Background: Stroke is a disease with high morbidity, disability, and mortality. The immune factor plays a crucial role in the progression of ischemic stroke, but the exact mechanism is not clear. The study aims to identify immune-related biomarkers and evaluate the infiltration pattern of immune cells.

Methods: We downloaded datasets of ischemic stroke patients from GEO, applied R language to discover differential expressed genes, and elucidated their biological functions by GO, KEGG analysis, and GSEA analysis. Then the hub genes were obtained using two machine learning algorithms (LASSO and SVM-REF) and the immune cell infiltration pattern was revealed by CIBERSORT. Gene-Drug target networks and mRNA-miRNA-lncRNA regulatory networks were constructed using Cytoscape. Finally, we used RT-qPCR to validate the hub genes and applied logistic regression methods to build diagnostic models, which were validated with ROC curves.

Results: We screened 188 differentially expressed genes whose functional analysis was enriched to multiple immune-related pathways. Then six hub genes (ANTXR2, BAZ2B, C5AR1, PDK4, PPIH and STK3) were identified using LASSO and SVM-REF. ANTXR2, BAZ2B, C5AR1, PDK4, and STK3 were positively correlated with neutrophils, T cells gamma delta, negatively correlated with T cell follicular helper cells and CD8, while PPIH showed the exact opposite trend. Immunoinfiltration indicated increased activity of monocytes, macrophages M0, neutrophils and mast cells and decreased infiltration of T cell follicular helper cells and CD8 in the IS group. The ceRNA network consists of 306 miRNA-mRNA interacting pairs and 285 miRNA-lncRNA interacting pairs. RT-qPCR results indicated that the expression levels of BAZ2B, C5AR1, PDK4 and STK3 were significantly increased in patients with ischemic stroke. Finally, we developed a diagnostic model based on these four genes. The AUC value of the model was verified to be 0.999 in the training set and 0.940 in the validation set.

Conclusion: Our research explored the immune-related gene expression modules and provided a specific basis for further study of immunomodulatory therapy of IS.

Abstract

Background: Stroke is a disease with high morbidity, disability, and mortality. The immune factor plays a crucial role in the progression of ischemic stroke, but the exact mechanism is not clear. The study aims to identify immune-related biomarkers and evaluate the infiltration pattern of immune cells.

Methods: We downloaded datasets of ischemic stroke patients from GEO, applied R language to discover differential expressed genes, and elucidated their biological functions by GO, KEGG analysis, and GSEA analysis. Then the hub genes were obtained using two machine learning algorithms (LASSO and SVM-REF) and the immune cell infiltration pattern was revealed by CIBERSORT. Gene-Drug target networks and mRNA-miRNA-lncRNA regulatory networks were constructed using Cytoscape. Finally, we used RT-qPCR to validate the hub genes and applied logistic regression methods to build diagnostic models, which were validated with ROC curves.

Results: We screened 188 differentially expressed genes whose functional analysis was enriched to multiple immune-related pathways. Then six hub genes (ANTXR2, BAZ2B, C5AR1, PDK4, PPIH and STK3) were identified using LASSO and SVM-REF. ANTXR2, BAZ2B, C5AR1, PDK4, and STK3 were positively correlated with neutrophils, T cells gamma delta, negatively correlated with T cell follicular helper cells and CD8, while PPIH showed the exact opposite trend. Immunoinfiltration indicated increased activity of monocytes, macrophages M0, neutrophils and mast cells and decreased infiltration of T cell follicular helper cells and CD8 in the IS group. The ceRNA network consists of 306 miRNA-mRNA interacting pairs and 285 miRNA-lncRNA interacting pairs. RT-qPCR results indicated that the expression levels of

BAZ2B, C5AR1, PDK4 and STK3 were significantly increased in patients with ischemic stroke. Finally, we developed a diagnostic model based on these four genes. The AUC value of the model was verified to be 0.999 in the training set and 0.940 in the validation set.

Conclusion: Our research explored the immune-related gene expression modules and provided a specific basis for further study of immunomodulatory therapy of IS.

Introduction

Stroke, of which more than 80% are ischemic (Hasan et al., 2018), is the second leading cause of death and the third leading cause of disability in adults (Campbell and Khatri, 2020). It seriously affects patients' quality of life and causes a heavy burden to the family and society. Therefore, our study focuses on discovering novel targets for diagnosing and treating ischemic stroke (IS). At present, the diagnosis of ischemic stroke (IS) mainly depends on clinical manifestations and neuroimaging, such as computed tomography (CT) (Harston et al., 2015) and magnetic resonance imaging (MRI) (Zameer et al., 2021). The most effective early treatment methods are thrombolysis and intravascular therapy (Cassella and Jagoda, 2017, Hasan et al., 2018), both of which have time limitations to administer. Nonetheless, the clinical manifestations of the disease are variable, and the cost of administering CT and MRI scans is expensive and time-consuming. If the symptoms are not typical or the above examinations cannot be performed in a timely manner, diagnosis and treatment may be delayed. At the same time, the above treatment methods carry the risk of bleeding. This has led us to search for new diagnostics and treatments. Genetic factors are related to the occurrence and prognosis of stroke (Malik et al., 2018, Torres-Aguila et al., 2019). Possible stroke-related gene loci, such as ANK2, CDK6 and KCNK3, were found by whole genome sequencing (Malik et al., 2018). However, the specific mechanism of action is not clear. CYP450, COX-2, PTGIS, TBXAS1, P2RY1, and TGB3, or GPIIa are candidate genes that may be associated with stroke prognosis (Torres-Aguila et al., 2019). Presently, bioinformatics technology has been widely applied to various diseases, so we use bioinformatics technology to screen and identify key genes associated with IS, and build a classification diagnosis model based on these genes, to provide certain auxiliary methods for the diagnosis of ischemic stroke and potential therapeutic targets for the management of diseases. Immune factors are also closely associated with ischemic stroke (Iadecola et al., 2020, Levard et al., 2021). In the acute phase, the immune response is activated immediately when the brain is in ischemia. Damaged or dead brain cells release damage-associated molecular patterns (DAMPs) (Wu et al., 2022). These substances quickly activate intracranial immune cells (microglia, etc.), release chemokines and cytokines, and trigger a series of inflammatory cascades (Anrather and Iadecola, 2016, Levard et al., 2021). More importantly, immune cells in the peripheral blood can penetrate the central nervous system (CNS) through the damaged blood-brain barrier (BBB) (Jayaraj et al., 2019), further exacerbating the damage. At the same time, these DAMPs and cytokines can enter the bloodstream and activate the systemic immune system and inflammatory response, which can lead to severe immunosuppression and even fatal infections (Iadecola et al.,

2020). In the chronic phase, adaptive immune responses to the brain are mobilized due to antigen presentation, which may be the basis of neuropsychiatric sequelae, poststroke dementia/fatigue/depression, and the root cause of post-stroke morbidity (Iadecola et al., 2020). Epidemic-modulated therapy may be a good alternative to IS therapy. Several studies have shown that immune regulation can delay disease progression and improve neurological function and prognosis. These changes highlight the need to maintain a stable immune microenvironment in the central nervous system (Javidi and Magnus, 2019, Jayaraj et al., 2019). TGF- β 1 has a significant neuroprotective effect (Taylor et al., 2017) and can reduce post-stroke infection (Cekanaviciute et al., 2014, Doll et al., 2014). Relevant targeted drugs are now being developed. Specific inhibitors of IL-1 β can delay atherosclerosis by interfering with immune pathways associated with atherosclerotic plaque formation (Khambhati et al., 2018). Meanwhile, IL-1 receptor antagonists have been found to effectively reduce peripheral inflammation in patients with acute ischemic stroke and improve clinical outcomes in these patients (Smith et al., 2018). In conclusion, the analysis of immune infiltration analysis and the study of the relationship between target genes and immune cell distribution may help to elucidate the immune-related molecular mechanism of IS and provide the specific basis for immunoregulatory therapy. At the same time, the prediction of drug target gene action network may provide a new target for the treatment of IS.

Competing endogenous RNA (ceRNA) does not represent a specific type of RNA, but a regulatory mechanism. By combining with microRNA response elements (MREs) existing on mRNA, miRNAs inhibit mRNA translation or lead to its degradation, thus achieving the function of regulating gene expression after transcription (Salmena et al., 2011). Different mRNAs can compete to bind to the same miRNA and thus participate in the regulation of gene expression. With the deepening of transcriptome studies, it is found that MREs exist not only on mRNA, but also on lncRNA, circRNA and other types of RNA, which means that the same miRNA can bind to several and multiple types of RNA, and a competitive relationship is formed between RNA molecules that bind to the same miRNA. This forms the ceRNA network. If the regulation of ceRNA is abnormal, it may cause the occurrence of diseases, as shown in the research fields of tumors (Karreth et al., 2015), stroke (Li et al., 2020) and other complex diseases. It has been reported that miRNA regulates gene expression by silencing target genes and plays an important role in neurological diseases such as IS (Bulygin et al., 2020, Chi et al., 2020). In addition, the occurrence, progression and prognosis of acute ischemic stroke are also related to abnormal lncRNA expression (Bai et al., 2014, Feng et al., 2019, Li et al., 2020, Wang et al., 2020, Fu et al., 2021). Therefore, they are potential candidates for stroke diagnosis. lncRNAs are also involved in the progression of inflammation (Feng et al., 2019, Zhang and Niu, 2020) and apoptosis (Chen et al., 2017, Liu et al., 2019, Zhong et al., 2020). Therefore, the construction of ceRNA network may help to predict the possible molecular mechanism related to the onset of IS. Most studies have used databases to predict miRNA target genes and lncRNAs. Our analysis is based on hub genes to predict their targeted miRNAs, and then construct a ceRNA network of mRNA-miRNA-lncRNA.

In this study, least absolute shrinkage and selection operator (LASSO) regression and support vector machine-recursive feature elimination (SVM-RFE) algorithm were applied to screen essential genes, and their relationship was subsequently analyzed with immune cells. The combined use of two algorithms will make the process more rigorous and standard. Then a ceRNA network of hub genes-miRNA-lncRNA was established. Finally, a logistic regression diagnostic model was built based on hub genes to provide an auxiliary method for the diagnosis of IS. The technical route refers to the following Figure 1.

Materials & Methods

Obtaining and processing profile datasets

We obtained and downloaded the ischemic stroke gene expression profile from Gene Expression Omnibus (GEO, <http://www.ncbi.nlm.nih.gov/geo>) (Table 1). The criteria for screening were that the data in the dataset contained both IS and control groups (CTL), and the number of cases in each group was no less than 20. Patients in IS group were those diagnosed with acute ischemic stroke. In addition, the data were based on whole blood samples with full gene expression profiles. After screening, GSE16561 (Barr et al., 2010) and GSE58264 (Stamova et al., 2014) matched the criteria. GSE16561 was used as a training set. GSE58294 was for the validation of biomarker genes. We applied the Perl language script (<https://www.perl.org/>) to get the gene name corresponding to each probe from the platform annotation file; the names were then converted. In this process, we used the average of all probes' expressions if there were multiple probes corresponding to the same gene name.

Differential Expression Analysis

We applied R package limma (Ritchie et al., 2015) (version 3.6.0) to perform differential expression analysis to identify DEGs between groups in the dataset GSE16561. FoldChange > 1.5 and adjusted P-value < 0.05 were taken as significant criteria. DEGs were represented by heatmap, designed by the pheatmap package (Kolde, 2012) (version 1.0.12), and volcano maps, created by the ggplot2 package (Wickham, 2009) (version 3.3.5).

Function enrichment analysis

We not only annotated the function of the differential expression genes themselves, Gene Ontology (GO) enrichment, but we also studied the pathway by Kyoto Encyclopedia of Genes and Genomes (KEGG) analysis. GO Enrichment and KEGG pathways analysis results were obtained using clusterProfiler (Yu et al., 2012). GSEA software was used to analyze the potential molecular mechanisms and signaling pathways of Hub genes in IS patients. C2 (c2.cp. Kegg. v7.4.symbols. gmt) was selected as the reference gene set for analysis. The R package clusterProfiler also conducted the GSEA analysis of the IS and CTL group, adjusted P-value < 0.05.

Screening for hub genes

Two machine learning methods (LASSO and SVM-REF) were used to identify the hub genes of IS. These two methods were first applied to analyze breast tumors (Wang and Liu, 2015), and later also to neurological diseases such as AD (Liu et al., 2021). LASSO regression is characterized by variable selection and complexity adjustment while fitting a generalized linear model. Thus, whether the target dependent/response variable is continuous, binary or multivariate discrete, it can be modelled and predicted (Friedman et al., 2010). The LASSO analysis was undertaken using the glmnet package (Engelbrechtsen and Bohlin, 2019) with the following parameters: response type set to binomial, alpha set to 1, and 10-fold cross-validation to adjust the optimal value of the parameter λ . SVM has shown many unique advantages in solving small samples, nonlinear and high-dimensional pattern recognition, and can be extended to other machine learning problems such as function fitting. SVM-RFE, on the other hand, is used as a practical feature selection technique to find the best variables by removing the feature vectors generated by SVM (Wang and Liu, 2015). The algorithm was constructed by the e1071 package, and $\text{half.above}=100$ and $k=5$ are used as parameter criteria. The hub genes were the intersecting genes obtained by the two machine learning algorithms.

Evaluation of immune cell infiltration

Analysis of immune cell infiltration relied on CIBERSORT, which is a widespread tool to research the proportion of 22 immune cells in specimens. Furthermore, we analysed the Spearman correlation between immune cells and key genes. The corplot software package (Friendly, 2002) calculated the Pearson correlation coefficient between hub genes and each immune cell.

Construction of the ceRNA Network

Firstly, the miRanda, MicroRNADB, and TargetScan databases were used to simultaneously predict the target miRNAs of hub genes and get the intersection. Obtained miRNA-mRNA interaction pair file. Secondly, the spongeScan database (<http://spongescan.rc.ufl.edu>), was used to predict the lncRNA based on the result file from the previous step. Finally, the ceRNA network was formed, and the feature files were jointly built based on the lncRNA-miRNA-mRNA files. Visualise ceRNA regulatory networks using Cytoscape (Shannon et al., 2003).

Gene- Drug Target Network Analysis

The Drug-Gene Interaction Database (DGIDB, <http://www.dgidb.org/>), an online database that collects data on drug and gene interactions, is the source of material for building the network. The hub gene-drug interaction pair was compared with the DGIDB database to identify immunomodulatory drugs that may be related to ischemic stroke. Gene-Drug Target Network was constructed based on the above information.

Samples collection

Our samples were all obtained from patients attending the Department of Neurology of the Second Affiliated Hospital of Harbin Medical University, approved by the Medical Ethics Committee of the Second Affiliated Hospital of Harbin Medical University (NO.KY2022-285) (Figure S1), and all enrolled individuals signed an informed consent form (Document S2). 5 cases in the disease group and 5 cases in the healthy control group. Disease group (IS group) inclusion criteria: Acute ischemic stroke confirmed by MRI, meeting the diagnostic criteria in the International Classification of Diseases (9th Revision). Exclusion criteria: Patients with a history of haematologic, type 1 diabetes, autoimmune, thyroid, neoplastic, renal or liver diseases were excluded. Fasting venous blood sample of 5ml were collected from both groups. Peripheral blood for the disease group was required to be collected within 24 hours of onset.

Real-Time Quantitative PCR (RT-qPCR)

RT-qPCR was used to detect the expression of six hub genes in whole peripheral blood of clinical samples. Total RNA was isolated from each sample using Trizol reagent according to the manufacturer's instructions. Reverse transcription from RNA to cDNA was performed using HiScript Q RT SuperMix for qPCR (+gDNA wiper) (Vazyme Biotech, Nanjing). RT-qPCR was performed on cDNA samples using ChamQ SYBR Color qPCR Master Mix (2X) (Vazyme Biotech, Nanjing). Results were analyzed by the $2^{-\Delta\Delta Ct}$ method and expressed as fold changes, with GAPDH selected as the internal reference gene. The PCR primers were designed by Majorbio (Majorbio, Shanghai) (Table S3). A *P*-value less than 0.05 was considered statistically significant.

Statistical analysis

The Shapiro-Wilk test was used to assess whether the continuous data were normally distributed in the control and IS groups. Normally distributed data were counted using the independent samples t-test. Non-normally distributed data were evaluated using the Wilcoxon-Mann Whitney test. A *P*-value < 0.05 was considered statistically significant.

Development and Validation of a Diagnostic Model

On the one hand, boxplots were used to show the expression of hub genes in GSE58294 as a validation dataset. We considered the difference statistically significant at a *P*-value < 0.05. On the other hand, a logistic regression algorithm was used to build a diagnostic model for IS classification based on crucial genes. The Proc R package was applied to generate the ROC curve and calculate the area under the ROC curve (AUC) (Stamova et al., 2014) to verify the accuracy of the genes and the model in dataset GSE16561. In addition, we calculated the AUC values of the key genes and logistic regression models in dataset GSE58294 to validate the diagnostic models' classification performance. To avoid the occurrence of overfitting, we chose

to reduce the complexity of the model and reduce the parameters to make the model simpler. When training the model, the dataset was partitioned in a 7:3 ratio for training the model and predicting the accuracy of the created model, respectively, to balance the accuracy. Finally, the visual analysis of the above process was completed using ggplot2.

Results

Differential Expression Analysis

The volcano plot (Fig. 2A) showed that by using R package limma, we obtained 188 differential expression genes (Table S4), of which 85 genes were down-regulated in expression and 103 genes were up-regulated in expression. The top 50 differentially expressed genes are shown in a heatmap (Fig. 2B), created by the pheatmap package.

Function enrichment analysis

The GO analysis results (Table S5) were presented in a barplot (Figure 3A), bubble plot (Figure 3B), and circle plot (Figure 3C). GO-Biological Process (BP) shows that DEGs were primarily involved in immune-related biological processes, including immune response–regulating signaling pathway, positive regulation of cytokine production, and immune response–regulating cell surface receptor signaling pathway; GO- Molecular Function (MF) enrichment results showed DEGs were primarily associated with integrin binding oxidoreductase activity, acting on NAD(P)H quinone or similar compound as acceptor and immunoglobulin binding and GO- Cellular Component (CC) analysis was significantly enriched in platelet alpha granule, secretory granule lumen, etc. KEGG pathways of each module were listed in Figure 4 and Table S6, mainly enriched in MAPK signaling pathway, Cell adhesion molecules, Complement and coagulation, The Cascades, and so on. The GO and KEGG pathway analysis results suggested that the immune system played a crucial role in IS.

We further conducted GSEA analysis to avoid missing the functions of some insignificant but biologically significant genes, biological characteristics, and regulatory networks. GSEA results (Figure 5; Table S7) showed that the pathway involved axon guidance, complement and coagulation cascades, Fc gamma r mediated phagocytosis, focal adhesion, and regulation of actin cytoskeleton in IS group (Figure 5A). Complement and coagulation cascades, the identified pathway of IS, were consistent with the result of KEGG, and the other pathways are related to immunity or cellular metabolism. Genes in the treatment group (IS group) were enriched at the top, which means that this gene set was upregulated. Conversely, genes in the control group (Figure 5B) were enriched at the bottom with a down-regulation trend.

Identification of the hub gene

To explore the biomarkers of IS, we performed feature screening through LASSO regression and the SVM-RFE algorithm. 12 genes were identified as the most associated with IS by LASSO

regression (Fig. 6A). The SVM-RFE algorithm evaluated 34 characteristic genes in IS (Fig. 6B). Both machine algorithms were subjected to 10-fold cross-validation to ensure the accuracy of the results. Then, 6 differential expression genes (ANTXR2, BAZ2B, C5AR1, PDK4, PPIH, and STK3) (Fig. 6C) were identified as the hub genes by these two joint algorithms for subsequent research.

Results of Immune Cell Infiltration Analysis

The immune cell infiltration analysis results (Table S8) were presented by barplot (Figure 7A) and heatmap (Figure 7B). Barplot showed a difference in the percentage of immune cells between IS group and CTL. Compared with the CTL, Monocytes, macrophage M0, Neutrophils, and Mast cells activated infiltration increased, but T cells follicular helper, CD8 T cells infiltration decreased in IS group. The relationship between immune cells and key genes is presented in Figure 8. ANTXR2, BAZ2B, C5AR1, PDK4, and STK3 were positively correlated with neutrophils and negatively correlated with T cells follicular helper and CD8 T cells; but the PPIH gene was positively associated with T cells follicular helper and CD8 T cells and negatively correlated with Mast cells activated and neutrophils; Only PPIH was a down-regulated expression gene, while the other five genes (ANTXR2, BAZ2B, C5AR1, PDK4, and STK3) were all up-regulated expression. Meanwhile, the correlation between individual hub genes and immune cells is shown by a Scatter plot (Figure S9-16). R-value indicates positive and negative correlation. P-value<0.05 is statistically significant. These evidence suggest that changes in the immune microenvironment of IS patients may be related to these 6 Hub genes.

Construction of ceRNA Networks for Hub Genes

Many studies have confirmed that ceRNA regulatory networks play a role in the biology and pathophysiology of various diseases. We also constructed networks (Figure 9; Table S17) to determine whether 6 hub genes have similar regulatory relationships. 6 hub genes were separately entered into the database, yielding a total of 306 miRNA-mRNA interaction pairs, of which there were 117 ANTXR2-miRNA interaction pairs and 87 BAZ2B-miRNA interaction pairs, and 285 miRNA-lncRNA interaction pairs. We hypothesised that ANTXR2 and BAZ2B might be involved in the regulation of ceRNA. According to the value of a degree (Table S18), hsa-miR-766-3p, hsa-miR-149-3p, hsa-miR-1972, hsa-miR-186-5p, hsa-miR-1207-5p, MUC19 and LINC01002 may play a vital role in the ceRNA network.

Establishment of Drug-Hub Genes Regulatory Networks

Drugs related to the 6 essential genes were screened out, and 3 genes, including BAZ2B, C5AR1, and STK3, had target drugs. A gene-drug network is shown in Figure 10 and Table S19. We retrieved a total of 58 drugs acting on the Hub gene. BAZ2B is predicted to have the most targets of drug action, a total of 30.25 drugs targeted STK3. Only one drug targeted C5AR1.

Validation of Hub Genes and Diagnosis Model

The results of RT-qPCR showed that the expression of BAZ2B, C5AR1, PDK4, and STK3 was significantly higher in the ischemic stroke group (Figure 11 and Table S20). A diagnosis model for IS classification was established using a logistic regression algorithm based on the 4 key genes. The results show that the diagnostic model could distinguish patients from normal samples. The ROC curves for the HUB genes and models are shown in Fig 12A and Fig12B. The AUC values are as follows: BAZ2B (AUC=0.892), C5AR1 (AUC=0.966), PDK4 (AUC=0.891), STK3 (AUC=0.966), and Model (AUC=0.999). Finally, we verified the accuracy of hub genes (Figure 12C) and the model (Figure 12D) using another dataset, GSE58294. AUC values for genes and models were as follows: BAZ2B (AUC=0.936), C5AR1 (AUC=0.734), PDK4 (AUC=0.697), STK3 (AUC=0.751), and Model (AUC=0.940). The boxplot (Figure 13) shows the differential expression of hub genes in the CTL and IS groups in the validation dataset. Our established model performs well in distinguishing between IS and normal samples.

Discussion

Ischemic stroke is a disease that threatens people's health worldwide, with high incidence, high disability rate, and high mortality. In addition to the current diagnosis and therapy, it is urgent to develop more convenient diagnosis and treatment programs to help solve this problem. Primary ischemic brain injury is combined by multiple mechanisms, including excitotoxicity, oxidative stress, apoptosis, and inflammation (Moskowitz et al., 2010). After that, a series of immune cascade reactions can further aggravate the damage to the brain tissue, such as the production of proinflammatory cytokines and the activation of destructive serine proteases (Xu et al., 2011, Anrather and Iadecola, 2016). In our research, we explored possible biomarkers of IS, mechanisms of action, and potential drug targets in terms of inflammation and immunity.

In this study, 188 DEGs were observed through R package limma. By applying the joint LASSO and SVM algorithm, we finally obtained 6 genes (ANTXR2, BAZ2B, C5AR1, PDK4, PPIH, and STK3) most associated with IS. But only BAZ2B, C5AR1, PDK4, and STK3 were upregulated expression in ischemic stroke patients as verified by RT-PCR. C5AR1 has been proven to play a crucial role in regulating inflammatory and neurocognitive functions in ischemic stroke, Alzheimer's disease, malaria, and neuropathic pain (Brandolini et al., 2019, McDonald et al., 2015, Moriconi et al., 2014). A markedly increase in C5AR1 expression was observed in the MCAO- and OGD-induced models. Meanwhile, C5AR1 inhibitors have significant neuroprotective effects and remarkably inhibit neuro-inflammation and apoptosis in primary cortical neurons and MCAO-induced stroke models (Shi et al., 2017, Brandolini et al., 2019). TLR4 and C5AR1 promote apoptosis and inflammation by activating of the cAMP/PKA/I- κ B/NF- κ B signaling pathway during brain ischemia-reperfusion (Zaal et al., 2017a, Kim and Jang, 2017, Shi et al., 2021). Some study shows that C5AR1 can inhibit human monocyte-derived dendritic cells, potentially exacerbating inflammatory responses (Zaal et al., 2017a, Zaal et al., 2017b).

However, there are no studies on the correlation between BAZ2B, PDK4, and STK3 genes and ischemic stroke. The biological function of BAZ2B, remains unclear, besides the involvement in nucleosome remodelling (Oppikofer et al., 2017). But it includes at least four functional domains that could encode or bind multiple proteins or DNA to perform various roles. Due to this characteristic, we speculate that BAZ2B may be associated with many diseases, including ischemic stroke. But current studies are limited to suggesting that it is associated with neurodevelopment and that its functional loss and haploinsufficiency is one of the causes of autism and may act through transcriptional regulation (Krupp et al., 2017, Scott et al., 2020). Another study found that BAZ2B activates M2 macrophages to participate in the inflammatory response (Xia et al., 2021), indicating its research value in immunity. PDK4 is a mitochondrial matrix enzyme essential in cellular energy regulation, which regulates the pyruvate dehydrogenase complex in the central nervous system and has important implications for neuron-glia metabolic interactions (Jha et al., 2012). Atherosclerosis is the result of cholesterol and lipid deposition in the arterial wall, usually associated with calcification, and is the most common cause of ischemic stroke. Ma et al found that PDK4 could promote vascular calcification by interfering with autophagic activity and metabolic reprogramming (Ma et al., 2020), contributing to the development of atherosclerosis. STK3 (MST2) is a component of the MAPK module and Hippo signaling pathway. In studies of cardiovascular disease, STK3 was found to mediate mir155 to initiate inflammation and redox stress, leading to vascular smooth muscle cell proliferation and remodeling. It regulates the ERK1/2 signaling pathway by competing with MAP2K of the MAPK pathway, which in turn triggers inflammation and oxidative stress after vascular injury (Thiriet, 2018). And in ischemic stroke, the MAPK pathway also acts by regulating cytokines, inflammation, apoptosis and death (Sun and Nan, 2016, Qin et al., 2022), STK3 is highly expressed in most cell types in the brain and may play a role in stroke by regulating the MAPK pathway. It has also been described as a substrate for CASP6 to intervene in neurodegeneration and apoptosis. (van Raam et al., 2013, Riechers et al., 2016). Cho et al. found that STK3 increases phagocytosis of adipocytes, leading to obesity due to reduced catabolic function of adipocytes. In obese human patients, STK3 expression levels were elevated. STK3 inhibitors improved metabolic patterns in obese mouse models, suggesting that there may be a viable pathway to investigate and develop drugs targeting STK3 to treat obesity-related diseases including stroke (Cho et al., 2021). All of the above suggest that STK3 may be relevant to the onset of ischemic stroke, but the exact mechanism needs to be further investigated.

The critical pathways enriched by GO and KEGG analysis were related to immunity, including the immune response—regulating signaling pathway, immune response—regulating cell surface receptor signaling pathway, and MAPK signaling pathway. Notably, C5AR1 and STK3 were enriched in the positive regulatory pathway of the MAPK cascade. Previous studies have found that MAPK signaling pathway in inflammation and BBB dysfunction MAPK comprises three main effectors: ERK1/2, JNK, and p38 (Sun and Nan, 2016, Qin et al., 2022). C5AR1 affects inflammation in bone by activating the MAPK pathway and regulating gene expression in

pathways associated with insulin and transforming growth factor- β (Modinger et al., 2018). STK3, as described above, mediates cardiovascular injury through the MAPK pathway and also promotes apoptosis by inducing the activation of JNK (Chen et al., 2018). These results are consistent with our bioinformatics analysis and suggest that the MAPK signaling pathway plays an important role in these key gene-mediated biological processes. In addition, the results of the GSEA enrichment analysis showed that C5AR1 was involved in complement, and coagulation cascades pathway which had been proven to correlate with IS (Berkowitz et al., 2021). And the functions of PDK4 are all focused on the involvement of lipid metabolism in the process of atherosclerosis. These results are also in accordance with the role of C5AR1 and PDK4 found in some studies (Berkowitz et al., 2021, Ma et al., 2020).

Many stroke models have confirmed that neutrophils in the acute phase of ischemic stroke are among the earliest immune cells recruited into the brain tissue (Gokhan et al., 2013, Kaito et al., 2013, Jickling et al., 2015). Activated neutrophils may contribute to the development of ischemic stroke by stimulating the systemic inflammatory response and destroying the BBB. Van Duijn et al. found that CD8 T cells can exacerbate the inflammatory response by secreting various inflammatory cytokines, resulting in increased instability of atherosclerotic plaques. But CD8 T cells also have an anti-atherosclerotic effect, which is mediated by stimulation of inhibitory receptor production and cytolytic killing of antigen-presenting cells (van Duijn et al., 2018). The results of immunological infiltration analysis by CIBERSORT revealed that Monocytes, macrophage M0, Neutrophils, and Mast cells activated were increased, while T cells follicular helper and CD8 decreased infiltration in IS group, which was consistent with the previous studies (Zheng et al., 2022). Our research also showed that neutrophils were significantly and positively correlated with gene ANTXR2, BAZ2B, C5AR1, PDK4, and STK3, negatively correlated with PPIH; CD8 was significantly and negatively correlated with gene ANTXR2, BAZ2B, C5AR1, PDK4, and STK3, positively correlated with PPIH. This evidence further suggests that neutrophils play a significant role, and hub genes are involved in regulating the immune microenvironment in IS patients.

The ceRNA network we conducted included nodes (6 mRNAs, 249 miRNAs, 218 lncRNAs) with 591 edges. In these nodes, the miRNAs with high degrees, hsa-miR-766-3p, hsa-miR-149-3p, and hsa-miR-186-5p, have been reported as essential molecules in cerebral ischemic/reperfusion injury (Cai et al., 2019, Hu et al., 2020, You et al., 2022). But the mode of regulation between them and hub genes still needs further validation. Meanwhile, we constructed a Hub gene-based Gene-Drug regulatory network and predicted possible targeted drugs. The result reflected that BAZ2B had the most targets of drug action and the likely reason was that it had multiple functional areas. The network provides a theoretical basis for developing targeted immunotherapies for IS.

Finally, based on the four key genes mentioned above, we constructed an IS diagnostic model using logistic regression methods. We also verified the validity of the model in a publicly

available dataset. Bioinformatics analysis combined with machine learning methods achieved good results.

However, there are some limitations to our study. First, although we analyzed clinical data and performed RT-qPCR validation, the sample size was relatively limited. Second, more in vivo and in vitro studies are needed to identify and validate the underlying mechanisms between these genes and stroke. These will be the most critical aspects of our future research. We hope to complete it in further studies to gain insight into the immunological pathogenesis of ischemic stroke and to provide additional options for clinical treatment.

Conclusions

We explored 6 hub genes (ANTXR2, BAZ2B, C5AR1, PDK4, PPIH, and STK3) for ischemic stroke and revealed the immune cell infiltration pattern via bioinformatics analysis and machine learning algorithm. Secondly, we successfully constructed the ceRNA and Drug-Gene networks, which provide new ideas to explore the possible molecular mechanisms and develop targeted drugs of IS. Finally, BAZ2B, C5AR1, PDK4, and STK3 were verified to be the biological markers of ischemic stroke. Based on the 4 genes, we developed a diagnostic model and validated its effectiveness, providing additional tools for screening and diagnosing of ischemic stroke.

Figure 1

The technical route

Abbreviations: IS, ischemic stroke; CTL, Healthy Control

Figure 2

Differential Expression Analysis

(A) The differential expression analysis results are shown in the volcano plot. The x-axis represents \log_2 (fold change), and the y-axis represents $-\log_{10}$ (adjusted p. value). Green dots represent downregulated genes, red dots represent upregulated genes, and black dots represent genes with no evident differential expression. (B) Heatmap of DEGs. Each column in the graph represents a sample, each row represents a gene, and the expression status of the gene is indicated from high to low in orange to blue, respectively, and at the top of the heatmap, red/blue represents the IS group/control group, respectively. Abbreviations: IS (ischemic stroke), Control (Healthy Control), DEGs (differential expression genes)

Figure 3

Show the top 10 significantly enriched BP (biological process), CC (cellular component) considerably, and MF (molecular function) in the barplot and the bubble plot.

(A) In the barplot, the bar size represents the number of genes, and the colour shades represent the P-value. (B) In the bubble plot, the x-axis represents the gene ratio, the y-axis represents the $-\log_{10}$ (FDR) value, the bubble size represents the number of genes, and the colour shades represent the size of the P-value. (C) The Gene Ontology (GO) enrichment analysis results of DEGs are shown as circle plots. First circle: enriched classification, outside the process, is the sitting scale for the number of genes. Different colours represent different classifications; Second circle: the number of genes in the category in the background and the Q or P value. The more genes the longer the bar and the smaller the value the redder the colour; Third circle: the total number of foreground genes; Fourth circle: RichFactor value for each classification (the number of foreground genes divided by the number of background genes in that classification), with each cell of the auxiliary background line indicating 0.1.

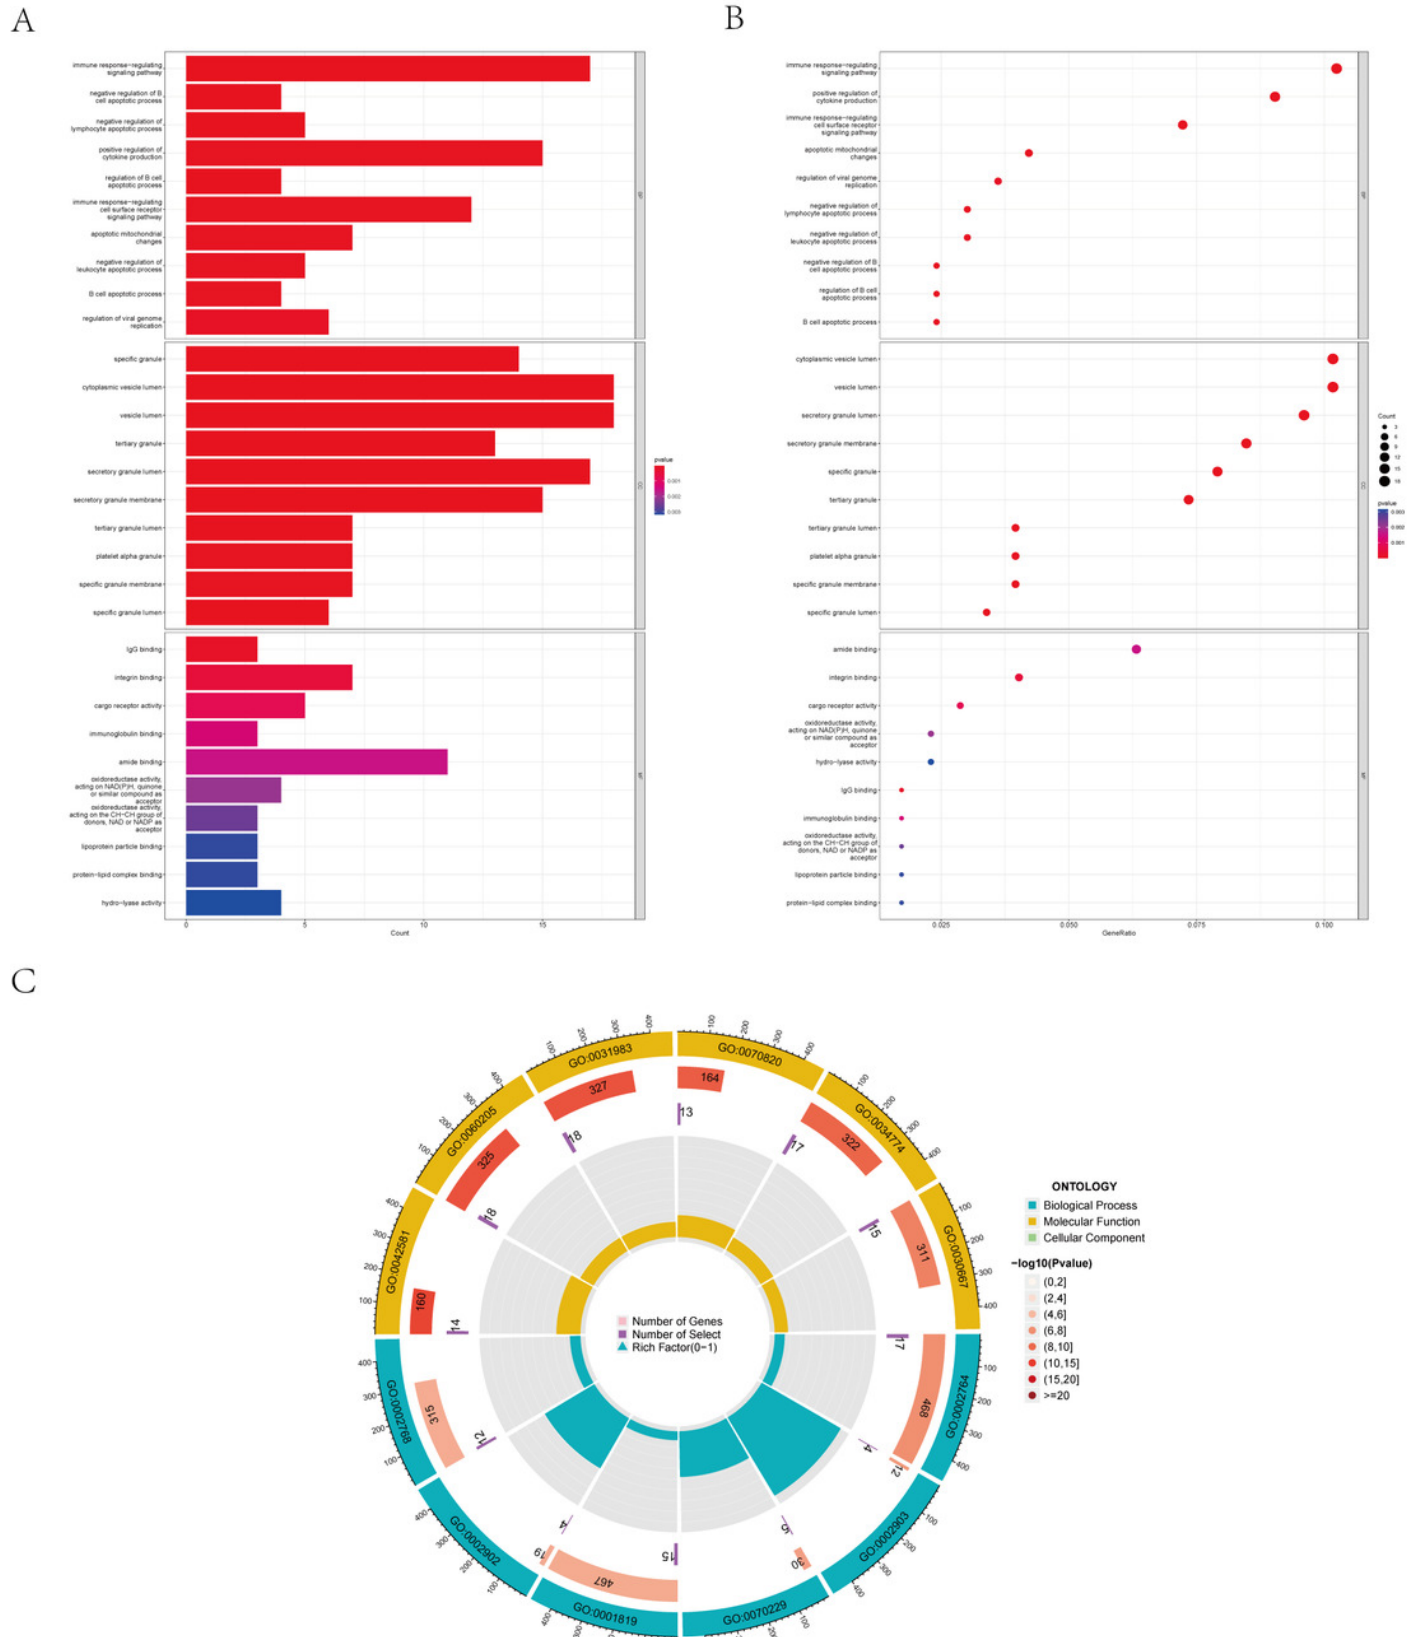

Figure 4

The KEGG pathway analysis results of DEGs are shown as the barplot and the bubble plot.

(A) In the barplot, the bar size represents the number of genes, and the colour shades represent the P-value. (B) In the bubble plot, the x-axis represents the gene ratio, the y-axis represents the $-\log_{10}$ (FDR) value, the bubble size represents the number of genes, and the colour shades represent the size of the P-value.

Figure 5

Gene Set Enrichment Analysis of IS and CTL group in the GSE dataset.

The different colours represent the different pathways obtained by enrichment. The figure has three parts. Part I: The top part is a line graph of the Gene Enrichment Score. The vertical axis is the corresponding Running ES. There is a peak at the top or bottom of the line. The core genes are those before the peak for the treatment group with a positive Enrichment score, while for the CTL group with a negative Enrichment score, the core genes are those after the peak. The horizontal axis represents each gene under this gene set and corresponds to the barcode-like vertical line in the second part. The second part: Hits, each vertical line corresponds to a gene under this gene set. The third part: is the distribution of rank values for all genes, and the vertical coordinate is the ranked list metric, which is the value of the rated amount of that gene. (A) the GSEA results of IS group. (B) the GSEA results of the CTL group.

Figure 6

Immune infiltration landscape between IS and Control obtained by CIBERSORT analysis.

(A) The bar-plot diagram indicates the relative percentage of different types of immune cells between IS and CTL. (B) The heatmap shows the correlation in the infiltration of innate immune cells. (C) Violin plot showing the difference in immune cell infiltration between IS (red) and Control (purple), $P < 0.05$, was considered statistically significant.

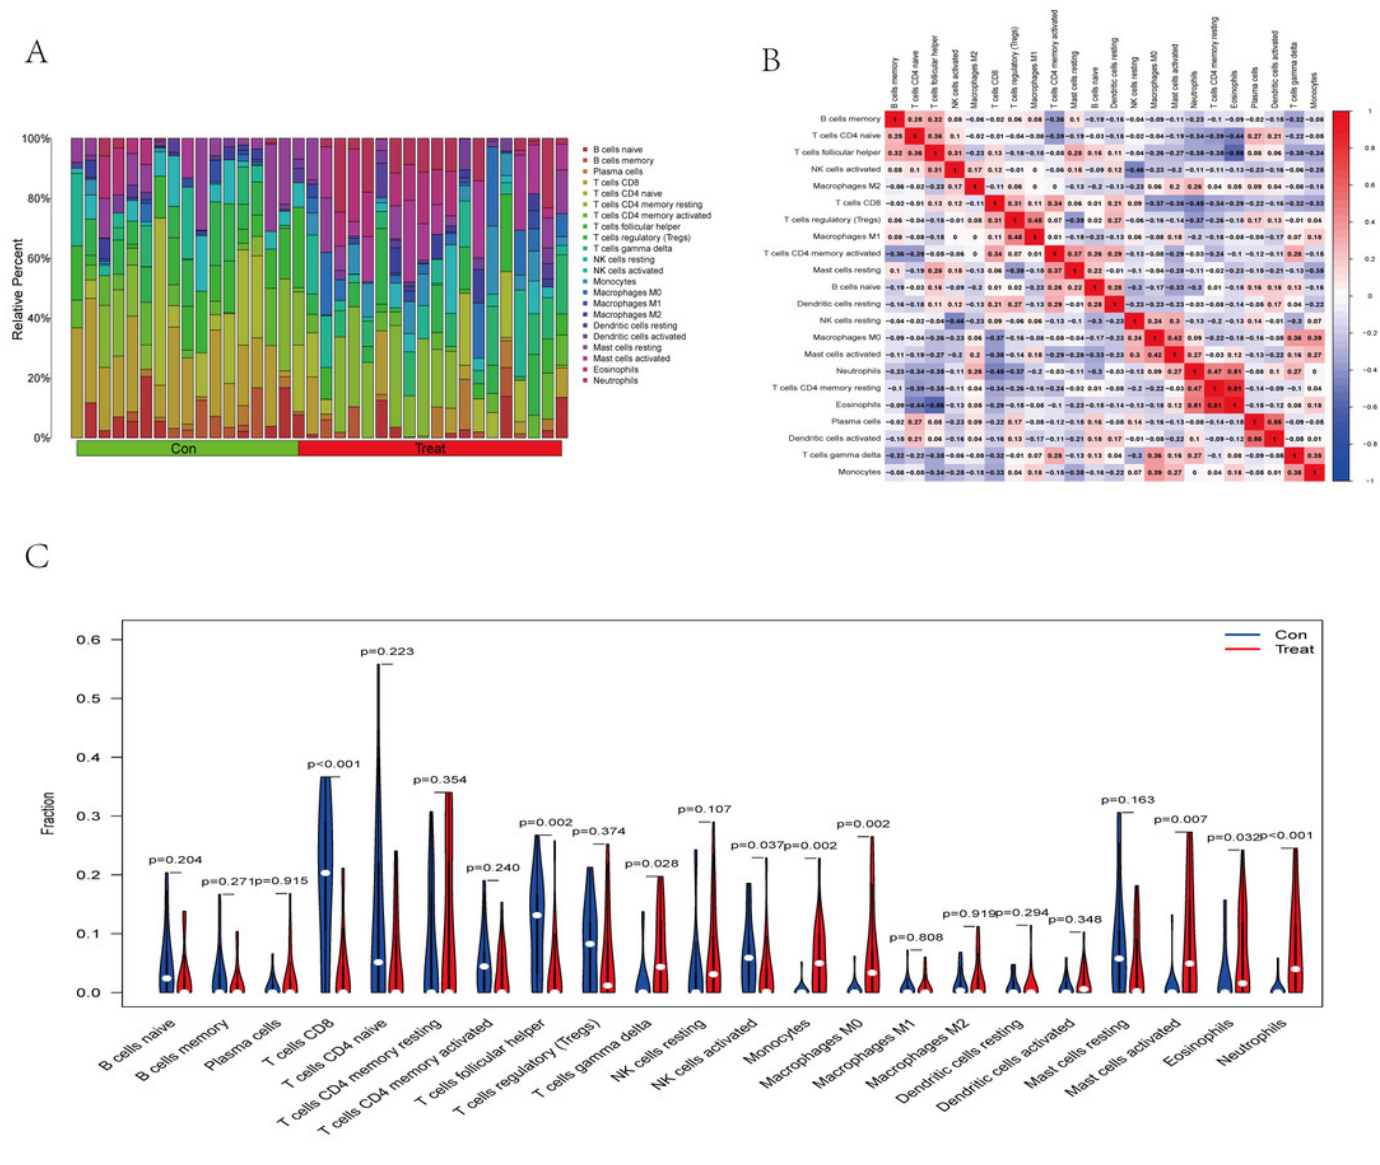

Figure 7

The identification of 6 Hub genes.

(A) The LASSO logistic regression algorithm identified 12 IS-related features with a 10-fold cross-validation set for selecting the penalty parameter to determine the optimal lambda value. (B) A total of 34 feature genes were filtered out using the SVM-RFE algorithm. (C) Venn diagram of genes extracted from LASSO and SVM-RFE methods. Abbreviations: LASSO (least absolute shrinkage and selection operator), SVM (support vector machine), RFE (recursive feature elimination).

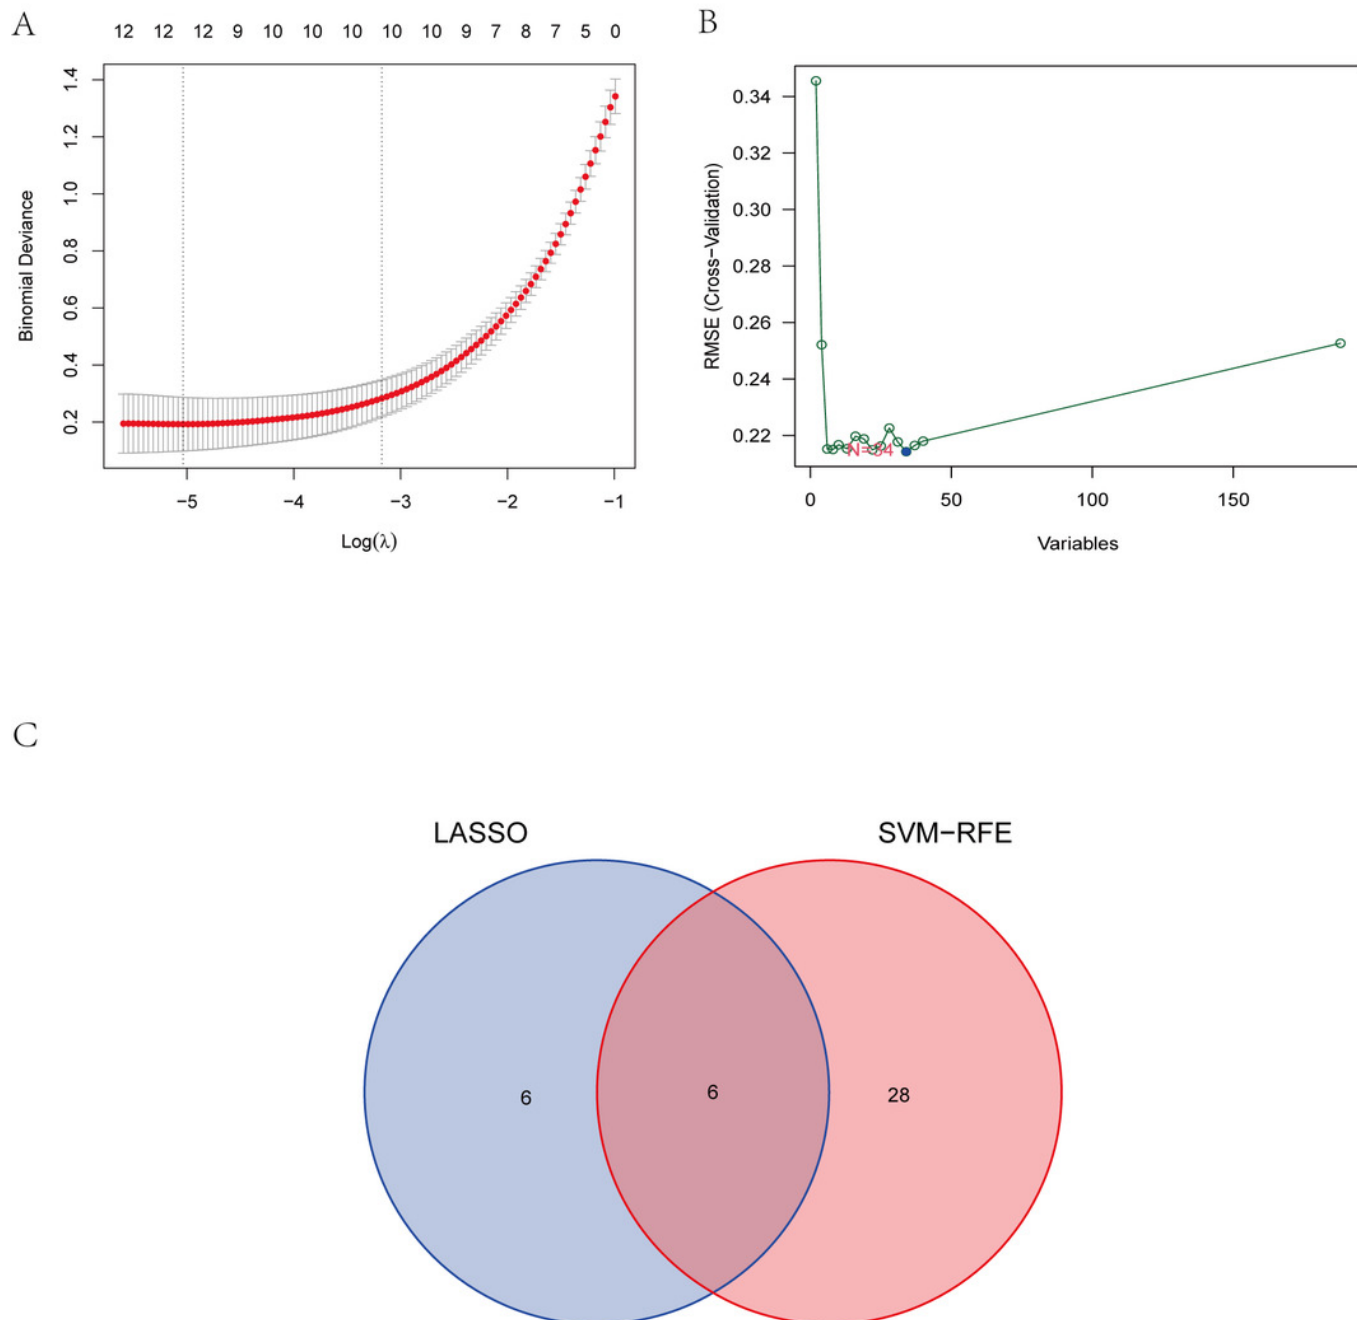

Figure 8

Lollipop charts show the correlations between hub genes and the infiltration level.

Figure 9

A ceRNA network based on Hub genes.

The network includes nodes (6 mRNAs, 249 miRNAs, 218 lncRNAs) with 591 edges. Red orbs represent Hub genes, green orbs represent miRNAs, and purple orbs represent lncRNAs.

Figure 10

Prediction of marker gene-targeted drugs.

Red orbs represent up-regulated mRNA and purple orbs represent drugs.

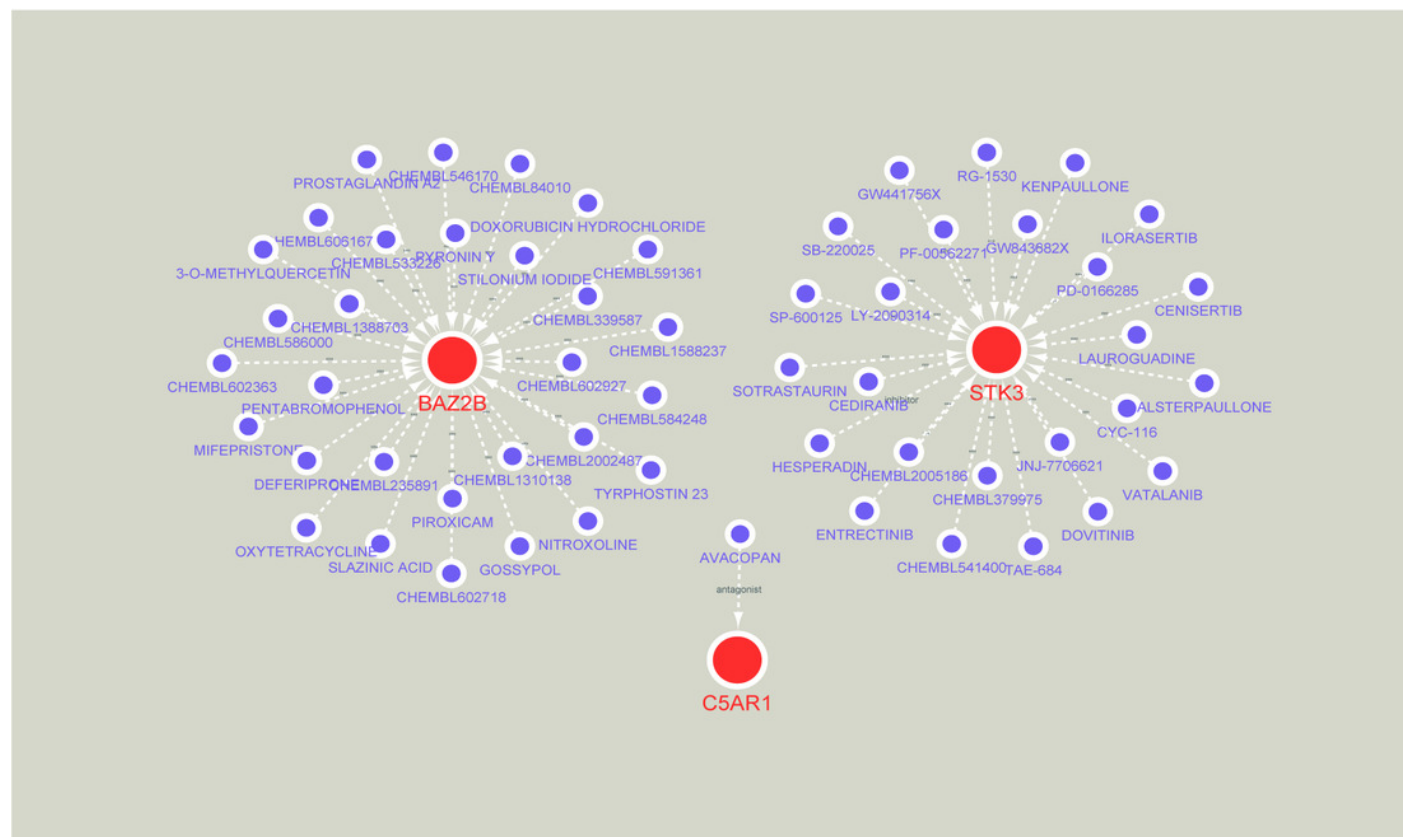

Figure 11

Prediction of marker gene-targeted drugs.

The relative expression levels of (A) ANTXR2 $P=0.2233$ (B) BAZ2B , $P=0.0034$ (C) C5AR1, $P=0.0018$ (D) PDK4, $P=0.0026$ (E) PPIH, $P=0.9792$ (F) STK3, $P=0.0226$ in IS and CTL. # $P>0.05$, $P<0.05$ $P\geq 0.01$, ** $P<0.01$*
