results reported here; similar methods applied to rocks with  
457 lower density variation may yield clearer  $\mu$ CT data and therefore more complete  
458 identification of fossils within the samples. Filtering during pre-processing, or correction  
459 applications in post-processing software packages, can reliably improve these artifacts,  
460 but often at the cost of introducing noise along the axis of sample rotation (Kyriakou,  
461 Prell & Kalender, 2009; Yousuf & Asaduzzaman, 2009).

#### 462 **Relevance for Paleoecological Interpretation**

463 Broad categories of biofacies are generally consistent between residue- and  
464  $\mu$ CT-derived taxon abundances as interpreted using NMDS. While total counts for  $\mu$ CT  
465 are much lower than those of residues, relative abundances in the former largely  
466 recapitulate the latter with some notable exceptions; ostracods are almost absent from  
467  $\mu$ CT data, due to resolution constraints imposed from the diameter of the cores, even  
468 when highly abundant in residues, and bryozoan counts tend to be much higher in

469 residues than in  $\mu$ CT due to breakage transforming one large fragment into many small  
470 fragments. For this reason, the application of  $\mu$ CT data alone to describe  
471 paleoecological structure should be undertaken with caution. Ordinations used in  
472 paleoecology are sufficiently complex that such biases in recovery can, by introducing  
473 error and uncertainty upstream, irreparably taint conclusions drawn downstream.

474 Overall, the use of  $\mu$ CT counts on their own to characterize silicified remains in  
475 these limestone biofacies is of uncertain value. Sample volume constraints make bulk  
476 samples unfeasible, and the cost of instrument time can be a roadblock to replication  
477 and large-scale sampling. However,  $\mu$ CT may be best suited when chemical preparation  
478 is dangerous or impractical due to matrix or fossil mineralogy, or when studying  
479 sponges, bryozoans, corals, or other modular organisms for which fragmentation during  
480 washing can obscure or inflate the number of individuals present. Samples best suited  
481 to the approach outlined in this study will be densely fossiliferous (mitigating the  
482 limitation of sample volume), bear taxa with morphological features conducive to  
483 identification in  $\mu$ CT (related to shape rather than texture) and contain grains more  
484 susceptible to dissolution than the matrix or cement joining them together. Such rocks  
485 should also have a contrast in density, whereby the material of interest has a higher X-  
486 ray attenuation, for better visualization, whilst keeping in mind the potential effects of  
487 beam hardening artifacts. Conodonts and other phosphatic fossils, for example, are  
488 occasionally known from silicified sediments, and characterizing taxonomic  
489 assemblages using  $\mu$ CT techniques may constitute an alternative to digestion from the  
490 toxic and hazardous hydrofluoric acid normally used to extract fossils from siliceous  
491 cements (Green, 2001).

492

493 **Conclusions**

494

495 The main goal of this study was to quantify the effects of taxonomic affinity and

496 body size on the likelihood of fossil recovery as revealed by different extraction

497 methods. Breakage remains an unavoidable concern with acid maceration, one which

498  $\mu$ CT can provide insight to, though not without its own caveats. While  $\mu$ CT imaging of

499 silicified fossils in limestone matrix can resolve morphological features of interest, the

500 issues faced in this specific study may limit this technique's ability to answer broader

501 paleoecological questions. Analyzing original rock contents as a means of detecting

502 breakage during preparation may be valuable as a control on fragmentary abundance

503 counts, but limitations of sample size and the potential for taxonomic bias to affect

504 ordinations present serious pitfalls to analysis or characterization of biofacies. It can,

505 however, be useful in establishing broad categories if not finer gradations between

506 related assemblages. Since the drawbacks resulting from beam hardening and other

507  $\mu$ CT artifacts are heavily dependent on the properties of the sample, these methods

508 may prove more effective when applied to rocks containing different fossil taxa or with

509 different lithologic compositions from the materials studied here.

510 Variation in fossil recovery can stem not only from easily observable

511 sedimentological features such as grain size and composition but also from redox

512 chemistry and solute profiles of pore fluids during burial and early diagenesis, which can

513 be challenging to infer from samples without more in-depth geochemical analyses.

514 Original shell composition, both in terms of organic content and aragonitic versus

515 calcitic (high- or low-magnesium) mineralogy is likely relevant due to its influence on the

516 spontaneity and kinetics of silicification chemistry. Information on the breadth of

517 variation is limited but suggests a wide range of possible taxonomic outcomes based on  
518 sample lithology.

**Table 2** (on next page)

Jacobs et al Table 2

Table 2. Anatomical measurements and classifications by taxon and sclerite. Measurements taken from CT and residue imagery for each of several common taxa. The main sclerites of trilobites (excluding hypostomes and librigenae) were assigned different sets of measurements due to fundamental differences in structure. Lengths, widths, and heights are measured in mm; angles are measured in degrees; other category variables were recorded as Booleans. \* Raphiophorids have an effaced prosopon with indistinct furrows, making identification of the occipital lobe difficult in CT especially. For this family of trilobites, occipital width was instead measured as the full width (tr.) of the sclerite from gena to gena at the occiput. \*\* For eyeless trilobites of the families Metagnostidae and Raphiophoridae, interocular distance was excluded. \*\*\* This is the angle formed at the apex between the axis of coiling and a line tangent to the outer walls of the body whorls.

Taxon		Measurements and Classifications
Trilobita	Cranidium	Maximum width (tr.) of occipital lobe*, maximum width (tr.) between eyes**, total length (sag.)
	Thoracic segment	Maximum width (tr.) of axial ring, width (tr.) between fulcra of left and right pleurae, length (sag.) of axial ring
	Pygidium	Maximum width (tr.) of first axial ring, total length (sag.)
Bryozoa		Growth form: dendroid or fenestrate
Gastropoda		Presence/absence of outer walls of whorls, total height of shell, height of last complete whorl, width of last complete whorl, half-angle of teleoconch***
Ostracoda		Body length (a.-p.), body height (d.-v.), articulation/disarticulation, presence/absence of lateral spine

**Table 4**(on next page)

Jacobs et al Table 4

Table 4. Taxonomic Effects on Recovery. Contingency table containing counts of fossils with distinctive geometry identified in CT imagery and either recovered or not recovered in residue. Residuals of recovered counts are standardized to the expected number of recovered specimens for a taxon; positive residuals indicate disproportionately high likelihood of recovery in residues, while negative values indicate lower-than-average likelihood of recovery. Statistically significant results ( $p < 0.05$ ) are shaded.

<b>Taxon</b>	<b>Not Recovered</b>	<b>Recovered</b>	<b>Recovered residual</b>	<b>p-value</b>
Asaphidae	3	2	0.213	0.84
Cheiruridae	1	1	0.285	0.67
Metagnostidae	2	4	1.855	0.11
Pterygometopidae	4	1	-0.787	0.46
Raphiophoridae	37	20	-0.376	0.90
Remopleurididae	13	8	0.493	0.81
Unknown Trilobita	71	28	-7.389	0.04
Bivalvia	1	1	0.285	0.67
Bryozoa (thin)	4	4	1.140	0.39
Bryozoa (fenestrate)	2	4	1.855	0.11
Gastropoda	4	6	2.425	0.10

1

**Table 5** (on next page)

Jacobs et al Table 5

Table 5. Comparison of Taxonomic Abundances. Contingency table containing total counts of taxa identified in CT and in residue imagery. Residuals of recovered counts are standardized to the expected number of recovered specimens for the combination of taxon and preparation; positive CT residuals indicate overrepresentation in CT for that taxon, while positive residue residuals indicate overrepresentation in residues (relative to average proportional abundance for all fossils). Statistically significant results ( $p < 0.05$ ) are shaded.

<b>Taxon</b>	<b>CT</b>	<b>Residue</b>	<b>CT residual</b>	<b>Residue residual</b>	<b>p-value</b>
Asaphidae	6	20	0.715	-0.326	0.43
