This study aimed to investigate whether athletes (ATL) and sedentary (SED) individuals had similar accuracy in matching intended to actual force during ballistic (BAL) and tonic (TON) isometric contractions. A cross-sectional study in which forty subjects were enrolled and divided into ATL (n=20; 22.4±2.3yrs; 73.2±15.7kg; 1.76±0.08m) and SED (n=20; 24.6±2.4yrs; 68.2±15.0kg; 1.73±0.1m) groups. The isometric quadriceps strength was measured with a load cell applied to a custom-built chair. For each condition, subjects performed first three maximal voluntary isometric contractions (MVIC) as reference. Then, subjects had to match for three trials the intended force intensities (i.e., 25%, 50%, and 75% of the MVIC) without any external feedback. The accuracy (AC) was calculated as the difference in percentage between the intended and the actual force. A Likert scale was administered for each trial to assess the subjective matching between the intended and the actual force. Statistical analysis showed that ATL group was more accurate ( $p < 0.001$ ) than the SED group, while the AC ( $p < 0.001$ ) was lower when the force intensities increased, independently from the group. Moreover, significantly greater AC ( $p < 0.001$ ) and subjective matching were found in BAL and TON contractions, respectively. These results suggest that: (i) sports practice could enhance muscle recruitment strategies increasing the accuracy in the isometric task; (ii) protective mechanisms or proximity to the levels of daily living forces could account the decrement of accuracy at high force intensities; (iii) different control systems act in modulating BAL and TON contractions.

## 22 **Abstract**

23 This cross-sectional study aimed to investigate whether athletes (ATL) and sedentary (SED)  
 24 individuals had similar accuracy in matching intended to actual force during ballistic (BAL) and  
 25 tonic (TON) isometric contractions. A cross-sectional study in which forty subjects were enrolled  
 26 and divided into ATL (n=20; 22.4±2.3yrs; 73.2±15.7kg; 1.76±0.08m) and SED (n=20;  
 27 24.6±2.4yrs; 68.2±15.0kg; 1.73±0.1m) groups. The isometric quadriceps strength was measured  
 28 with a load cell applied to a custom-built chair. For each condition, subjects performed first three  
 29 maximal voluntary isometric contractions (MVIC) as reference. Then, subjects had to match for  
 30 three trials the intended force intensities (i.e., 25%, 50%, and 75% of the MVIC) without any  
 31 external feedback. The accuracy (AC) was calculated as the difference in percentage between the  
 32 intended and the actual force. A Likert scale was administered for each trial to assess the subjective  
 33 matching between the intended and the actual force. Statistical analysis showed that ATL group  
 34 was more accurate ( $p < 0.001$ ) than the SED group, while the AC ( $p < 0.001$ ) was lower when the  
 35 force intensities increased, independently from the group. Moreover, significantly greater AC ( $p <$   
 36  $0.001$ ) and subjective matching were found in BAL and TON contractions, respectively. These  
 37 results suggest that: (i) sports practice could enhance muscle recruitment strategies increasing the  
 38 accuracy in the isometric task; (ii) protective mechanisms or proximity to the levels of daily living  
 39 forces could account the decrement of accuracy at high force intensities; (iii) different control  
 40 systems act in modulating BAL and TON contractions.

# 47 **Introduction**

48 Intended force refers to muscle tension sensations experienced during contraction (Jones & Hunter,  
49 1983). It results from a neuronal process influenced by two factors: the corollary discharge of the  
50 central motor command (i.e., the motor signal informs the sensory system about the planned or  
51 implemented action) and afferent feedback from the working muscles (Jones & Hunter, 1983;  
52 Pageaux, 2016). Indeed, peripheral inputs from the neuromuscular spindles and Golgi tendon  
53 organs provide information to higher centers about the in-place contraction (Carson, Riek &  
54 Shahbazzpour, 2002; Proske & Allen, 2019). Moreover, the cerebellum ensures movement accuracy  
55 and sensory perception by communicating with the brain areas and sensory channels (Bhanpuri,  
56 Okamura & Bastian, 2012).

57 Historically, to the extent of standardizing the means of rating the perceived effort at specific  
58 muscular forces, scientific literature (Cooper et al., 1979; Jones & Hunter, 1982) focused on the  
59 relationship between actual and intended force in different muscle groups. The work by Cooper  
60 and colleagues (Cooper et al., 1979) suggested that a single motor performance, namely isometric  
61 or dynamic contraction, can be perceived with remarkable precision by both small (e.g., adductor  
62 pollicis) and large (e.g., quadriceps) muscle groups. However, a perceptual underestimation of  
63 force might occur in larger muscle groups, more commonly involved in gross movements, when  
64 lower levels of force are required, to accomplish fine movements (Jones & Hunter, 1982).

More recently, the scientific interest moved to deepen the relationship between actual and intended force at different intensities of a maximal voluntary contraction (MVC). Indeed, in a motor task, the force intensity is influenced by the recruitment and firing rate of the motor unit and by the type of contraction (i.e., ballistic or tonic), (Miyamoto, Kizuka & Ono, 2020). Ballistic contractions are performed with maximal velocity and acceleration, while tonic contractions generate a slow and maintained force (Zher and Sale, 1994). Previous studies pointed out conflicting results on the force intensities and the subjects' accuracy in matching intended and actual force. In detail, West and colleagues showed that when subjects were asked to produce a specific force level during an isometric knee-extension task (i.e., without MVC reference), they were more accurate at lower intensities, whereas they overestimated the intended force in high-intensity contractions (West et al., 2005). Similarly, Miyamoto and colleagues (Miyamoto, Kizuka & Ono, 2020) showed that the intended force did not accurately match the target contraction without visual feedback, with a more precise performance at high rather than low intensities. To the best of our knowledge, none of the above-mentioned studies considered the subjects' sports experience as a potential influencing variable in force modulation (i.e., ballistic and tonic) at different intensities (Baweja et al., 2009; Miyamoto, Kizuka & Ono, 2019). Indeed, samples were scarcely described without considering that physical activity level and sports experiences could have affected the results. In this regard, athletes are likely to manage better physiological function, muscle contractions, and sports demands than their sedentary counterparts (Thorstensson et al., 1977; Hagberg et al., 1988). Moreover, team sports practice helps athletes more easily govern motor patterns than sedentary individuals due to their higher ability to perform motor tasks under stressful conditions in open-skill contexts (Cortis et al., 2009). Therefore, this study aimed to investigate whether athletes and sedentary individuals had similar accuracy in matching the intended and the actual force during

ballistic and tonic contractions in an isometric leg extension task. In detail, hypothesizing that sports practice could positively influence subjects' ability to modulate force, we expected that the group of athletes could better exert force at the required percentage of the maximal effort.

## Materials & Methods

### Subjects

Forty young, healthy subjects between 18 and 35 years old (age:  $23.5 \pm 2.6$  yrs; mass:  $70.7 \pm 15.3$  kg; height:  $1.74 \pm 0.08$  m) volunteered to participate in the study. They were divided into two groups: sedentary (SED;  $n = 20$ ;  $F = 13$ ;  $24.6 \pm 2.4$  yrs;  $68.2 \pm 15.0$  kg;  $172.8 \pm 9.60$  m) and elite athletes (ATL;  $n = 20$ ;  $F = 6$ ;  $22.4 \pm 2.3$  yrs;  $73.2 \pm 15.7$  kg;  $1.76 \pm 0.08$  m). At the time of recruitment, the SED group had (i) no history of competitive sport practice and (ii) no current practice of any physical activity. The ATL group currently practiced an individual ( $n=4$  track and field;  $n=1$  canoeing;  $n=1$  fencing;  $n=1$  gymnastics) or team ( $n = 6$  basket;  $n = 3$  rugby;  $n = 2$  volleyball;  $n = 2$  soccer) sport discipline at a competitive level. The experimental protocol received approval (HEC-DSB/05-21) from the Human Ethical Committee of the department of Biomedical Sciences of the University of Padova and adhered to the principles of the Declaration of Helsinki. All the subjects involved in the study were informed about the methods and aims of the study, gave their written consent, and were free to renounce the study at any stage.

### Study design

We outlined a cross-sectional design in which subjects were asked to perform isometric leg-extension strength tests at different intensities (25%, 50%, and 75% of the MVC) without any feedback. Two different muscle contractions were studied: tonic (TON) and ballistic (BAL). In the

TON condition, subjects reached the intended force level with a slow and maintained three-second muscle contraction. Conversely, in the BAL condition, the intended force had to be reached instantaneously. At a preliminary stage, the Waterloo Footedness-revised (WFQ-R) and Global Physical Activity (GPAQ) questionnaires were administered to subjects to identify the dominant leg for the execution of the tests and to estimate the subjects' physical activity level, respectively. After each contraction, subjects were administered a Likert Scale to assess their self-perceived accuracy in the strength task. Muscle contractions and the intensities within each type of contraction were randomized.

### **Isometric lower-limb strength**

The dominant lower limb strength was evaluated through an isometric voluntary quadriceps contraction. The experimental setup consisted of a custom-built chair (**figure 1A**) instrumented with a uni-axial load cell (MuscleLab, Ergotest Innovation, Stathelle, Norway) positioned three centimeters above the lateral malleolus. The subjects performed the strength test seated with the knee flexed at 90 degrees and secured to the chair with straps to minimize additional body movements. Subjects were asked to keep their hands crossed over the chest for the whole test duration. After a standardized warm-up (i.e., a 10-min walk on a treadmill at 5 km/h and 10 repetitions of half-squat exercise), each subject was familiarized with the experimental setup by performing ten sub-maximal isometric quadriceps contractions with real-time visual feedback on the level of the exerted force. Then, after a 5-minute rest, subjects performed the test without any external feedback. Specifically, subjects were required to exert, for each of the two contractions (i.e., BAL and TON), first the maximal voluntary isometric contraction (MVIC) and then the three submaximal intensities (i.e., 25%, 50%, and 75% of the MVIC). Regardless of the condition and the intensities, three trials and an in-between recovery of 40 seconds were set for each intensity.

In the BAL condition, the subjects were asked to reach as fast as possible the required submaximal force intensity (**figure 1B**). Conversely, in the TON condition, the subjects manually triggered an accelerometer synchronized with the force signal and defined the moment their actual force was supposed to correspond to the intended force (**figure 1C**).

## Questionnaires

*Waterloo Footedness Questionnaire-revised (WFQ-R)*. The questionnaire contains 19 items (van Melick et al., 2017). Twelve items are specifically addressed to determine limb dominance, and subjects marked a preference (i.e., right or left limb) for the action indicated by each item. In detail, subjects were required to mark with a double sign (+ +) whether they had an absolute preference for a limb. Conversely, if they had a preference but could perform the action with both limbs, they were asked to mark the preference with a single sign (+). Subjects marked both limbs with a single sign if they had no preference. Finally, seven items assess the current and past injuries with a “yes/no” answer.

*Global Physical Activity Questionnaire (GPAQ-2)*. Before trials, each subject was administered the GPAQ-2 to estimate the daily physical activity level (Bull, Maslin & Armstrong, 2009). With 16 items, GPAQ-2 covers several physical activity components, such as intensity, duration, and frequency. It assesses the three domains in which physical activity is performed: (i) occupational physical activity, (ii) transport-related physical activity, and (iii) physical activity during discretionary or leisure time. The sum of the total Metabolic Equivalent (MET) minutes/week of activity was computed for a typical week in each domain.

*Likert scale*. A single-item Likert scale was administered to subjects after each submaximal condition (i.e., 25%, 50 %, and 75% MVIC). It assesses the subjective matching between the

intended force and the actual force. In detail, the single-item scale (i.e., “How confident are you in having correctly adhered to the required force?”) ranged from 1 (*not confident at all*) to 7 (*absolutely confident*).

## Data analysis

For the MVIC trials, the highest lower-limb peak force in both TON and BAL conditions was considered among the three trials and expressed as a percentage of body mass (BM%). In the BAL contraction, the three peak values referred to each intended force condition were averaged. In the TON contractions the force signal was averaged within a 200 ms time window starting from the trigger input. The actual force was always normalized to the BM and expressed as a percentage of the MVIC. The accuracy (AC) was calculated as the difference in percentage between the intended and the actual force. In detail, the lower AC values, the higher the accuracy, with a 0 score indicating optimal accuracy. The sum of the Likert scores of the three trials for each intensity (i.e., 25%, 50%, and 75% of the MVIC) was considered for the statistical analysis.

## Statistical analysis

A priori power analysis calculation (G\*Power 3.1.9.2 software) showed that a total sample size of 36 participants and a medium effect size of 0.25 would provide a power of 0.8 with an alpha error probability of 0.01. The mean value and standard deviation (SD) among the three trials for both TON and BAL conditions were calculated for the MVIC, the submaximal intensity (i.e., 25%, 50%, and 75% MVIC), and the AC. The Shapiro-Wilk test was used to check the data normality distribution of MET and MVIC (%BM) values. Then, an unpaired sample t-test was used for baseline comparisons between groups (SED vs. ATL). For the AC and Likert scores, a three-way mixed-model analysis of variance (ANOVA) was used to investigate the significant main effect of

force intensities (25%, 50%, and 75%), groups (SED vs. ATL), and contractions (TON vs. BAL), and their interactions. Mauchly's test was used to assess the statistical assumption of Sphericity. If Mauchly's Test yields a p-value less than .05, the Greenhouse-Geisser correction was used. The significance level was set at  $p < 0.05$ . JASP Software, version 0.16.3.0, was used for statistical analysis.

## Results

All the subjects completed the study. Unpaired t-test for baseline comparisons showed statistically significant differences between SED and ATL groups for MET (min/week) and MVIC (%BM) in both BAL and TON contractions (**Table 1**).

The results for the strength test (%BM) for the 25%, 50%, and 75% MVIC in both BAL and TON contractions are presented in **Table 2**.

The AC results are presented in **Figure 2**. The three-way ANOVA analysis showed a significant main effect of contractions ( $p < 0.001$ ;  $F = 19.74$ ;  $\eta_p^2 = 0.34$ ), force intensities ( $p < 0.001$ ;  $F = 63.09$ ;  $\eta_p^2 = 0.62$ ), and an interaction between them ( $p < 0.001$ ;  $F = 14.27$ ;  $\eta_p^2 = 0.27$ ). Moreover, a significant main effect of the group ( $p < 0.05$ ;  $F = 4.73$ ;  $\eta_p^2 = 0.11$ ) was observed. In detail, the Bonferroni-Holm post hoc comparisons, shown in **Figure 2**, highlighted the differences among strength tests and between groups. The ATL group showed lower values than the SED group. Following, between-group differences expressed in percentage for (i) BAL contraction (25% MVIC: -3.79%, 50% MVIC: -36.67%, and 75% MVIC: -9.60%) and (ii) TON contraction (25% MVIC: -27.98%, 50% MVIC: -30.36%, and 75% MVIC: -26.76%).

The results for the Likert scores in the 25%, 50%, and 75% MVIC in both BAL and TON contractions are presented in **Figure 3**. The three-way ANOVA analysis showed a significant main effect of contractions ( $p < 0.001$ ;  $F = 48.85$ ;  $\eta_p^2 = 0.56$ ), and a significant interaction between force

intensities and groups ( $p < 0.05$ ;  $F = 3.49$ ;  $\eta_p^2 = 0.08$ ). In detail, the Bonferroni-Holm post hoc comparisons are shown in **Figure 3**.

## Discussion

The purpose of this study was to investigate the relationship between intended and actual force comparing athletes and sedentary individuals during BAL and TON contractions. The main finding confirmed our hypothesis, showing that the ATL group could exert force at the required MVIC percentage more accurately than the SED group, independently of the type of contraction. Since the recruitment and firing rate of the motor units and the contraction type could affect both force production (Enoka & Fuglevand, 2001) and the relationship between intended and actual force (Miyamoto, Kizuka & Ono, 2020), we can assume that sports practice could enhance muscle recruitment strategies (Enoka & Fuglevand, 2001) and the ability to modulate force.

Similarly, the higher levels of physical activity and training of ATL account for the higher MVIC values. Therefore, the baseline results supported the hypothesis that the subjects' sports practice could be an influencing variable in force production and claimed for group division when investigating the relationship between intended and actual force. For what concerns the force values recorded in the present study, it is interesting to note that, under all conditions and independently from the group, the actual force tended to overestimate the intended force (**table 2**). Indeed, this underproduction of force was in line with previous results performed on isometric knee extension (Cooper et al., 1979), isokinetic knee extension (Jackson et al., 2006), isometric elbow flexion and extension (John, Liu & Gregory, 2009), and isometric thumb adduction (Cooper et al., 1979). Although the causes of errors in estimation of muscular effort are not completely understood, some possible explanations have been addressed. For instance, a first theory suggests that during voluntary motor task performance, descending motor command signals include

physiological noise derived from neuronal and synaptic action potential discharges, which leads to variability in muscle force production (Harris & Wolpert, 1998). In detail, neuronal noise increases with the magnitude of the motor command (i.e., the intensity of a motor task), (John, Liu & Gregory, 2009). A second theory hypothesizes that transient post-contractile potentiation of spinal reflex pathways may summate with previously set motor commands, producing errors in effort perception (Hutton, Enoka & Suzuki, 1984).

Even though the actual force globally undershot the intended force, the deviation from the actual force was less marked in the ATL than in the SED group. It is generally accepted that modulation of force is accomplished by a combination of rate coding of individual motor units and recruitment of more or fewer motor units (Clamann, 1993). Moreover, muscle adaptations (e.g., following training) at both neural and morphological levels concur to underpin the enhanced ability of force regulation in skeletal muscle (Folland & Williams, 2007; Carroll et al., 2009). Thus, chronic exposure to training and exercises with repetitive movements against loads for a long time, as competitive athletes regularly do, could have substantially increased their ability to modulate force (Maden-Wilkinson et al., 2020).

A better accuracy, in both SED and ATL groups, was observed at lower (i.e., 25% MVIC) rather than higher (50% and 75% MVIC) force intensities. Previous results showed that the presence of an anchoring process (i.e., MVIC as reference), as in our study, seemed to address results in different directions (West et al., 2005). Indeed, West and colleagues reported that when the experimental task was performed prior to the MVIC, the actual force matched the intended force at the intermediate level (i.e., 50% MVIC), while the most accurate match occurred at 25% MVIC without the anchoring process. In contrast with our results, other studies on precision grip (Kumar, Narayan & Chouinard, 1997), power grip (Kumar, Narayan & Chouinard, 1997), chest press

(Jackson & Dishman, 2000), and brachial biceps and triceps isometric contractions showed that the actual force matched the intended force at intermediate level (i.e., 40-50% MVC). In our study, the intended force and the actual force output were less associated at higher intensities (50% and 75% MVIC), and thus, the intended force resulted in a more marked perceptual overestimation in these conditions. Hence, our results suggested that a perceptual mistake occurred at higher force intensities even with previous knowledge of the maximal effort (i.e., the MVIC test) as an anchoring process. Even though our data cannot explain why subjects produced the most accurate match at the lower force intensity (25% MVIC), two possible speculations may be acknowledged. First, West and colleagues explained that subjects subconsciously under-produced force at higher intensities as a protective mechanism (West et al., 2005). Indeed, the perceptual overestimation occurred to maintain a reserve capacity and prevent mechanical and metabolic damages, which may occur in further force generation. Second, lower force percentages are used in everyday contexts, most for simple motor tasks (e.g., walking or getting up from a chair). Therefore, subjects could have performed a better perceptual estimation because of the proximity to the levels of force they are accustomed to, regardless of the group. Our findings highlighted that the relationship between intended and actual force was more accurate in the BAL than in the TON condition. Since the BAL contraction occurred rapidly and without afferent sensory feedbacks (Vincken, Gielen & van der Gon, 1984), it was mostly controlled by central predetermined regulatory mechanisms through a feedforward strategy (Hanneton et al., 1997). Conversely, TON contraction had a longer duration, and during this time, information from sensory receptors could interfere with the ongoing task (Desmurget & Grafton, 2000). Indeed, feedback control mechanisms are predominant during the skill acquisition process and essential for constructing a newly learned movement (Seidler, Noll & Thiers, 2004). In our case, the

isometric contraction at leg extension represented a basic motor behavior, where corrective feedbacks used in complex motor skills were mostly unnecessary. About that, Lohse and colleagues (Lohse, Sherwood & Healy, 2011) found that an internal focus of attention (i.e., focusing on muscle contraction) decreased accuracy in a basic motor behavior (i.e., 30% MVIC) compared to an external focus of attention (i.e., focusing on pushing over the force platform). Similarly, subjects in the longer TON contraction could have internally directed their attention on muscles, calling into play counterproductive corrective feedback. This hypothesis could account for the worse accuracy in the TON than BAL contraction, where feedforward mechanisms revealed to be more effective.

Finally, subjects' self-perception, deepened through the Likert scale rating at the end of each contraction, highlighted no differences between groups. This result was unexpected, since the ATL group was more accurate in force production, letting suppose a greater awareness in force modulation. However, the motor task studied in this research was a simple one. Thus, we can speculate that a more sport-oriented task could have differentiated the self-confidence performance between athletes and sedentary individuals. Moreover, a main effect of the contraction type was observed in the Likert aggregate scores, with a greater self-confidence towards the TON against the BAL contraction. Since the BAL contraction was the most accurate, we can speculate that the longer time the subjects had to modulate the force led to a perceptual mistake in their self-perceived accuracy in the TON condition.

The present study has some potential limitations to be acknowledged. Although the group included athletes and sedentary individuals, the ATL group contained athletes from different sports disciplines. Recruiting athletes from similar sports disciplines with the predominant use of lower limbs could have enhanced the differences with sedentary peers. Moreover, a dynamic or sport-

oriented task could have enhanced the accuracy and the self-confidence, being closer to the sport disciplines practiced.

## Conclusions

The present study expanded the previous results on the relationship between the intended and the actual force by investigating whether sports practice could be an influencing factor. Since, the accuracy between intended and actual forces seems to decrease as a function of the increment of the force intensity, our results suggested to coaches and practitioners to focus on training the force accuracy at high intensity. Sports situations require of fast movements, and in most situations, high level of strength thus the accuracy is supposed to be an important factor to achieve prominent performance. Indeed, repetitive training may improve the accuracy of force production also at high force levels. Differences in accuracy between ballistic and tonic contraction suggest different control mechanisms. Further work is needed to explore these hypotheses as well to deepen the perceptual overestimation detected at the higher isometric force intensities.

## Figure legends

**Figure 1. Graphical representation of the experimental design.** Custom-built chair instrumented with a uni-axial load cell (A); ballistic isometric condition with a representative force graph (B); tonic isometric condition with a representative graph of the force. The trigger input marked the beginning of the matching between intended and actual forces, according to the subject's perception (C).

**Figure 2. Isometric strength results.** Accuracy (AC) in athletes (ATL) and sedentary (SED) individuals during ballistic and tonic contraction at the different force intensities (25%, 50%, and 75% MVIC). Data are presented as mean  $\pm$  standard deviation. # ( $p < 0.001$ ); \*\*\* ( $p < 0.001$ ).

**Figure 3. Results of the perceived accuracy.** Likert Scores between actual and intended force in athletes (ATL) and sedentary (SED) individuals during ballistic and tonic contraction at different

force intensities (25%, 50%, and 75% MVIC). Data are presented as mean  $\pm$  standard deviation.  
 \*\*\* ( $p < 0.001$ ).

# **Tables legends**

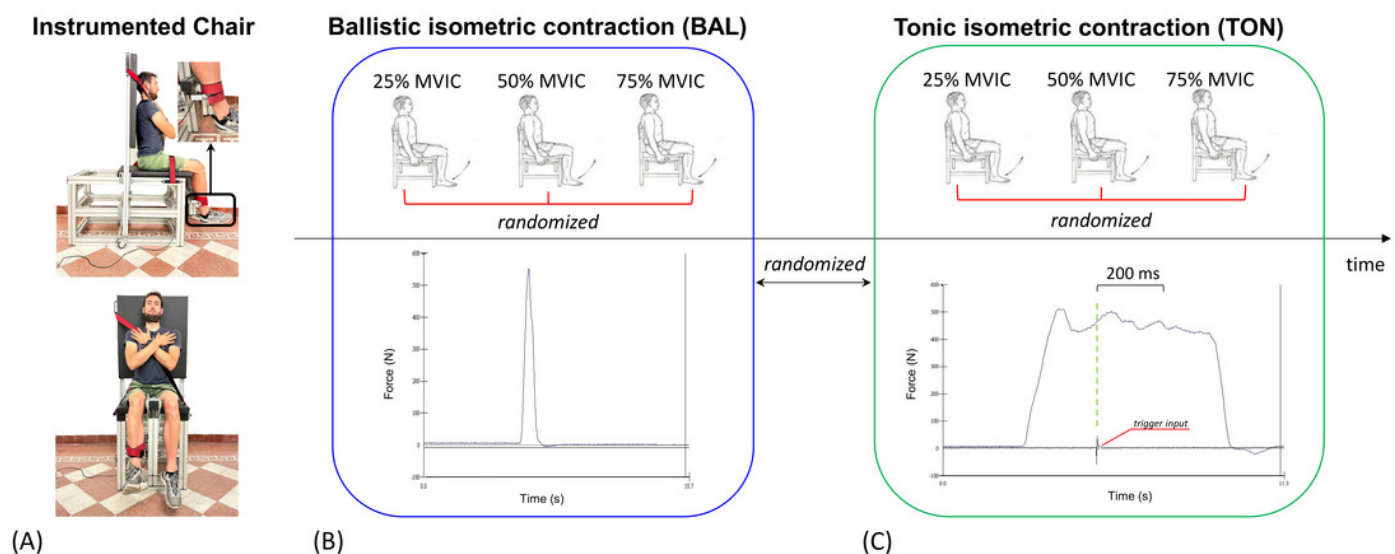

**Table 1. Baseline comparisons.** MVIC: maximal voluntary isometric contraction; BAL: ballistic contraction; TON: tonic contraction; SED: sedentary; ATL: athletes; BM: Body Mass. MET: Metabolic Equivalent. Data are presented as mean  $\pm$  standard deviation (SD).

**Table 2. Results of the actual force for all the intended force conditions (i.e., 25%, 50%, and 75% MVIC).** MVIC: maximal voluntary isometric contraction; BAL: ballistic contraction; TON: tonic contraction; SED: sedentary; ATL: athletes. Data are presented as mean  $\pm$  standard deviation.

# Figure 1

Graphical representation of the experimental design.

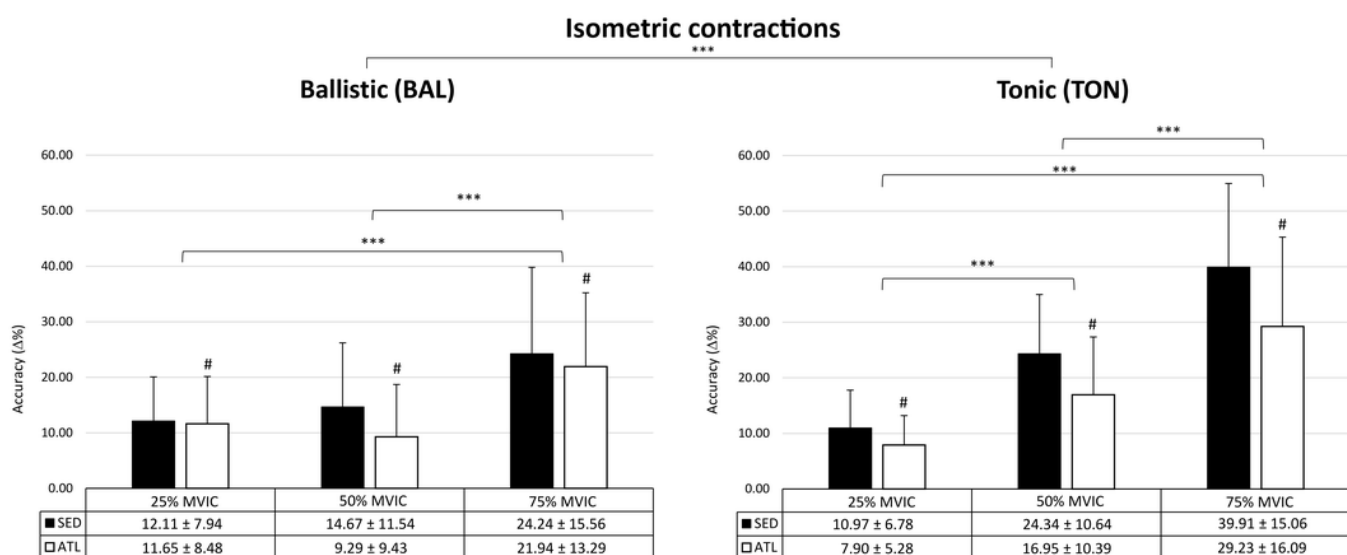

Custom-built chair instrumented with a uni-axial load cell (A); ballistic isometric condition with a representative force graph (B); tonic isometric condition with a representative graph of the force. The trigger input marked the beginning of the matching between intended and actual forces, according to the subject's perception (C).

# Figure 2

Isometric strength results.

Accuracy (AC) in athletes (ATL) and sedentary (SED) individuals during ballistic and tonic contraction at the different force intensities (25%, 50%, and 75% MVIC). Data are presented as mean  $\pm$  standard deviation. # ( $p < 0.001$ ); \*\*\* ( $p < 0.001$ ).

# Figure 3

Results of the perceived accuracy.

Likert Scores between actual and intended force in athletes (ATL) and sedentary (SED) individuals during ballistic and tonic contraction at different force intensities (25%, 50%, and 75% MVIC). Data are presented as mean  $\pm$  standard deviation. \*\*\* ( $p < 0.001$ ).

# **Table 1**(on next page)

Baseline comparisons.

MVIC: maximal voluntary isometric contraction; BAL: ballistic contraction; TON: tonic contraction; SED: sedentary; ATL: athletes; BM: Body Mass. MET: Metabolic Equivalent. Data are presented as mean  $\pm$  standard deviation (SD).

**Table 1. Baseline comparisons.**

	SED Group	ATL Group	p value
<b>MET</b> (min/week)	1408.00 ± 1333.96	7675.20 ± 4480.24	p < 0.001
<b>MVIC-BAL</b> (%BM)	50.785 ± 25.784	77.38 ± 21.45	p < 0.001
<b>MVIC-TON</b> (%BM)	69.34 ± 23.00	105.84 ± 19.48	p < 0.001

MVIC: maximal voluntary isometric contraction; BAL: ballistic contraction; TON: tonic contraction; SED: sedentary; ATL: athletes; BM: Body Mass. MET: Metabolic Equivalent.

## Table 2 (on next page)

Results of the actual force for all the intended force conditions (i.e., 25%, 50%, and 75% MVIC).

MVIC: maximal voluntary isometric contraction; BAL: ballistic contraction; TON: tonic contraction; SED: sedentary; ATL: athletes. Data are presented as mean  $\pm$  standard deviation.

**Table 2. Results of the actual force for all the intended force conditions (i.e., 25%, 50%, and 75% MVIC).**

Intended force	SED Group		ATL Group	
	BAL (%MVIC)	TON (%MVIC)	BAL (%MVIC)	TON (%MVIC)
<b>25% MVIC</b>	30.43 ± 13.65	16.05 ± 9.41	34.34 ± 11.09	23.76 ± 9.60
<b>50% MVIC</b>	44.03 ± 17.96	25.96 ± 11.35	47.09 ± 13.07	36.64 ± 14.92
<b>75% MVIC</b>	53.26 ± 19.12	35.08 ± 15.06	53.87 ± 14.63	46.45 ± 17.34

MVIC: maximal voluntary isometric contraction; BAL: ballistic contraction; TON: tonic contraction; SED: sedentary; ATL: athletes.
