

# Seasonal availability of edible underground and aboveground carbohydrate resources to human foragers on the Cape south coast, South Africa

Jan C De Vynck, Richard M Cowling, Alastair J Potts, Curtis W Marean

The coastal environments of South Africa's Cape Floristic Region (CFR) provide some of the earliest and most abundant evidence for the emergence of cognitively modern humans. In particular, the south coast of the CFR provided a uniquely diverse resource base for hunter-gatherers, which included marine shellfish, game, and carbohydrate-bearing plants, especially those with underground storage organs (USOs). It has been hypothesized that these resources underpinned the continuity of human occupation in the region since the Middle Pleistocene. Very little research has been conducted on the foraging potential of carbohydrate resources in the CFR. This study focuses on the seasonal availability of plants with edible carbohydrate at six-weekly intervals over a two-year period in four vegetation types on South Africa's Cape south coast. Different plant species were considered available to foragers if the edible carbohydrate was directly (i.e. above-ground edible portions) or indirectly (above-ground indications to below-ground edible portions) visible to an expert botanist familiar with this landscape. A total of 52 edible plant species were recorded across all vegetation types. Of these, 33 species were geophytes with edible USOs and 21 species had aboveground edible carbohydrates. Limestone Fynbos had the richest flora, followed by Strandveld, Renosterveld and lastly, Sand Fynbos. The availability of plant species differed across vegetation types and between survey years. The number of available USO species was highest for a six-month period from winter to early summer (Jul-Dec) across all vegetation types. Months of lowest species' availability were in mid-summer to early autumn (Jan-Apr); the early winter (May-Jun) values were variable, being highest in Limestone Fynbos. However, even during the late summer carbohydrate "crunch", 25 carbohydrate bearing species were visible across the four vegetation types. To establish a robust resource landscape will require additional spatial mapping of plant species abundances. Nonetheless, our results demonstrate that plant-based carbohydrate resources available to Stone Age foragers of the Cape south coast, especially USOs belonging to the Iridaceae family, are likely to have comprised a reliable and nutritious source of calories over most of the year.

**31 Abstract**

32

33 The coastal environments of South Africa's Cape Floristic Region (CFR) provide some of the  
34 earliest and most abundant evidence for the emergence of cognitively modern humans. In  
35 particular, the south coast of the CFR provided a uniquely diverse resource base for hunter-  
36 gatherers, which included marine shellfish, game, and carbohydrate-bearing plants, especially  
37 those with underground storage organs (USOs). It has been hypothesized that these resources  
38 underpinned the continuity of human occupation in the region since the Middle Pleistocene. Very  
39 little research has been conducted on the foraging potential of carbohydrate resources in the  
40 CFR. This study focuses on the seasonal availability of plants with edible carbohydrate at six-  
41 weekly intervals over a two-year period in four vegetation types on South Africa's Cape south  
42 coast. Different plant species were considered available to foragers if the edible carbohydrate  
43 was directly (i.e. above-ground edible portions) or indirectly (above-ground indications to  
44 below-ground edible portions) visible to an expert botanist familiar with this landscape. A total  
45 of 52 edible plant species were recorded across all vegetation types. Of these, 33 species were  
46 geophytes with edible USOs and 21 species had aboveground edible carbohydrates. Limestone  
47 Fynbos had the richest flora, followed by Strandveld, Renosterveld and lastly, Sand Fynbos. The  
48 availability of plant species differed across vegetation types and between survey years. The  
49 number of available USO species was highest for a six-month period from winter to early  
50 summer (Jul-Dec) across all vegetation types. Months of lowest species' availability were in  
51 mid-summer to early autumn (Jan-Apr); the early winter (May-Jun) values were variable, being  
52 highest in Limestone Fynbos. However, even during the late summer carbohydrate "crunch", 25  
53 carbohydrate bearing species were visible across the four vegetation types. To establish a robust  
54 resource landscape will require additional spatial mapping of plant species abundances.  
55 Nonetheless, our results demonstrate that plant-based carbohydrate resources available to Stone  
56 Age foragers of the Cape south coast, especially USOs belonging to the Iridaceae family, are  
57 likely to have comprised a reliable and nutritious source of calories over most of the year.

60

61

62 **Introduction**

63

64 The Cape south coast has likely been occupied by hominins for at least the last 1 million years  
65 and the earliest archaeological remains attributable to *Homo sapiens* dates to approximately  
66 160,000 years ago (Jerardino & Marean, 2010). The archaeological record on the Cape south  
67 coast for the period between 160,000 and 50,000 years is unusually data rich and well dated.  
68 This region and time period is crucial to our understanding of modern human origins as it  
69 provides some of the earliest evidence for the emergence of complex behaviours associated with  
70 cognitively modern humans, making it highly significant to human origins studies (Marean et al.,  
71 2014). The archaeological record documents human occupation during periods of glacial  
72 maxima, such as Marine Isotope Stages 6 and 4, when climatic conditions over much of the rest  
73 of Africa were too harsh for human occupation or could sustain only very small populations  
74 (Bar-Matthews et al., 2010; Marean et al., 2014). It has been hypothesised that the richness of  
75 the record and continuity of occupation along the Cape south coast, and the Cape Floristic  
76 Region (CFR) more generally, is a consequence of an unusually rich resource base unique to  
77 this area (Parkington 2001, 2003, 2006; Marean, 2010, 2011). The coastline in this region offers  
78 a highly productive inter-tidal zone for shellfish collection for human foragers. During glacial  
79 phases, an extensive plain was exposed off the current coast that supported a diverse plains game  
80 fauna, which would have offered excellent hunting opportunities (Klein, 1983; Marean, 2010).  
81 The CFR is also home to a globally exceptional flora with many species offering harvestable  
82 edible carbohydrates (Deacon, 1970, Parkington & Poggenpoel, 1971; Van Wyk & Gericke,  
83 2000; Van Wyk, 2002; Schwegler, 2003; Dominy et al., 2008; De Vynck, Van Wyk & Cowling,  
84 2016). These include geophytic underground storage organs (USOs) that are both highly diverse  
85 and locally abundant (Goldblatt, 1978; Procheş, Cowling & du Preez, 2005; Procheş et al., 2006;  
86 Singels et al., 2015), as well as many species with aboveground carbohydrates such as fruit,  
87 vegetables, seed pods and seeds (De Vynck, Van Wyk & Cowling, 2016). Together these  
88 resources may have provided a complementary set of protein and carbohydrate-rich foods to a  
89 human forager, thus explaining the continuity of human occupation through glacial maxima.

90

91 However, to date the actual availability and productivity of these potential food resources to a  
92 human forager has been largely based on conjecture. For example, Marean's (2010) argument  
93 that CFR geophyte diversity directly resulted in a wide range of collectable plant foods would  
94 not hold if most of those plants were poisonous, very low in caloric returns, very costly to  
95 procure, or unavailable for large parts of the year. To better understand the record for hunter-  
96 gatherer foraging in this region, we must develop robust understandings of the foraging potential  
97 of the plant foods. This includes analyses of their nutritional character (Kyriacou et al., 2014),  
98 availability in the landscape and importantly their seasonal availability to a forager.

99

100 This study solely focuses on the temporal availability of edible carbohydrate from a range of  
101 plant species in four vegetation types on South Africa's Cape south coast. Availability is  
102 estimated based on the visibility of plant parts that directly or indirectly lead to edible  
103 carbohydrate. We focus on visibility as a proxy for availability as human foragers primarily rely  
104 on sight and have a poor sense of smell. Thus, above-ground edible carbohydrate may be readily  
105 visible and available when plants are in fruit, but below-ground carbohydrate can only be found  
106 if there are above-ground indicators such as leaves, flowers, or dried stalks. To the best of our  
107 knowledge at this time, above ground visibility of plant foliage is the most reliable determinant  
108 that a human forager could positively identify and extract the underground resource. The  
109 ultimate goal is to combine these observations with studies of nutrition, abundance estimates and  
110 return rates, so as to contribute to the resourcescape for a paleoscape model for the Cape south  
111 coast (Marean et al., 2015). More generally, our paper adds to a growing literature on the  
112 importance of geophytes and aboveground carbohydrates to hunter-gatherer diet worldwide (  
113 Kaye & Moodie, 1978; Hatley & Kappelman, 1980; Vincent, 1985; Murray et al., 2001; Bird,  
114 Bliege Bird & Parker, 2005; Bliege Bird et al., 2008), and expands the range of variation of those  
115 data to a region that is megadiverse in plant species yet relatively unstudied in regards to plants,  
116 and geophytes in particular, as a food resource.

117

## 118 **Methods**

119

## 120 Study area

121 The study area is situated in the coastal plain between the Breede and Gouritz rivers on the Cape  
122 south coast (Fig. 1). The rainfall regime shows little seasonality and rain may fall at any time of  
123 the year although slight rainfall peaks are observed in March–April and with more pronounced  
124 peaks during August and October–November (Engelbrecht et al., 2014). The overall climate of  
125 the study area is semi-arid to sub-humid with annual rainfall ranging from 350 to 550 mm. The  
126 three summer months (Dec-Feb) are the most stressful for plant growth, owing to generally  
127 lower rainfall and persistently higher temperatures.

128

129 [Fig. 1 here]

130

131 Vegetation of the Cape coastal lowlands is under strong edaphic control (Thwaites & Cowling,  
132 1988; Rebelo et al., 1991; Cowling and Potts, 2015) and the study area has a wide range of  
133 geologies which generate different soil types. These include Table Mountain Group sandstones  
134 (visible on the coast), Bokkeveld shales (exposed on the inland margin of the study area),  
135 Cretaceous Enon Formation conglomerates and mudstones (~25 km from the coast), and  
136 Bredasdorp Formation limestones (Rogers, 1984; Malan, 1987). In addition, near the coastal  
137 margin aeolian sands of marine origin mantle the geology and this varies in pH with age;  
138 younger sands are alkaline and older sands are leached and acidic (Rebelo et al., 1991; Abanda,  
139 Compton & Hannigan, 2011). Shale- and mudstone-derived soils are moderately fertile, while  
140 those associated with leached sands are infertile. The calcareous sands associated with limestone,  
141 calcrete and coastal dunes are also relatively infertile due to their high alkalinity and subsequent  
142 low levels of plant-available phosphorus (Thwaites & Cowling, 1988).

143

144 The Cape Floristic Region (CFR) is home to four biomes, namely Fynbos, Renosterveld, Forest  
145 and Subtropical Thicket (Bergh et al. 2014). The vegetation types chosen for this study are  
146 representative of dissected coastal margin of the southern CFR, namely Fynbos (two types),  
147 Renosterveld and Subtropical Thicket (Rebelo et al., 1991). Generally, Fynbos communities are  
148 richest in species, especially local endemics (Cowling, 1990); Renosterveld harbours a high

149 diversity of USO-bearing geophytes (Proches et al., 2006 ), while Subtropical Thicket has a high  
150 diversity of fruit-bearing trees and shrubs (Cowling et al., 1997).

151

152 This study monitored the phenological phase of edible plants - periodic life cycle events -  
153 growing in single plots located in Renosterveld, Sand Fynbos, Limestone Fynbos, and  
154 Strandveld (a form of Subtropical Thicket). Renosterveld occurs on the relatively fertile and fine-  
155 grained soils derived from shales and mudstones, and is a fire-prone grassy shrubland often  
156 dominated by *Elytropappus rhinocerotis* (renosterbos). Sand Fynbos occurs on infertile acid soils  
157 and is a fire-prone heath-like shrubland, characterised by the presence of Restionaceae and  
158 Proteaceae. Limestone-derived soils support Limestone Fynbos, a highly endemic-rich  
159 vegetation type (Willis et al., 1996). Marine sands are associated with Subtropical thicket, either  
160 in its solid form or as thicket clumps in a matrix of Fynbos. This vegetation is colloquially  
161 known as Strandveld. Plant compositional change, or beta diversity, between these edaphically  
162 differentiated vegetation types is extremely high; consequently few species are shared among  
163 these four vegetation types and regional-scale plant richness is very high (Cowling, 1990).

164

#### 165 **Data collection**

166

167 The monitoring period was from May 2010 until April 2012. In the year prior to monitoring  
168 (2009), the rainfall was far below average across all plots (~70% of the mean annual rainfall).  
169 The effects of the previously dry year were still evident when monitoring started. Above average  
170 rainfall was experienced over the two years of monitoring (see Fig. S1 in supplementary  
171 materials for climate diagrams and Fig. S2 for spatial relation of weather stations to survey  
172 plots).

173

174 Monitoring plots were located in representative areas of each of the major vegetation types (one  
175 plot per vegetation type) described above: Renosterveld, Sand Fynbos, Limestone Fynbos, and  
176 Strandveld (Fig. 1). These plots were located within protected areas and were considered to be in  
177 a pristine condition. Further biophysical data for the plots are provided in the supplementary  
178 materials (Table S1). The Sand Fynbos site had burnt four years before the start of the survey

179 period and this would likely have enhanced the visibility of USO species (Deacon, 1993), many  
180 of which flower more profusely in the early post-fire years (Le Maitre & Midgley, 1992).

181

182 Each plot was divided into six  $20 \times 300$  m transects (3.6 ha in total). Monitoring consisted of  
183 surveying each plot every six weeks over a two-year period by one of the authors (JC De  
184 Vynck), who is a trained field botanist familiar with the vegetation in this landscape. Along each  
185 transect, the following were counted: 1) individuals of species bearing underground storage  
186 organs (USOs) which would be apparent to a forager (i.e. in a phenological phase where one or  
187 more aboveground organs were visible) and, 2) individuals of species with edible aboveground  
188 carbohydrates; these included fruits, leaves, seed pods, seeds, and inflorescences. In our  
189 sampling approach we adopted a forager's perspective by only including species known to be  
190 edible (De Vynck, Van Wyk & Cowling, 2016) and excluding any plants considered too small to  
191 harvest. We included as edible any USOs that required cooking in order to render them edible  
192 (e.g. tubers of *Rhoicissus digitata* and corms of *Chasmanthe aethiopica* and *Watsonia* spp.)  
193 (Wells, 1965; Parkington & Poggenpoel, 1971; Deacon, 1976, 1979; Liengme, 1987; Opperman  
194 & Heydenrych, 1990; Skead, Manning & Anthony, 2009).

195

196 As stated above, availability of edible carbohydrates was based on direct or indirect visibility of  
197 the resource. For example, USOs in their dormant phase are not visible aboveground and can  
198 therefore not be procured by foragers. However, visible phases of USOs include any above  
199 indicator of their presence, such as green leaves, flowers or dry wilted leaves. The nutritional  
200 content may vary through these phases, but is not the focus of this study. The majority of species  
201 with aboveground carbohydrates (e.g. fruiting species) are perennially visible, but were only  
202 recorded as 'available' to foragers when edible carbohydrates were visible.

203

## 204 **Data analysis**

205

206 For each plot, the number of visible, and hence available, species with edible carbohydrates over  
207 time was determined; this was calculated as the number of individuals observed in a given  
208 survey that would provide access to edible carbohydrate divided by the maximum number of  
209 individuals observed across all surveys (for a given species within a plot). In order to calculate

210 the number of species with edible carbohydrate for a given period within a plot, the continuous  
211 proportions of individuals with edible carbohydrate per species were converted to binary  
212 presence or absence categories using a 10% threshold. Thus, we considered edible carbohydrate  
213 offered by a given species readily visible and available in the landscape if at least 10% of the  
214 maximum observed individuals were visible with direct or indirect access to carbohydrates. The  
215 number of species with edible carbohydrate considered available in each plot through time was  
216 calculated. All analyses were conducted in R version 2.15 (R Development Core Team, 2014)

## 217 **Results**

218

219 Within the four 3.6 ha plots spread across the four vegetation types, 52 edible plant species were  
220 recorded. Of these, 33 species were geophytes with edible underground storage organs (USOs)  
221 and 21 species had aboveground edible carbohydrates (Table 1; see Table S3 and S4 in  
222 supplementary materials for full species list per type). Note that some species had more than one  
223 edible part. Richness of edible species varied across the vegetation types (Table 1): Limestone  
224 Fynbos had the richest flora, followed by Strandveld, Renosterveld and lastly, Sand Fynbos.

225

226 **[Table 1 here]**

227

228 Species varied in the length of time they were available through the year [Fig. 2; see  
229 supplementary materials for full list of species phenology diagrams (Table S2.1 to S2.8) and  
230 phenphase synchronicity among the species (Fig. S3)]. Species with USOs were available for  
231 longer periods of the year relative to those with edible aboveground carbohydrates. The  
232 availability of USO species differed across vegetation types and between survey years (Fig. 3).  
233 Nonetheless, the number of available USO species was highest for a six-month period from  
234 winter to early summer (Jul-Dec) across all vegetation types. Months of lowest species'  
235 availability were in mid-summer to early autumn (Jan-Apr); the early winter (May-Jun) values  
236 were variable, being highest in Limestone Fynbos. In the wetter second year, the summer  
237 “crunch” period – where few USO species were available – was at least one month shorter than  
238 in the first year. The number of species with available edible aboveground carbohydrates also

239 varied across vegetation types and sample years. Species richness peaked in spring (Sep-Nov) for  
240 all vegetation types; relatively high availability extended into summer (Dec-Feb) but autumn and  
241 early winter were lean months for harvesting aboveground carbohydrates in all vegetation types,  
242 especially Renosterveld and Sand Fynbos. The presence of two *Carpobrotus* species, which bear  
243 ripe fruits during the drier months, was a key factor for the extension of aboveground availability  
244 period in Limestone Fynbos.

245 An impressive 25 species provided edible carbohydrate during the late summer (Feb – Mar)  
246 “crunch period (Table 2). Twelve of these were USOs and Limestone Fynbos supported the  
247 most species (16) with available carbohydrate present at this time.

248

249 [Fig. 2 here]

250 [Fig. 3 here]

251 [Table 2 here]

252

## 253 Discussion

254

255 Substantial archaeological evidence exists for the use of underground storage organs (USOs),  
256 fruits and leaves by Late Stone Age peoples in southern Africa (Deacon & Deacon, 1963;  
257 Parkington & Poggenpoel, 1971; Deacon, 1970, 1976, 1984; Opperman & Heydenrych, 1990;  
258 Deacon & Deacon, 1999). This evidence is substantiated by direct observations of contemporary  
259 hunter-gatherer communities in Africa (Lee, 1969, 1973, 1984; Silberbauer, 1981; Youngblood,  
260 2004; Berbesque & Marlowe, 2009; Marlowe & Berbesque, 2009). The diversity and abundance  
261 of edible plants, especially USOs, along the Cape coast, together with a rich source of both  
262 marine and terrestrial based protein, has been hypothesised to be key components facilitating the  
263 persistence of Middle Stone Age (MSA) people in the region during glacial phases when other  
264 African regions may have been resource poor (Marean, 2010). However, very little research has  
265 been conducted on the potential availability of food plants to hunter-gatherers on the Cape south  
266 coast to corroborate this hypothesis. In the same study area, Singels et al. (2015) found

267 surprisingly high edible biomass values for USOs (maximum values range from 600 kg/ha in  
268 Sand Fynbos to 5 000 kg/ha in Limestone Fynbos), although these were restricted to occasional  
269 biomass hotspots within a matrix of much lower biomass. Also, these USO hotspots were found  
270 within all vegetation types. Here we address the temporal availability of belowground (i.e.  
271 USOs) and aboveground sources of carbohydrates across the four principal vegetation types of  
272 the Cape south coast. We use this to speculate on the importance of carbohydrates as fallback  
273 foods for coastal hunter-gatherers, and what role this may have played in the emergence of  
274 cognitively modern people in the region (Marean, 2010).

275

276 The number of species with edible carbohydrate resources that are visible and available to  
277 foragers was highest between winter and early summer in the study area. This is consistent with  
278 the dominant cool-season phenology of plants in the Cape Floristic Region (Pierce, 1984). This  
279 six-month period provides a diversity of USOs associated with corms belonging to petaloid  
280 geophytes, mostly members of the Iridaceae (e.g. *Babiana*, *Freesia*, *Gladiolus*, *Watsonia*). These  
281 species provide relatively large (10-100 g) starch-rich and low-fibre food parcels that are  
282 inexpensive to harvest (Parkington, 1977; Deacon, 1993; Singels et al., 2015), and many do not  
283 require cooking for digestion (Youngblood, 2004; Dominy et al., 2008; J. De Vynck pers. obs.,  
284 2011). Also available during the cooler and mostly wetter months are fruits borne largely by  
285 Subtropical thicket species (e.g. *Carissa*, *Diospyros*, *Olea*, *Searsia*) as well as leaf crops  
286 (*Trachyandra* spp.). There are currently no data on the biomass, nutritional value and foraging  
287 returns for aboveground sources of carbohydrate in the Cape Floristic Region. Fruit loads of  
288 mature thicket shrubs and trees range from tens of thousands of fruits per plant for *Sideroxylon*  
289 *inerme* (fruit diameter 10 mm) and *Searsia* spp (3 mm) to fewer than 100 fruits for *Euclea*  
290 *racemosa* (7 mm), *Cassine tetragona* (8 mm) and *Osyris compressa* (20 mm) (Cowling et al.,  
291 1997). Mat-forming *Carpobrotus* species may bear several tens of large (35 mm diameter) fruits  
292 (J. De Vynck pers. obs., 2011).

293

294 Late summer to early autumn periods have considerably fewer available edible species than in  
295 the other times of the year. This is a period when all traces of leaves and inflorescences of the  
296 dominant deciduous geophyte component have disappeared (Deacon, 1993). However, even  
297 during this relatively warm and dry period, we recorded some 25 available species across the

298 four vegetation types (Table 2). These include USOs such as hysteroanthous, autumn-flowering  
299 *Gladiolus* (cormous) and *Pelargonium* (tuberous) spp, the corms of evergreen *Watsonia* spp.,  
300 and the fibrous tubers of the evergreen liana, *Rhoicissus digitata*. Also apparent are the fruits  
301 *Carpobrotus* spp, the fruits of many thicket shrubs and trees, and the leaf crop, *Tetragonia*  
302 *decumbens*. Nonetheless, the late summer – early autumn months could represent a carbohydrate  
303 “crunch” for foragers: at this time the number of edible plant species is at its lowest and the high-  
304 biomass items available to foragers (e.g. *Pelargonium* spp., *R. digitata*) are fibrous and require  
305 cooking for digestion (Deacon, 1995; Wandsnider, 1997; Laden & Wrangham, 2005; Dominy et  
306 al., 2008; Schnorr et al., 2015).

307

308 Overall, the plant-based carbohydrate resources available to Stone Age foragers of the Cape  
309 south coast, especially USOs belonging to the Iridaceae (Deacon, 1976, 1993), are likely to have  
310 comprised a reliable and nutritious source of calories over most of the year. Moreover,  
311 availability of USOs showed little between-year variation, most likely due the existence of  
312 sufficient storage reserves to enable at least leaf growth every year (Ruiters and McKenzie,  
313 1994) despite variation in rainfall. In an assessment of foraging potential of six USO species  
314 growing in our study area, Singels et al. (2015) showed that 50% of foraging events conducted  
315 yielded enough calories to meet the daily requirements of a hunter-gatherer of small stature  
316 within two hours.

317

318 The juxtaposition within a 10 kilometre foraging radius of four major vegetation types,  
319 belonging to three regional biomes (Fynbos, Renosterveld and Subtropical Thicket; Bergh et al.,  
320 2014), would have enabled humans to forage in very different resourcescapes on a daily basis.  
321 While the Limestone Fynbos and Strandveld – the two vegetation types closest to the coast – are  
322 likely to have offered the best foraging returns for much of the year, Renosterveld provides an  
323 abundance of Iridaceae corms in the spring and Sand Fynbos harbours evergreen *Watsonia* spp.,  
324 which can be harvested during the late summer-autumn “crunch” (Singels et al., 2015).  
325 Ethnographic evidence suggest that the harvesting of Iridaceae corms (*uintjies*) in spring was an  
326 important event for the San of the Cape west coast (Van Vuuren, 2014).

327

328 Given the temporal and spatial availability of edible plant species in the Cape, we argue that is  
329 highly likely that USOs, fruit, seedpods, seeds, inflorescences and leaf crops were harvested as  
330 fallback foods by Stone Age people living in this region. The likely preferred food for south  
331 Cape coastal hunter-gatherers comprised the region's diverse and abundant marine resources  
332 (Marean et al., 2007; Jerardino & Marean, 2010; Parkington, 2010), and a diverse ungulate  
333 plains fauna, including in the Pleistocene, several species of now extinct megafauna, associated  
334 with the submerged Agulhas Bank (Klein, 1983; Parkington, 2001, 2003; Matthews, Marean &  
335 Nilssen, 2009; Marean, 2010; Faith, 2011). However, these resources were not always available  
336 to harvesters and hunters, and the contraction and expansion of the Agulhas Plain ecosystem and  
337 its ungulate communities must have been a major driver of changing foraging patterns on the  
338 south coast (Marean et al., 2014). It has been hypothesized that the mammal fauna formed a  
339 migratory community that moved west during the winter rains and east to intercept the summer  
340 rains. Thus, the local abundance of many of the larger ungulates may have plummeted during  
341 the winter months when populations migrated west to graze winter-growing grasses of the west  
342 coast. Marine invertebrates, harvested from the intertidal, comprised the most reliable and  
343 accessible source of protein for hunter-gatherers living on the Cape south coast (Marean, 2011).  
344 Evidence for their use has been found in MSA sites such as Pinnacle Point (PP) 13B dating back  
345 to ~160 ka (Marean et al., 2007; Jerardino & Marean, 2010) and at early modern human sites that  
346 date between 110-50 ka such as Blombos Cave (Henshilwood et al., 2001; Langejans et al.,  
347 2012), and Klasies River Mouth (Voigt, 1973; Thackeray, 1988). Late Stone Age sites suggest an  
348 increase in the intensity of intertidal foraging (Marean et al., 2014) and indications of resource  
349 depletion (Klein & Steele, 2013). Using experienced foragers of Khoe-San descent, J. De Vynck  
350 et al. (unpublished data) showed exceptionally high peak return rates (~4,500 kcal hr<sup>-1</sup>) from the  
351 Cape south coast intertidal under ideal harvesting conditions. However, owing to tidal  
352 constraints, and the fierce sea conditions experienced there, harvesting was only possible for 10  
353 days a month, for 2-3 hours on each day; lowest returns were recorded in winter and spring – a  
354 time of strong winds and high seas – and highest returns in summer and autumn, when sea  
355 conditions were calmer (J. De Vynck et al., unpublished data). Consequently, there would have  
356 been periods of various lengths – ranging from days to weeks – when hunter-gatherers depended  
357 on, or fell back upon carbohydrates for sustenance. As pointed out above, the winter and early  
358 spring months likely coincided with a scarcity of protein but an abundance of carbohydrates. At

359 these times, plant carbohydrates, especially USOs, may have comprised 100% of dietary intake,  
360 which would categorise them as a staple fallback food (Marshall & Wrangham, 2007).

361

362 It has been hypothesized that the persistence of a small group of hominins on the Cape south  
363 coast – as opposed to their widespread extinction elsewhere in Africa during Marine Isotope  
364 Stage 6 (MIS6, 193 000 -125 000 BP) (Foley, 1998; Lahr & Foley, 1998; Fagundes et al., 2007;  
365 Basell, 2008; Masson-Delmotte et al., 2010) – was a consequence of the Cape’s relatively  
366 moderate climate during the largely glacial MIS6 and its rich and diverse resource base. The  
367 persistently warm Agulhas Current reduced the regional impact of glacial cooling substantially  
368 (Negre et al., 2010; Zahn et al., 2010). Marean (2010) has hypothesised that during strong glacial  
369 environments, such as those experienced in MIS6, the Cape south coast provided a unique  
370 juxtaposition of resources important for hominin persistence, namely a diverse USO flora and a  
371 rich and productive marine ecosystem. At that time the exposed Agulhas Plain (Fisher, Barr-  
372 Matthews & Marean, 2010) was mantled in substrata that likely supported Renosterveld,  
373 Limestone Fynbos and Strandveld (Cawthra et al., 2015), offering a wide array of USOs, fruit  
374 and leaf crops which would comprise reliable fallback foods when it was not possible to forage  
375 in the intertidal and game was scarce. The cognitive challenges of exploiting marine resources  
376 (e.g. comprehending lunar cycles), and defending them against competition from adjacent  
377 groups, led to a coastal adaptation that may have contributed to the emergence of cognitively  
378 modern *Homo sapiens* (Marean, 2011). Similarly, the ability to recognise which and when  
379 vegetation types are most productive for carbohydrates, identifying hotspots of productivity and  
380 distinguishing between edible and toxic USOs, must have been challenging (Deacon, 1995).  
381 Here we have established the temporal availability of plant species with edible carbohydrates  
382 across four dominant vegetation types along the south coast. Much additional research must be  
383 done to evaluate more comprehensively the role of above- and belowground carbohydrates in the  
384 ecology and evolution of the human lineage in the Cape Floristic Region and elsewhere. Work is  
385 currently underway to establish the return rates of carbohydrate resources harvested by  
386 contemporary subjects of Khoe-San descent, in the different vegetation types and in different  
387 seasons; and on the rates of depletion of resources in successively harvested areas. This needs to  
388 be complemented with data on the nutritional value of the consumed parts of the species  
389 selected. Ultimately, we aim to use these data to populate the carbohydrate resourcescape in an

390 agent-based model aimed at predicting the effects of spatial and temporal variability – governed  
391 by changes in climate and the resource base over the seasonal cycle as well as the glacial-  
392 interglacial cycle of the Pleistocene – on the population size and structure, mobility, social  
393 organization, territoriality, and technology of Cape hunter-gatherers (Marean et al., 2015).

394

### 395 **Acknowledgements**

396

397 We thank the Cape Nature team – Rhett Heismann, Jean Du Plessis and Leandi Wessels – for  
398 access, support, information and GIS assistance. We also thank the Hessequa Municipality, and  
399 in particular Hendrik Visser, for their help and support. The authors are also grateful for the  
400 climate data supplied by South African Weather Service. Peter Henzi and an anonymous  
401 reviewer provided valuable comments that improved the manuscript.

706

707

708 Table 1: Summary of edible species in 3.6 ha plots situated in four dominant vegetation types  
709 along the Cape south coast.

	USOs	Fruit	Other <sup>1</sup>	All
Renosterveld	8	6	2	16
Sand Fynbos	5	4	1	10
Limestone Fynbos	21	11	7	39
Strandveld	15	8	5	28
Across all types <sup>2</sup>	33	14	8	52

710 <sup>1</sup> 'Other' includes species with edible: seed pods, seeds, leaves, and inflorescences.

711 <sup>2</sup> Note that this is the number of unique species (i.e. some species are shared between vegetation types or  
712 have more than one edible part).

713

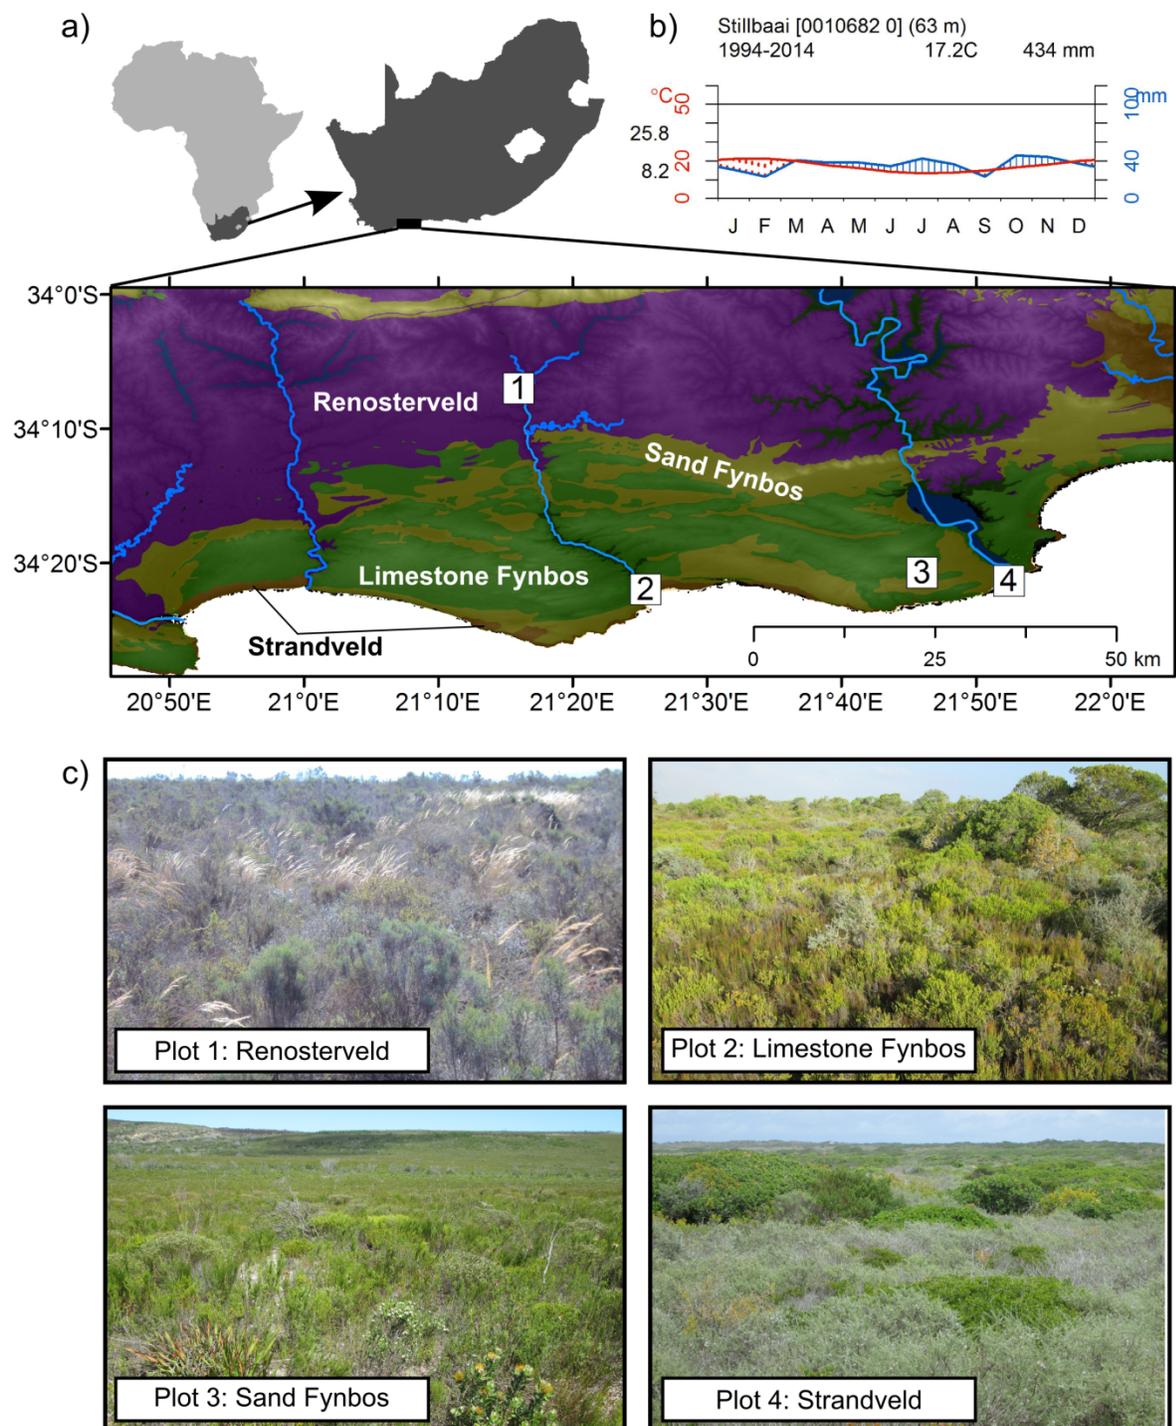

714

715

716 Table 2: Species available during the ‘carbohydrate-crunch’ late summer period (February-  
717 March) in both survey years.

718

Vegetation type	Carbohydrate category	Species
Renosterveld	Underground storage organ	<i>Babiana patula</i> ; <i>Cyphia digitata</i> ; <i>Watsonia meriana</i>
	Aboveground	<i>Diospyros dichrophylla</i> (fruit); <i>Osyris compressa</i> (fruit); <i>Sideroxylon inerme</i> (fruit)
Limestone Fynbos	Underground storage organ	<i>Cyphia digitata</i> ; <i>Gladiolus exilis</i> ; <i>Pelargonium lobatum</i> ; <i>Pelargonium triste</i> ; <i>Rhoicissus digitata</i> ; <i>Watsonia fergusoniae</i>
	Aboveground	<i>Carissa bispinosa</i> (fruit); <i>Carpobrotus accinaciformis</i> (fruit); <i>Carpobrotus edulis</i> (fruit); <i>Cynanchum obtusifolium</i> (seedpods); <i>Euclea racemosa</i> (fruit); <i>Osyris compressa</i> (fruit); <i>Searsia glauca</i> (fruit); <i>Sideroxylon inerme</i> (fruit); <i>Tetragonia decumbens</i> (leaves); <i>Zygophyllum morgsana</i> (seed)
Sand Fynbos	Underground storage organ	<i>Gladiolus guthriei</i> ; <i>Watsonia fourcadei</i>
	Aboveground	<i>Carpobrotus edulis</i>
Strandveld	Underground storage organ	<i>Chasmanhte aethiopica</i> ; <i>Ferraria crispa</i> ; <i>Rhoicissus digitata</i>
	Aboveground	<i>Carissa bispinosa</i> (fruit); <i>Carpobrotus accinaciformis</i> (fruit); <i>Osteospermum moniliferum</i> (fruit); <i>Schotia afra</i> (seed); <i>Tetragonia decumbens</i> (leaves)

719

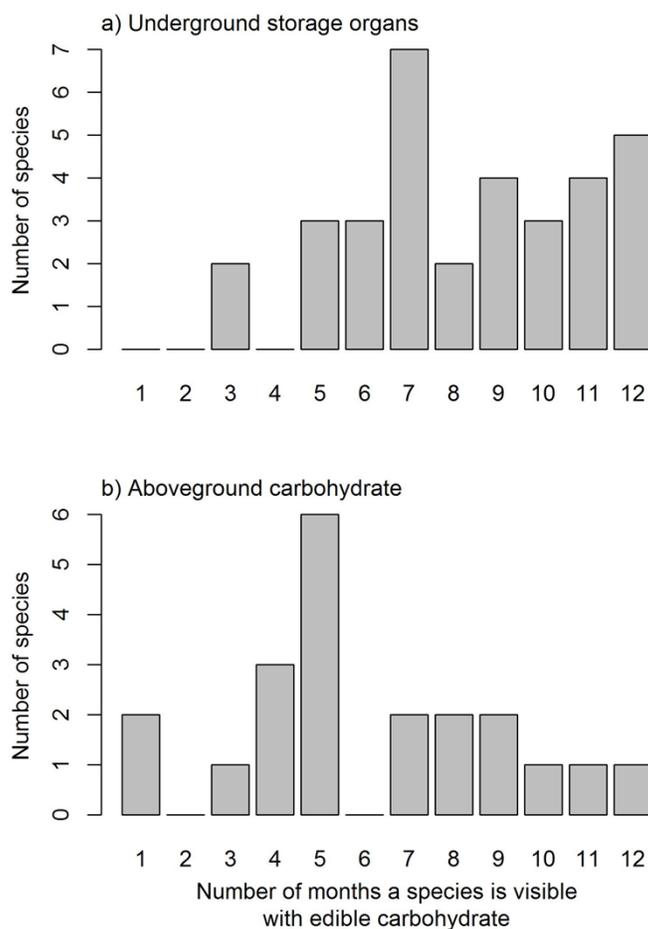

720 Figure 1: a) The location and major vegetation types of the study region and the plot localities [1:

721 Renosterveld (purple); 2: Limestone Fynbos (green); 3: Sand Fynbos (yellow); and 4: Strandveld

722 (orange; restricted to the coastal margin; see Table S1 for further plot details)]. b) A Walter-Leith

723 climate diagram from the town of Still Bay (~5 km from plot 2). c) Photos taken within the four  
 724 plots in the different vegetation types.

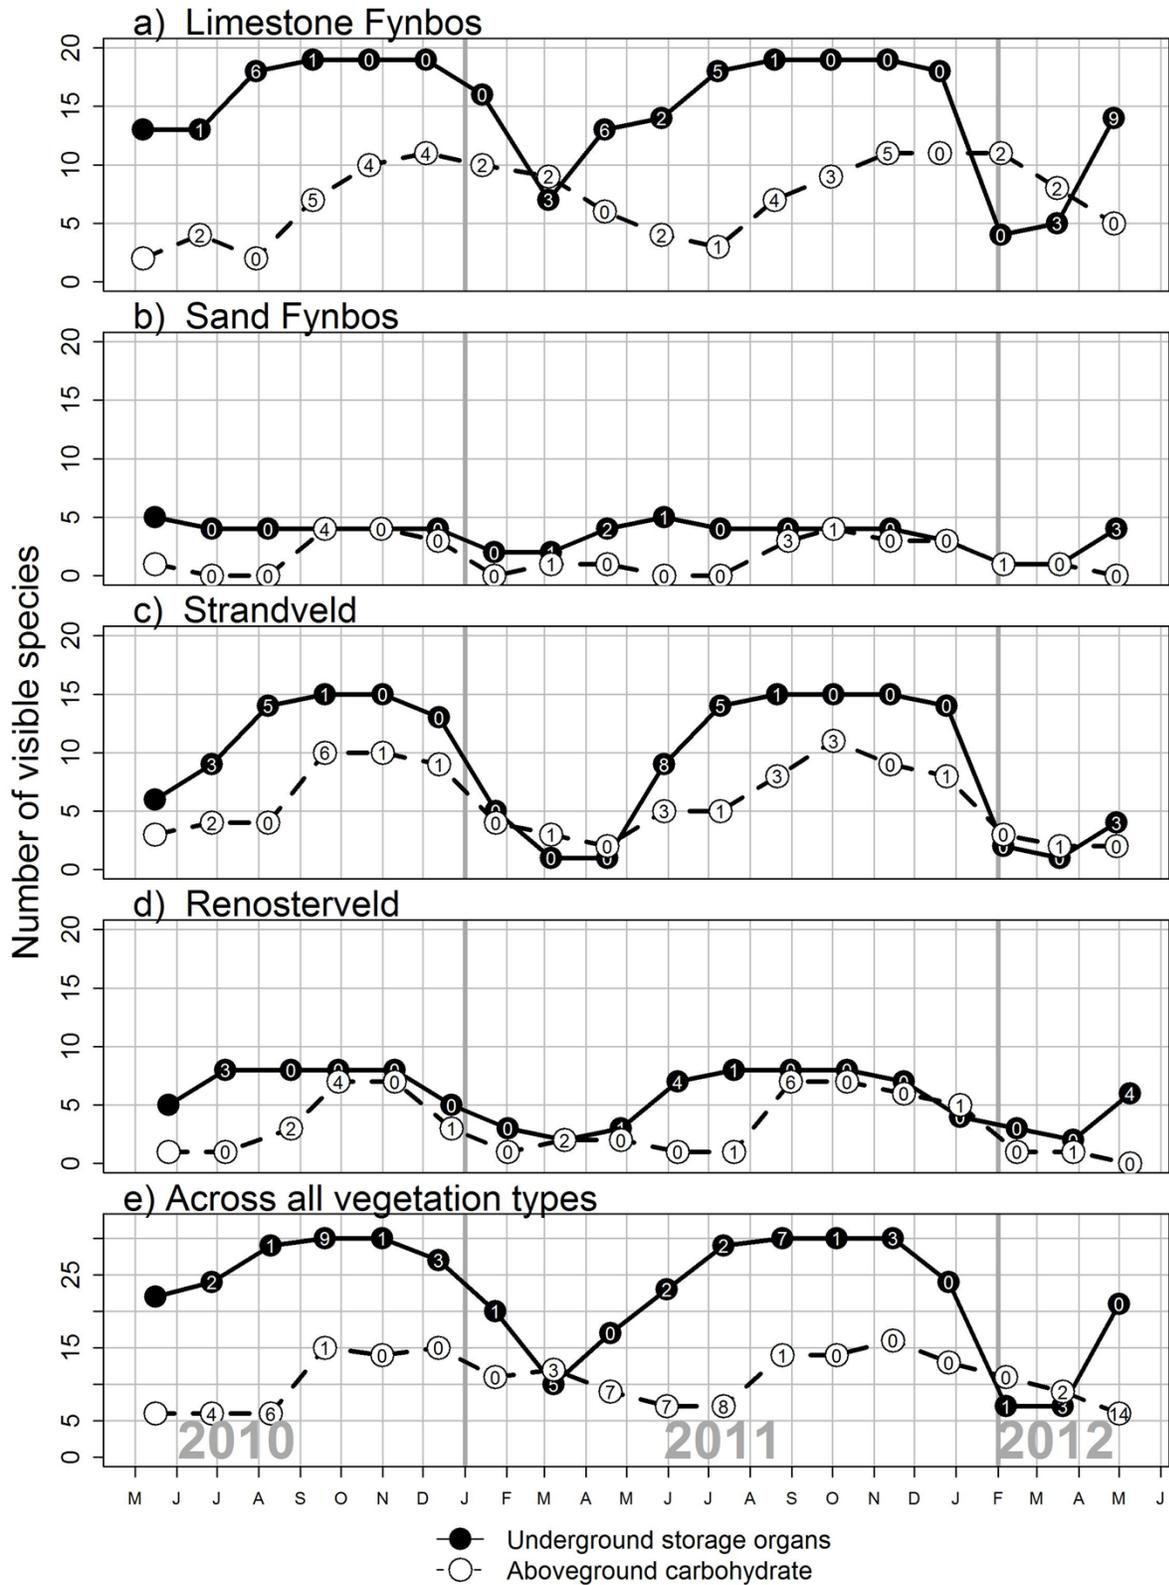

725

726

727

728 Figure 2: A breakdown of the number of months in which different plant species (with edible  
 729 carbohydrates) are visible through the year separated into a) underground storage organs (USOs)  
 730 and b) aboveground carbohydrate (e.g fruit, seed pods, seeds, leaves or inflorescences).

732 Figure 3: The seasonal availability of edible species visible to a human forager in four vegetation  
733 types dominant along the Cape south coast. Underground storage organs are geophytes that have  
734 tubers, corms, bulbs or rhizomes, while above-ground carbohydrate includes specie with edible  
735 fruit, seed pods, seeds, leaves or inflorescences. The number of new species observed since the  
736 previous survey is shown in each circle; this provides an indication of species turnover.  
737
