The impacts of nitrogen deposition and earthworms on soil respiration and microbial communities in the Huang-Huai-Hai Plain have received increasing attention in the literature. However, research on the impact of earthworms and nitrogen deposition frequency on soil carbon dioxide (CO₂) emission and the microbial community is still limited. We conducted a field study in a farming ecosystem to investigate the effects of earthworm activity and nitrogen deposition frequency on soil respiration in the Huang-Huai-Hai Plain. Nitrogen deposition frequency had a significant effect on soil respiration, but neither earthworms nor their interaction with Nitrogen deposition frequency were not significant. Low-frequency nitrogen addition (NL) significantly increased soil respiration by 25%, while high-frequency nitrogen addition (NH), earthworm addition (E), earthworm and high-frequency nitrogen addition (E*NH), and earthworm and low-frequency nitrogen addition (E*NL) also increased soil respiration by 21%, 21%, 12%, and 11%, respectively. The main reason for the rise in soil respiration was alterations in the bacterial community. While soil pH, soil NO₃⁻-N, and fungal diversity were lower under the NL treatment than under the NH treatment, the bacterial richness was higher. The abundance of Corynebacteriales, Gammaproteobacteria, and keystone taxa (Myxococcales) were favorably connected with the CO₂ emissions, while Verrucomicrobia, Thermoleophilia, and Verrucomicrobia were negatively correlated. Our results demonstrate the ecological importance of the bacterial community in mediating carbon cycling in the Huang-Huai-Hai Plain and show that the enhanced CO₂ emissions were affected by the diverse soil bacterial community composition deriving from different frequent nitrogen depositions.

Low-frequency nitrogen deposition addition affects CO₂ emission through regulating soil bacterial community composition

Abstract

The impacts of nitrogen deposition and earthworms on soil respiration and microbial communities in the Huang-Huai-Hai Plain have received increasing attention in the literature. However, research on the impact of earthworms and nitrogen deposition frequency on soil carbon dioxide (CO₂) emission and the microbial community is still limited. We conducted a field study in a farming ecosystem to investigate the effects of earthworm activity and nitrogen deposition frequency on soil respiration in the Huang-Huai-Hai Plain. Nitrogen deposition frequency had a significant effect on soil respiration, but neither earthworms nor their interaction with Nitrogen deposition frequency were not significant. Low-frequency nitrogen addition (NL) significantly increased soil respiration by 25%, while high-frequency nitrogen addition (NH), earthworm addition (E), earthworm and high-frequency nitrogen addition (E*NH), and earthworm and low-frequency nitrogen addition (E*NL) also increased soil respiration by 21%, 21%, 12%, and 11%, respectively. The main reason for the rise in soil respiration was alterations in the bacterial community. While soil pH, soil NO₃⁻-N, and fungal diversity were lower under the NL treatment than under the NH treatment, the bacterial richness was higher. The abundance of Corynebacteriales, Gammaproteobacteria, and keystone taxa (Myxococcales) were favorably connected with the CO₂ emissions, while Verrucomicrobia, Thermoleophilia, and Verrucomicrobia were negatively correlated. Our results demonstrate the ecological importance of the bacterial community in mediating carbon cycling in the Huang-Huai-Hai Plain and show that the enhanced CO₂ emissions were affected by the diverse soil bacterial community composition deriving from different frequent nitrogen depositions.

Introduction

Large amounts of CO₂ are released into the environment by soil through respiration, which

raises atmospheric CO₂ concentrations and undermines ecological sustainability (Bond-Lamberty et al., 2010). The carbon budget of terrestrial ecosystems can be seriously affected by even minor changes in soil respiration (Heimann et al., 2008). One of the most active parts of the terrestrial ecosystem, the agricultural system is crucial to the global carbon cycle (Crippa et al., 2021). Soil carbon emissions from farmland must be understood in order to predict and manage soil carbon stores (Wu et al., 2019). The main elements of soil respiration are soil microbial and plant root respiration, both of which are regulated by biotic and abiotic factors (Chen et al., 2019; Lei et al., 2021), such as root dynamics, microclimate, substrate availability, nutrition levels, and soil microbial activity (Allison et al., 2010; Talmon et al., 2011; Wagai et al., 2013; Bolat et al., 2016; Wang et al., 2019). These variables have been incorporated into parameterizing models that forecast shifts in the global carbon cycle.; However, there is still remains uncertainty in estimating soil respiration, which limits our capacity to forecast carbon cycling under scenarios of climate change (Liu et al., 2020b). Microbial ecology is one of the most promising fields in the hunt for novel indicators of soil carbon cycling (Liu et al., 2020b). Soil microorganisms play significant roles in predicting CO₂ emission through microbial processes (Liu et al., 2018). Both theoretical and practical evidences point to the possibility of predicting soil carbon fluxes using the functional and taxonomic characteristics of soil microbial communities (Liu et al., 2019; Allison et al., 2010; Liu et al., 2018). For instance, changes in the soil microbial community composition have an impact on soil carbon respiration and fixation (Monteux et al., 2018; Müller et al., 2018). Previous studies have revealed that the compositions of these microbial communities may play a role in regulating CO₂ emissions (Chen et al., 2021; Wang et al., 2019) since copiotrophs have a faster respiration rate than oligotrophs and that proteobacteria and actinobacteria are positively connected with CO₂ emissions (Liu et al., 2018; Chen et al., 2021; Liu et al., 2020). So far, the extent to which the structure and the composition of the microbial community altered CO₂ emission in farming systems has not yet been thoroughly determined.

Fertilization is typically thought to be the primary method for increasing crop yield, it also has a significant impact on the carbon pool and carbon flux in the soil. The structure and function of the world's ecosystems are significantly impacted by changes brought on by anthropogenic atmospheric nitrogen deposition (Cao et al., 2021). The influence of nitrogen deposition is still being debated despite the fact that many nitrogen addition experiments have been carried out to examine how ecosystem carbon exchange mechanisms respond to nitrogen deposition (Cao et al., 2020; Yang et al., 2020). The frequency of nitrogen amendment is a key factor in methods for simulating nitrogen deposition. In reality, nitrogen deposition occurs continuously, therefore 12 times applications each year rather than a single or two or three additions more nearly resemble atmospheric nitrogen deposition (Cao et al., 2020). At present, there are few reports on the effects of nitrogen deposition frequency on soil respiration, particularly when it comes to microbial communities. Hence, nitrogen deposition frequency experiments that integrate plant, soil and microbial components of ecosystems are needed to fill this gap in understanding (Cao et al., 2020).

In soil formation and function processes, earthworms play a crucial role as keystone detritivores and ecosystem engineers (Yang et al., 2019; Fahey et al., 2013). They can affect soil

carbon dynamics since they are ecosystem engineers living in the soil (Jennings et al., 2016). Previous research has demonstrated that soil CO₂ emissions can rise as a result of earthworm invasion (Lubbers et al., 2013). Through their interactions with microbes, macro, and microfauna, earthworms greatly influence the decomposition process and increase heterotrophic activity, which in turn affects soil carbon dioxide emissions (Fisk et al., 2004). Earthworms directly or indirectly affect the nitrogen cycle and have the potential to alter ecosystem functions and services in relation to the nitrogen cycle (Xue et al., 2022). However, there is still limited research on the effects of simulated nitrogen deposition frequency and earthworm addition on ecosystem carbon emissions. Therefore, disentangling how nitrogen deposition frequency and earthworm addition affect CO₂ emission and its relationship with the soil microbial community is of great significance for mediating C cycling in farmland.

Here, we aimed to explore how the microbial community regulates the response of CO₂ emission to different frequencies of nitrogen deposition and earthworm addition. In this study, one growing season field experiment with six treatments was performed in the Huang-Huai-Hai Plain. The specific questions of this study we tied to address: (1) How does CO₂ emission respond to nitrogen deposition frequency and earthworms? (2) What were the underlying mechanisms influencing CO₂ emission response to nitrogen deposition frequency and earthworms?

Materials and methods

Research site

This research was performed at the farm of Jinming Campus of Henan University, Kaifeng City, Henan Province, China (34°49'N, 114°18'E). A permanent 25 × 10 m² rainout shelters with steel frames and covered with clear polyethylene roof was built in late summer 2021 to control precipitation inputs each year, to avoid extreme rainfall that death of soybean and earthworms. The appropriate rainfall amounts were selected to simulate natural precipitation in the local area with the long-term means. The region belongs to the warm temperate continental monsoon climate with an annual mean temperature is 14 °C and the annual mean precipitation is 650 mm (80% occurring between July and August). The soil texture is sandy loam soil.

Experimental design

The experiment used a randomized block design involving two factors of nitrogen and earthworm, including six treatments: C(control), E (earthworm addition), NH (high-frequency nitrogen addition), NL (low-frequency nitrogen addition), E*NH (earthworm and high-frequency nitrogen addition), and E*NL (earthworm and low-frequency nitrogen addition). Each treatment was replicated five times with an area of 1m × 1 m per plot.

The total amount of earthworms (*Metaphire guillelmi*) added was controlled at 8.0-8.9g. Each block was surrounded by glass to prevent earthworms from escaping. Nitrogen (urea) was added by water dissolving and root topdressing. The total amount of nitrogen added was the same as the conventional local field nitrogen application. Two nitrogen deposition frequencies

were set based on previous research 10132752: high-frequency nitrogen application (12N) and low-frequency nitrogen application (2N). From seedling stage (VE) to drum stage (R6), high-frequency nitrogen was uniformly added 12 times / 29 N kg·hm⁻² and low-frequency nitrogen was uniformly added twice / 174 N kg·hm⁻². Earthworms were added in July 15th and August 21st, 2022.

Measurement of soil respiration

Soil respiration and temperature were measured every seven days during the Soybean growing season using a Li-8100 portable soil CO₂ flux system (Li-Cor, Inc. Lincoln, NE, USA) and a thermocouple probe (Li-8100-201, Li-Cor, Inc. Lincoln, NE, USA) connected to the Li-8100 in June 2022 to October 2022. Soil volumetric water content at 0-5cm soil depth was determined adjacent to each collar using a soil detector (TR-6D). All measurements were performed between 9 a.m. and 11:30 a.m. To avoid the respiration of aboveground parts of plants and litter decomposition, all living plants and litter inside the collars were removed by hand two days before soil respiration was measured. If it rains heavily, our measurement would be postponed for two days.

Soil sampling and analysis and plant index measurements

Each plot was destructively sampled in September 2022. Three soil cores were randomly collected and pooled by depth from each plot using a soil corer (inner diameter 5 cm) at 0-10 cm depths, sieved through a 2 mm mesh to separate gravel and roots, and divided into three parts. One subsample was stored at 4 °C for the analysis of the chemical properties of soil i.e. the N content in the form of ammonium and nitrate using a colourimetric method (Smart Chem 200 Discrete Auto Analyser, Systea, Italy). Another subsample was air-dried and ground for analysis of pH、total N (TN) and total carbon (TC). The soil pH was measured with a soil pH tester. The soil TN and TC concentrations were measured by a Vario ELIII Elementar (Elementar Analysensysteme GmbH, Germany) elemental analyzer. The third part was stored at -20 °C for the analysis of the microbial community diversity composition spectrum.

After removing the whole plant from the soil, rinsed it slowly with running water to separate the above and below-ground parts of the plant from the cotyledon nodes. The washed roots were dried in an oven at 65°C to a constant weight, and the root biomass was weighed. Aboveground biomass was weighed after two weeks of natural air drying. Grain yield was measured by removing the mature pods from the plants, placing them in paper bags, and leaving them in a ventilated place for drying to constant weight. The plant height was measured by selecting 3 plants from each plot and measuring them with a tape measure. The number of pods per plant and number of grains per plant were also artificially measured by selecting 3 plants from each plot. 100 grain weight was randomly selected from the grain yield of each plot and weighed by precision scale.

DNA extraction, PCR amplification, and Illumina sequencing

Soil DNA was extracted from each sample using E.Z.N.A Soil DNA Kit (Omega Bio-tek, Norcross, Georgia, USA) according to the manufacturer's protocol. The purity and concentration

of the extracted DNA were determined by a NanoDrop-2000 spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA). Purified soil DNA was fully pooled together after quantitative determination and then for downstream manipulations. The V3-V4 of bacterial 16S rRNA genes were amplified with the following universal primer set: upstream primers 338F (5'-ACTCCTACGGGAGGCAGCA-3') and downstream primers 806R (5'-GGACTA CHVGGGTWTCTAAT3'). For fungi, the primers ITS5 (5'-GGAAGTAAA AGTCGTAACAAGG -3') and ITS2 (5'-GCTGCG TTC TTCATCGATGC-3')⁴⁵ were used to amplify the ITS_V1 region of the rDNA gene. PCR reactions were performed in 25 μ L reaction mixtures containing 5 μ L 5 \times reaction buffer, 5 μ L 5 \times GC buffer, 2 μ L 2.5mM dNTPs, 1 μ L Forwardprimer (10uM), 1 μ L Reverseprimer (10uM), 2 μ L DNA Template, 8.75 μ L ddH₂O, 0.25 μ L Q5 DNA Polymerase. The reaction conditions were programmed of an initial denaturing step at 98°C for 2 min, denaturation 98°C 15s, annealing 55°C 30s, extension 72°C 30s, final extension 72°C 5min and 10°C hold 25-30cycles. Samples were sequenced in an Illumina MiSeq High-Throughput Sequencing (HTS) platform (Illumina, San Diego, CA, USA) at Personal Biotechnology Co. Ltd Shanghai, China to determine soil microbial community composition.

Statistical analyses

The sequenced data was performed using QIIME 2 2019.4 with slight modification. Briefly, raw sequence data were demultiplexed using the demux plugin followed by primers cutting with cutadapt plugin. Sequences were then merged, filtered and dereplicated using functions of fastq_mergepairs, fastq_filter, and derep_fulllength in Vsearch. All the unique sequences were then clustered at 98% (via cluster_size) followed by chimera removing. At last, the non-chimera sequences were re-clustered at 97% to generate OTU representative sequences and OTU table. Representative sequences were aligned with mafft and used to construct a phylogeny with fasttree. Alpha-diversity metrics (Observed_species, Simpson) were estimated using the diversity plugin with samples were rarefied. Meanwhile, principal coordinates analysis (PCoA) was selected to illustrate the clustering of different samples. ASVs were given a taxonomy using the Silva v132 99% OTU reference sequences and the classify-sklearn nave Bayes taxonomy classifier in the feature-classifier plugin (Liu et al., 2020).

Two-way ANOVAs ($p < 0.05$) was used to analyze the significant differences between nitrogen deposition frequency and earthworms on CO₂ emission and soil properties. One-way ANOVA with Duncan testing ($p < 0.05$) was used to evaluate the significant differences in soil properties and CO₂ emission among the six treatments. Linear regression analysis was used to study the relationship between soil respiration, soil property and soil microbial community under six treatments. Spearman's correlation analyses were performed to assess the relationships between soil properties, respiration, plant biomass and microbial community. Soil chemical properties data were analyzed with SPSS software (version 26, IBM, Chicago, IL, USA). We conducted a classification random forest analysis to identify the major statistically significant microbial predictors of the composition (relative abundance: number of sequences of major phyla/class/order level) of bacteria and fungi acting on soil respiration. The analysis was conducted using the rfPermute package of the R (4.2.2) statistical software. The significant

predictors from random forest analysis were further selected for structural equation modeling (SEM) analysis. SEM analysis was applied to determine the direct and indirect contributions of soil properties and the bacterial community to CO₂ emission. SEM analysis was performed using AMOS 22.0 software (SPSS, Chicago, IL, USA). The model fitness was evaluated by χ^2 ($p > 0.05$), comparative fit index, and root mean square error of approximation.

Results

Nitrogen and earthworm addition effects on soil respiration

Soil respiration varied with Soybean growth period, showing obvious seasonal variation (Fig. 1a). It was the lowest during the early vegetative stage (Jun.23 to Jul.14), reached maximum at the reproductive stage (Jul.21 to Sep.7), and started declining during the maturity period (Sep.7 to Sep.17). Total soil respiration varied during the study from 1.13 to 4.63 mmol m⁻² s⁻¹, with an average of 2.55 ± 0.12 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Fig. 1b). Compared with C, soil respiration in the NL increased significantly by 25 %. E*NH, E*NL, NH, and E increased by 21%, 21%, 12%, and 11%, respectively. Overall, soil respiration was significantly affected by nitrogen addition, but not by earthworm addition or interaction between nitrogen and earthworm addition. (Table 1).

Nitrogen and earthworm addition effects on soil properties, plant biomass and agronomic traits

Nitrogen addition significantly influenced soil pH, TN, NO₃⁻-N, and NH₄⁺-N. Soil moisture was significant in the addition of nitrogen and earthworm, as well as their interaction, while their interaction significantly affected grain yield (Table 1). The E*NL treatment had the highest soil TN, which was also significantly higher than the C and E treatments (Fig. 2a). The soil moisture was significantly lower under NH, NL, and E compared to E*NH (Fig. 2b). In comparison to the control plots (C, E; Fig. 2c), the soil NO₃⁻-N was considerably greater when nitrogen addition treatments (NH, NL, E*NH, E*NL) were used. Soil NH₄⁺-N was significantly higher in NH and E*NH than that of other treatments (Fig. 2d). Soil pH of E*NL, NL, NH, E*NH decreased 3.38%, 3.03%, 2.17%, 1.64%, and E increased 1.26% compared with C (Fig. 2e). The highest grain yield was observed in E*NH, which was also significantly greater than NH (Fig. 2f). However, neither the addition of nitrogen nor the interaction of earthworms had no significant influence on ST, TC, plant biomass and agronomic traits (except grain yield).

Soil microbial community composition for predicting soil respiration

Using random forest modeling, we identified the major bacterial and fungal phyla, classes and orders for predicting soil respiration. These taxa include several bacterial and fungal such as Corynebacteriales, Myxococcales, Sordariomycetes, Verrucomicrobia, Thermoleophilia, Agaricomycetes, Gammaproteobacteria, Blastocladiomycetes, and Proteobacteria (Fig. 3).

The Spearman's correlation coefficients between the microbial characteristics and the soil respiration as well as soil properties were estimated (Table 2). Soil respiration rate was correlated to bacterial simpson. Particularly, there were significant relationships between the respiration and major bacterial and fungal phyla. The findings demonstrated a strong correlation

between soil respiration and the abundances of Blastocladiomycetes and Agaricomycetes in the fungal compositions as well as Gammaproteobacteria, Verrucomicrobia, Thermoleophilia, and Myxococcales in the bacterial compositions. (Fig. 3 and Table 2).

Relationships between soil respiration and abiotic and biotic factors

Soil respiration showed positively dependent upon Nitrate N ($R^2 = 0.10$, $p < 0.05$, Fig. 4b), aboveground biomass ($R^2 = 0.16$, $p < 0.05$, Fig. 4c), Plant height ($R^2 = 0.15$, $p < 0.05$, Fig. 4e), Grain yield ($R^2 = 0.12$, $p < 0.05$, Fig. 4f), and negatively with soil pH ($R^2 = 0.18$, $p < 0.05$, Fig. 4a), but it was not correlated with root biomass (Fig. 4d).

Additionally, SR was significantly positively correlated with the relative abundance of Gammaproteobacteria and Corynebacteriales, as well as bacteria Pco1, and negatively correlated with the relative abundance of Myxococcales, Verrucomicrobia and Thermoleophilia (Fig. 5). Notably, the relative abundance of Thermoleophilia, Myxococcales and Verrucomicrobia was low in NL, while the relative abundance of Corynebacteriales and Gammaproteobacteria was high. In general, NL treatment raised the relative abundance of copiotrophs while decreasing the relative abundance of oligotrophs.

Structural equation modeling (SEM) further suggested that bacteria richness and microbial composition (Proteobacteria, Myxococcales) had strong direct effects on soil respiration (Fig. 6). However, nitrogen addition mostly had indirect impacts on soil respiration through pH, NO_3^- -N, Proteobacteria, Myxococcales, and bacteria richness, while earthworm addition had indirect impacts on soil respiration through NO_3^- -N, AGB, GRY and RB. Overall, the most important microbial attributes controlling soil respiration rates were the relative abundances of Proteobacteria and Myxococcales, and bacteria richness.

Discussion

Effects of nitrogen deposition frequency on soil respiration and microbial community

In order to increase crop output and soil quality, nitrogen fertilizer is frequently seen as a usual method (He et al., 2022). But fertilization practices can have a big impact on soil CO_2 emissions (Wang et al., 2021). In the current investigation, fertilizer treatments considerably improved soil CO_2 emission by 12-25% in comparison to the carbon treatment. This finding was in line with previous study findings that indicated enhanced CO_2 emissions in farmland ecosystems following fertilization (Yan et al., 2020; Lamptey et al., 2019). In addition, NL promoted soil respiration more than NH, indicating that nitrogen inhibited soil respiration with the increase of nitrogen frequency. The addition of nitrogen-promoted CO_2 emission could be attributed to the high level of NO_3^- -N and the low level of pH, which increase the bacterial richness and change microbial community composition, thus stimulating soil heterotrophic respiration and CO_2 emission. Similar findings from earlier investigations have been noted, for example, at the 2-N frequency, the addition of N led to a lower, more acidic pH (Ning et al., 2015); When the same total N loading is applied in a single pulse rather than repeatedly, the effects of soil acidification and mineral N toxicity are more likely to be exacerbated (Ning et al., 2015). Plants mainly capture N from the abundant soil N form across N addition gradient 11,

therefore NO_3^- -N plays an important role as the most abundant available nitrogen in our study. According to previous reports, changes in the soil microbial community might indirectly affect soil respiration by changing the pH of the soil (Whitaker et al., 2014; Liu et al., 2020a; Liu et al., 2020b). NO_3^- -N and pH were found to be important environmental factors in explaining changes in bacterial community composition (Chen et al., 2021).

In this study, NL treatment obviously increased the bacterial richness compared to C, while NH showed the opposite trend. The result was in accordance with previous researches. For instance, soil respiration rises when nitrogen levels rise, which is compatible with increased bacterial abundance and suggests that this reaction may be driven by an increased metabolic rate (Hagerty et al., 2014). As far as we know, there is almost no research on the impact of nitrogen addition at different frequencies on bacterial richness. Much of the research has been on the effects of adding different levels of nitrogen on microbial richness. For instance, research has shown that adding nitrogen within a specific range might increase the amount of bacteria quantity, but that adding nitrogen in excessive would have an opposite effect (Ma et al., 2007). In our study, low-frequency nitrogen increased bacterial richness relative to high-frequency nitrogen, which is consistent with other results in this study that low-frequency nitrogen played a promoting role relative to high-frequency nitrogen. The increase in NO_3^- -N and NH_4^+ -N and decrease in pH that nitrogen addition causes are directly correlated with the bacteria richness. Most bacteria prefer a pH that is close to neutral, and they are sensitive to pH variations (Anil et al., 2019). The alkaline soil in the study's location would make an ideal habitat for the soil microbial community to promote soil respiration (Chen et al., 2021). The substrate (such NO_3^- -N) that provides nutrients for microorganisms may be related to the rise in soil bacterial community richness (Chen et al., 2021). Nitrification of NH_4^+ -N accumulation may result in soil acidification and pH lowering, and the addition of nitrogen enhances this reaction and further lowers pH (Sun et al., 2019). Our research confirms these findings. In the 6th and 7th years following nitrogen application, Cao et al.'s (2020) research shown that HF considerably reduced the detrimental effects of nitrogen addition on plant and soil bacterial diversity. In the present study, NH reduced the negative effect of nitrogen addition on fungal diversity than NL, while the trend of bacterial diversity was the opposite, which may be due to the strong alkaline soil in our experimental site.

Effects of earthworm on soil respiration and microbial community

Earthworm activity can increase the contents of soil active organic carbon, soil inorganic nitrogen, microbial biomass carbon, and microbial biomass nitrogen (Yu et al., 2007; Li et al., 2002). Additionally, earthworm addition may also increase soil CO_2 emissions (Lubbers et al., 2013). In this study, earthworm addition enhanced soil CO_2 emissions, which is consistent with previous research results (Lubbers et al., 2013; Song et al., 2020; Yang et al., 2019). This could be explained by change in the composition of the microbial community brought on by the addition of earthworms, which is consistent with our findings (Yu et al., 2010). In our study, earthworm addition mainly altered the relative abundance of Myxococcales and Verrucomicrobia, thus affecting soil respiration. Furthermore, our results confirmed that the

addition of earthworms promoted seedling respiration rates for a short period of time (Butenschoen et al., 2007; Jennings et al., 2016).

In the present study, the addition of earthworms increased bacterial richness and affected the relative abundance of potential keystone taxa as well as the fungal community structure. It has been shown that soluble carbon and other compounds released in the digestive tract of earthworms contribute to bacterial proliferation (Barbosa et al., 2017). Changes in physical and chemical properties such as pH and available nitrogen led to changes in microbial community composition and fungal communities, after the application of earthworm feces (Zhao et al., 2016). Some studies indicated that earthworm addition increased soil pH (Wang et al., 2013), while others showed that earthworm addition decreased soil pH (Xu et al., 2021). This might be because earthworm activity altered the soil's water vapor coordination and acid-base neutral aggregate structure, encouraging soil acid-base balance (Yu et al., 2010).

Effects of nitrogen deposition frequency and earthworm on soil respiration

In the study, the addition of earthworms and the interaction between earthworms and nitrogen had no significant effect on soil respiration, which may be because the reduction of respiration rate caused by the absorption of sufficient nitrogen by plants and the increase of respiration rate caused by earthworm addition offset each other. Another possible explanation is that earthworm addition is not adapted to the habitat and cannot survive for a long time, so it has only a short-term (1-2 weeks) effect on soil respiration. Nevertheless, the effect of earthworms and nitrogen on soil respiration is additive, which has important practical significance. We offer scientific references for research on how soil respiration in the Yellow River beach area is impacted by soil animals and nitrogen deposition, and we examine whether the short-term (3-4 month) effects of earthworms may be ignored.

Microbial community and soil properties regulated CO₂ emission

Important microbial classification and functional properties have been reported to potentially predict changes in soil respiration. Based on the study of the random forest model, we were able to pinpoint the primary microbial taxa that predict soil respiration. They have been demonstrated to play a significant driving role in the rate of soil respiration. The Corynebacteriaceae upregulation belonging to Actinobacteria was known to be oligotrophic, which is better adapted to conditions with inadequate nutrient and carbon resources. As a result, it plays a part in the degradation of recalcitrant compounds (Fu et al., 2022). The findings of the investigation indicated that a major predictor of soil respiration was the unclassified Myxococcales cluster1-27 (Liu et al., 2019). Proteobacteria have been found to prefer soils with abundant carbon availability, hence this phylum might promote increases in the SOC fractions and respiration. Additionally, SOC fractions and respiration were substantially connected with Gammaproteobacteria, Sordariomycetes, and Agaricomycetes (Wang et al., 2018). Gammaproteobacteria and Corynebacteriales had a beneficial correlation with soil CO₂ emission in the current study, but Myxococcales, Verrucomicrobia, and Thermoleophilia had negative correlations. In the mixed conifer soil, nitrogen addition decreased the absolute abundances of

Thermoleophilia and Verrucomicrobia (Liu et al., 2021), which is consistent with our results, suggesting that nitrogen addition may alleviate the cost of nutrient stress and increase microbial growth (Hessen et al., 2004; Li et al., 2019). Copiotrophs and oligotrophs have the ability to use C for respiration, according to widely accepted reports. In general, it has been suggested that oligotrophs have slower respiration rates than copiotrophs (Liu et al., 2108; Chen et al., 2021; Liu et al., 2020). Verrucomicrobia, Thermoleophilia, and Corynebacteriales are categorized as oligotrophs, whilst Myxococcales and Gammaproteobacteria are thought to be potential copiotrophs (Chen et al., 2021). Thermoleophilia and Corynebacteriales, two crucial Actinobacterial groups for forecasting soil respiration, exhibited the lowest sum of relative abundance in the NL treatment compared to other treatments, although Gammaproteobacteria showed an increasing trend. Consequently, the relationship between bacterial community structure and CO₂ emission may be explained by the activity of bacterial communities in response to changes in the oligotroph-to-copiotroph ratio within the community, which may also explain why NL has the greatest CO₂ emissions.

The SEM demonstrated a strong association of bacterial community richness and the potential keystone taxa with the respiration rates, indicating that changes in the community composition of soil bacteria could result in predictable variations in soil respiration. Meanwhile, the important taxa may also alter the soil microbial community composition, which may have an impact on the rates of soil carbon respiration. These findings are consistent with recent research emphasizing the crucial function of key taxa and the microbial community composition in soil respiration (Liu et al., 2019; Liu et al., 2018; Wang et al., 2022). Importantly, our SEM revealed that soil properties like pH and NO₃⁻-N affected soil respiration rates indirectly by changing the soil microbial community rather than directly (Liu et al., 2019; Wang et al., 2022). Our results highlight the importance of core species and community composition as predictors in the development of the soil carbon model (Liu et al., 2019; Wang et al., 2018; Wang et al., 2022; Whitaker et al., 2014). Furthermore, our findings imply that bacteria communities are significantly better than fungus at forecasting changes in soil respiration. This is consistent with the widespread belief that bacterial communities, not fungi, control the majority of ecological activities in agricultural ecosystems (Van Der Heijden et al., 2007), suggesting that future research on major soil groups that regulate carbon emissions should pay more attention to the communities of bacteria. These results can help us anticipate more accurately how the world's carbon emissions will respond to climate change. They may also provide light on how to manage the widespread and highly valuable farming soil carbon storage in the future (Liu et al., 2019).

Conclusions

Our results reveal that nitrogen deposition frequency has a significant impact on CO₂ emissions. Changes in the bacterial community composition, which directly affect CO₂ emissions, as well as changes in soil pH and NO₃⁻-N, which have an indirect effect, are both responsible for low-frequency nitrogen's large increase in CO₂ emissions. Earthworm addition briefly increased soil respiration and contributed in an additive way to the reaction of CO₂ emissions to the frequency of nitrogen deposition, despite the fact that we did not see a

significant response of CO₂ emission to earthworm addition. Furthermore, our study advances our understanding of soil carbon emissions from croplands by highlighting the significance of microbial community composition and keystone species in forecasting soil CO₂ emissions. Overall, this study provides data support and fills the knowledge gap for studying the effects of nitrogen deposition frequency and soil animals on CO₂ emissions in the Huang-Huai-Hai Plain. This study provided further evidence that ecosystem structure and functional traits are influenced by the frequency of nitrogen deposition. More simulations of the nitrogen deposition process will be required in the future in order to better understand the microbiological alterations and mechanisms in ecosystems' carbon cycles.

2 **Table 1.** Results (F and p values) of two-way ANOVAs on the effects of Nitrogen addition (N), Earthworm addition (E), and
3 their interactions on Soil respiration (SR), Soil temperature (ST), Soil moisture (SM), Soil pH, Total C (TC), Total N (TN), Nitrate
4 N (NO₃⁻-N), Ammonium N (NH₄⁺-N), Aboveground biomass (AGB), Root biomass (RB), Plant height (PLH), Number of pods
5 per plant (NPP), Number of grains per plant (NGP), Grain yield (GRY), 100-grain weight (W100). Statistical differences are
6 indicated as *p < 0.05, **p < 0.01 and ***p < 0.001.

7

8

Table 2 (on next page)

Spearman's rank correlation coefficients (ρ) between the microbial (bacterial and fungal) characteristics soil properties, and plant biomass as well as soil respiration.

** . Correlation is significant at the 0.01 level; * . Correlation is significant at the 0.05 level.

Richness (number of OTUs), Simpson (alpha diversity), Pco1, Pco2 (beta diversity), Soil respiration (SR), Soil temperature (ST), Soil moisture (SM), Soil pH, Total C (TC), Total N (TN), Nitrate N (NO_3^- -N), Ammonium N (NH_4^+ -N), Aboveground biomass (AGB), Root biomass (RB).
