Preen oil – the secretion from the uropygial gland of birds – may have a specific function in incubation. Consistent with this, during incubation, the chemical composition of preen oil is more likely to differ between sexes in species where only one sex incubates than in species where both sexes incubate. In this study, we tested the generality of this apparent difference, by investigating sex differences in the preen oil composition of a shorebird species, the Kentish plover (*Anarhynchus*, formerly *Charadrius alexandrinus*). As both sexes incubate in this species, we predicted the absence of sex differences in preen oil composition during incubation. In the field, we sampled preen oil from 9 females and 11 males during incubation, which we analysed with gas chromatography–mass spectrometry (GC–MS). Consistent with predictions, we found no sex difference in preen oil composition, neither in beta diversity (Bray-Curtis dissimilarities) nor in alpha diversity (Shannon index and number of substances). In Kentish plovers, the preen oil secreted during incubation may serve olfactory crypsis and protection against ectoparasites, as both functions received empirical evidence from studies on other shorebird species. Preen oil may also be involved in olfactory signalling (e.g. for mate choice, parent-offspring communication), but this possibility remains to be investigated.

## 20 Abstract

21 Preen oil – the secretion from the uropygial gland of birds – may have a specific function in  
22 incubation. Consistent with this, during incubation, the chemical composition of preen oil is  
23 more likely to differ between sexes in species where only one sex incubates than in species  
24 where both sexes incubate. In this study, we tested the generality of this apparent difference, by  
25 investigating sex differences in the preen oil composition of a shorebird species, the Kentish  
26 plover (*Anarhynchus*, formerly *Charadrius alexandrinus*). As both sexes incubate in this  
27 species, we predicted the absence of sex differences in preen oil composition during incubation.  
28 In the field, we sampled preen oil from 9 females and 11 males during incubation, which we  
29 analysed with gas chromatography–mass spectrometry (GC–MS). Consistent with predictions,  
30 we found no sex difference in preen oil composition, neither in beta diversity (Bray-Curtis  
31 dissimilarities) nor in alpha diversity (Shannon index and number of substances). In Kentish  
32 plovers, the preen oil secreted during incubation may serve olfactory crypsis and protection  
33 against ectoparasites, as both functions received empirical evidence from studies on other  
34 shorebird species. Preen oil may also be involved in olfactory signalling (e.g. for mate choice,  
35 parent-offspring communication), but this possibility remains to be investigated.

40

## 41 Introduction

42 Most birds possess a sebaceous gland at the base of the tail – the uropygial gland (or preen  
43 gland) – that produces an oily secretion (preen oil) (Jacob and Ziswiler 1982). Birds spread preen  
44 oil over their plumage during preening (Moreno-Rueda 2017). The chemical composition of  
45 preen oil typically consists of wax esters and other substances, such as alcohols, aldehydes,  
46 alkanes, carboxylic acids and ketones (reviewed in Campagna *et al.* 2012, Alves Soares *et al.*  
47 *accepted*). Preen oil is multifunctional, serving plumage maintenance, protection against  
48 ectoparasites (e.g. feather degrading bacteria, eggshell bacteria, chewing lice) and waterproofing  
49 (reviewed in Moreno-Rueda 2017). Preen oil is also an important source of body odour in birds  
50 (Hagelin and Jones 2007) and may have odour-related functions, namely olfactory crypsis and  
51 olfactory communication (reviewed in Grieves *et al.* 2022).

52         The first step to investigate the potential function(s) of preen oil is to describe the  
53 variation in its chemical composition, notably seasonal changes and sex differences (Grieves *et*  
54 *al.* 2022). In many species, preen oil composition changes during breeding, specifically at the  
55 time of incubation and specifically in the incubating sex (Reneerkens *et al.* 2007), strongly  
56 suggesting that preen oil has a function associated to incubation. First, a function of preen oil  
57 during incubation could be protection against ectoparasites, in case incubating birds are exposed  
58 to high parasitic loads in the nest or to limit pathogenic infection of the eggs. This was shown in  
59 Eurasian hoopoes (*Upupa epops*) where only females (incubating sex) produce a dark preen oil  
60 that contains antibacterial substances during incubation, and that is smeared on the eggs to  
61 protect embryos from eggshell bacteria (Martín-Vivaldi *et al.* 2009, 2010). Second, a function of  
62 preen oil during incubation could be olfactory crypsis, in case the incubating birds (and their  
63 clutch or brood) are exposed to olfactorily searching nest predators (Reneerkens 2005). This is  
64 the case in shorebirds (order Charadriiformes), where preen oil composition shifts from

65 monoesters (more volatile) to diesters (less volatile) during incubation (seasonal change in preen  
66 oil; documented in 19 sandpiper, 6 plover and 1 oystercatcher species; Reneerkens *et al.* 2006),  
67 solely in the incubating sex (sex-specific seasonal change in preen oil; documented in 7  
68 sandpiper species; Reneerkens *et al.* 2007). The diester preen oil secreted during incubation is  
69 less volatile than the monoester preen oil, which makes the incubating birds (or their clutch or  
70 brood) less detectable to olfactorily searching nest predators (e.g. dog, Reneerkens 2005).  
71 Finally, a function of preen oil during incubation could be olfactory intraspecific signalling (e.g.  
72 for mate choice, “sex semiochemical hypothesis”, Grieves *et al.* 2022). For example, in three  
73 passerine species (order Passeriformes), preen oil composition differs between sexes during  
74 breeding (Whittaker *et al.* 2010, Amo *et al.* 2012, Grieves *et al.* 2019a), which allows birds to  
75 discriminate the sex of conspecifics by smell (Whittaker *et al.* 2011, Amo *et al.* 2012, Grieves *et*  
76 *al.* 2019b).

77         Although several shorebird species (order Charadriiformes) have been studied with  
78 regard to sex differences in preen oil (14 species), they were all studied using a fairly  
79 straightforward analytical method (Reneerkens *et al.* 2002, 2007). This method consists in  
80 describing preen oil composition using a single categorical variable (i.e. ester composition) with  
81 three categories (i.e. monoesters only, mixture of monoesters and diesters, diesters only).  
82 Reducing the complexity of preen oil composition (usually hundreds of substances) to a single  
83 categorical variable is simple but effective. Indeed, this method revealed striking sex differences  
84 in preen oil during incubation in uniparentally incubating species (diesters in the incubating sex,  
85 monoesters in the non-incubating sex), but not in biparentally incubating species (diesters in both  
86 sexes). However, subtle sex differences in biparentally incubating species may have been missed

87 using this categorisation, and may be uncovered using more advanced methods (e.g. multivariate  
88 analyses).

89         In this study, we sampled preen oil from female and male Kentish plovers (*Anarhynchus*  
90 *alexandrinus*, formerly *Charadrius alexandrinus*) during incubation, analysed their chemical  
91 composition using GC–MS, and tested for sex differences in alpha and beta diversity using  
92 multivariate statistical analyses. Given that both sexes incubate in this species (Kosztolányi and  
93 Székely 2002), and assuming that this species undergoes the same sex-specific seasonal changes  
94 in preen oil composition as the other shorebird species studied (Reneerkens et al. 2002, 2006,  
95 2007), we predicted an absence of sex differences in preen oil composition during incubation.  
96 Alternatively, sex differences in preen oil composition can be expected in case of sexual  
97 selection or other sex-dependent reason. It should be emphasized that, since we sampled preen  
98 oil only during the incubation period, our aim was not to investigate sex-specific seasonal  
99 changes and replicate studies from Reneerkens *et al.* (2002, 2007). Rather, we used their findings  
100 to make predictions on whether we should find sex differences during incubation in Kentish  
101 plovers.

102

## 103 **Methods**

### 104 *Study site and species*

105 Fieldwork was conducted on breeding Kentish Plovers at the Samouco saltpans complex  
106 (38°44'N, 8°59'W) on the south bank of the Tagus estuary, Portugal. In the study site, Kentish  
107 Plovers breed on dykes of abandoned saltpans, nesting in the ground sparsely covered by  
108 pebbles, wooden planks and salt marsh vegetation, isolated or in proximity to nests of black-

109 winged stilts *Himantopus himantopus* and little terns *Sternula albifrons* (Rocha et al. 2016). The  
110 population (20-76 breeding pairs) is resident and presents an extended breeding season, from  
111 early March, when males start to defend nesting sites, to the end of July. During the breeding  
112 season, mates generally re-nest with a different mate (sequential polygamy), but monogamy is  
113 also observed. Both parents incubate the eggs for a period of 25-26 days (Kosztolányi and  
114 Székely 2002).

#### 115 *Field methods*

116 As part of a colour-ringing marking program, from May to June 2019, Kentish Plovers were  
117 caught on their nests using walk-in funnel traps (Székely et al. 2008). The birds were sexed using  
118 plumage characteristics, measured and ringed (Székely et al. 2008). We collected preen oil from  
119 20 birds (9 females and 11 males) by gently massaging the preen gland papilla with a 100 µl  
120 microcapillary and snapping the end of the microcapillary (containing the extracted preen oil) in  
121 a 2 ml glass vial with Teflon seal (Rotilabo ®) while wearing nitrile gloves. For some breeding  
122 pairs, both partners of a breeding pair could be sampled ( $N = 8$  samples from 4 pairs), but for  
123 most pairs only a single bird was sampled ( $N = 12$  samples). Samples were stored at  $-20\text{ °C}$   
124 during seven months, before being transferred at  $-80\text{ °C}$  for seven months until analysis. Bird  
125 capture and sampling were carried out in accordance with the Portuguese Institute of Nature  
126 Conservation and Forestry (ICNF) guidelines (license N°1/2019) and no additional institutional  
127 animal care approval was required. To ensure the well-being of the birds, we took all necessary  
128 measures to minimize any stress caused by capture and handling. After capture, birds were  
129 placed inside a dark cotton bag before being ringed, measured and sampled. This procedure took  
130 less than ten minutes per bird. Birds were released immediately after sampling, they showed no

131 sign of discomfort or stress (e.g. increased respiratory rate, open mouth breathing, or closed  
132 eyes) and returned to incubate at their nest a few minutes after release.

### 133 *Chemical analysis*

134 All samples were first defrosted and then extracted by adding 500 µl of dichloromethane as a  
135 solvent to the vials containing the microcapillary and the preen oil. After briefly vortexing each  
136 sample, we transferred 100 µl of the solution (preen oil and dichloromethane) into a glass vial (2  
137 ml, Rotilabo ®) containing a 100 µl glass inset, using a blunt point glass syringe (which was  
138 washed with dichloromethane between each sample). For chemical analyses, we performed GC-  
139 MS, using a gas-chromatograph (GC-2030, Shimadzu, Kyoto, Japan) equipped with a VF-5ms  
140 capillary column (30 m x 0.25 mm ID, DF 0.25, 10 m guard column, Varian Inc., Lake Forest,  
141 USA) and helium (at a 1 ml/min flow rate) as a carrier gas, coupled to a mass spectrometer  
142 (GCMS-QP2020NX, Shimadzu) in split (1/10) mode. The settings for the gas chromatography  
143 were as follows; injection temperature: 310 °C, starting temperature: 150 °C, followed by an  
144 increase in temperature of 20 °C per min until reaching 280 °C, followed an increase of 5 °C per  
145 minute until reaching the end temperature of 310 °C, which was kept for 20 min. For the mass  
146 spectrometry, ion source temperature was set at 230 °C and interface temperature at 310 °C.  
147 Seven GC blank samples (containing dichloromethane only) were analysed among the preen oil  
148 samples.

### 149 *Chromatographic data processing*

150 GC-MS produces chromatograms, where each peak is a substance (defined by its retention time)  
151 and the area of the peak represents the abundance of the substance (see Fig. 1 for a typical  
152 chromatogram of Kentish Plover preen oil). We assumed that each peak represents a single

153 substance, but we acknowledge that a single peak can represent multiple substances that coelute  
154 (i.e. with the exact same retention time). We extracted peak retention times and areas from  
155 chromatograms using LabSolutions GCMS solution v4.52 (Shimadzu). Because the retention  
156 time of a substance can vary subtly between samples, we aligned the chromatograms using the  
157 *GCalignR* package (Ottensmann et al. 2018). We used the 20 preen oil samples and the seven  
158 GC blank samples for the alignment. Substances detected in GC blank samples, as well as  
159 substances detected in single samples, were removed to control for potential contamination. We  
160 verified the quality of the alignment with a shadeplot (Fig. S1) in PRIMER v7.0.20 (Clarke and  
161 Gorley 2015). Because the amount of preen oil collected was not standardized, we used relative  
162 abundances (i.e. peak area divided by total chromatogram area) for the analysis. As we have no  
163 prior knowledge about the substances potentially involved in sex differences, we log-transformed  
164 ( $\log(X+1)$ ) the relative abundances, thereby increasing the weight of low-abundance substances  
165 in the analysis (Clarke et al. 2014). We calculated the chemical diversity (Shannon index) and  
166 richness (number of substances) of each sample, as measures of alpha diversity, using the *vegan*  
167 package (Oksanen et al. 2019). If the detectability of substances was positively correlated to their  
168 retention time, there could be a methodological issue (e.g. more volatile substances evaporating  
169 or breaking more than less volatile substances). We verified that this was not the case, as the  
170 effect of the retention time on the detectability of substances was not positive linear (polynomial  
171 beta regression:  $\beta = 0.54$ ,  $P = 0.48$ ), but negative quadratic (polynomial beta regression:  $\beta = -$   
172  $5.57$ ,  $P < 0.001$ ). This shows that both more volatile and less volatile substances were less  
173 detected than substances with intermediate retention time (Fig. S2). All the chromatographic data  
174 processing was conducted in R v4.2.2 (R Core Team 2022) and is detailed in an R Markdown  
175 document (Baumer and Udwin 2015) in the Supplemental Information.

176 An accurate identification of the substances would have required sophisticated analytical  
177 methods, including calculating retention indices, comparing substances with commercially  
178 available standards and using two columns of different polarity (e.g. Alves Soares *et al.* 2024).  
179 For structural identification of esters, other methods could be conducted, such as combined GC  
180 and GC-MS using synthesized standards (Sinninghe Damsté *et al.* 2000, Rijnstra *et al.* 2007). As  
181 we were interested in quantitative, rather than qualitative, chemical differences, we did not need  
182 to identify the substances and used retention times instead. We putatively identified the chemical  
183 substances by comparing their mass spectrometry (MS) to that of the NIST library  
184 (NIST/EPA/NIH Mass Spectral Library 2017) and recording the substance name with the highest  
185 match, but this method is not accurate enough to identify substances with certainty. For this  
186 reason, we do not provide the list of putative (and likely erroneous) substance names. However,  
187 we recorded the class of the substances, in case the class of the putatively identified substances  
188 was the same across all samples (see Table S1 for the list of substances, including retention  
189 times, mean relative abundances and classes). The raw chromatographic data are available at the  
190 repository PUB – Publications at Bielefeld University (link and DOI to be added upon  
191 acceptance).

### 192 *Statistical analysis*

193 We tested for sex differences in preen oil composition using 20 samples (9 females, 11 males).  
194 First, to test for sex differences in the overall chemical composition (i.e. beta diversity), we  
195 performed a permutational multivariate analysis of variance (PERMANOVA) on Bray-Curtis  
196 dissimilarities using the *adonis2* function from the *vegan* package (Oksanen *et al.* 2019). Bray-  
197 Curtis dissimilarity is pertinent for the analysis of abundance data, notably because it ignores  
198 joint absences (Clarke *et al.* 2014). PERMANOVA was run with 9,999 permutations and

199 sequential effects (type I sums of squares). As fixed effects, we included *sex*, but also *number of*  
 200 *days after laying* to test for a potential seasonal effect as preen oil composition can change over  
 201 short periods (less than a week, Grieves *et al.* 2022), and the interaction between *sex* and *number*  
 202 *of days after laying*, as seasonal changes may differ between sexes (Grieves *et al.* 2022). Some of  
 203 our samples were collected from breeding partners (N = 8 “paired” samples from 4 breeding  
 204 pairs), and preen oil can be more similar within than between breeding pairs (Gilles *et al.* 2024).  
 205 However, using blocking permutations within breeding pairs is not appropriate to deal with the  
 206 possible pseudoreplication in this dataset, because in 12 cases there is only one data point from a  
 207 pair (i.e. only one possible choice within a pair); therefore we applied an alternative approach.  
 208 First, we randomly excluded four of the “paired” samples so that we included only independent  
 209 samples (N = 16 samples, only one sample from a breeding pair). The four excluded samples  
 210 always included two females and two males so that the ratio between the sexes was not distorted  
 211 (seven females and nine males). Second, we ran iterated PERMANOVAs (1,000 iterations) on  
 212 the 16 samples randomly selected before each run. We report the median (and interquartile  
 213 range) of the SS,  $R^2$  and  $F$  values from the iterated PERMANOVA runs.  $P$  values were  
 214 calculated as  $P = \frac{\sum_{i=1}^{N_{iterations}} (1 + \sum_{j=1}^{N_{perm}} I(F_j \geq F_{obs_i}))}{N_{iterations} \times (1 + N_{perm})}$  where  $N_{iterations}$  is the number of iterations of  
 215 PERMANOVAs,  $N_{perm}$  is the number of permutations per PERMANOVA,  $F_j$  is the  $F$ -statistic  
 216 for the  $j^{\text{th}}$  permutation,  $F_{obs_i}$  is the observed  $F$ -statistic in the  $i^{\text{th}}$  iteration, and  $I(\text{condition})$  is an  
 217 indicator function that equals 1 if the condition is true and 0 otherwise. We also tested for a sex  
 218 difference in dispersion (or variance) using the *betadisper* function from the *vegan* package  
 219 (Oksanen *et al.* 2019). We used non-metric multidimensional scaling (NMDS) plots for  
 220 visualization of differences in Bray-Curtis dissimilarity (beta diversity).

221           Second, to test for sex differences in chemical diversity (Shannon index) and richness  
222 (number of substances) (i.e. alpha diversity), we performed linear models (LMM) using the *lmer*  
223 function in the *lme4* package (Bates 2010). For both models, *sex* and *number of days after laying*  
224 were included as fixed effects, and *pair ID* as random effect. Using *pair ID* as a random effect,  
225 we controlled for the potential increased similarity within breeding pairs, and thus we could  
226 include all 20 samples (nine females and eleven males). We assessed the significance of fixed  
227 effects ( $\alpha = 0.05$ ) by checking whether their 95% confidence interval (95% CI) contained zero,  
228 using the *broom.mixed* package (Bolker et al. 2022). Assumptions of normality and  
229 homoscedasticity of the residuals were verified using the *performance* package (Lüdecke et al.  
230 2021). All plots were created with *ggplot2* (Wickham 2016), all analyses were performed in R  
231 v4.2.2 (R Core Team 2022). Data and code are available in the Supplemental Information and at  
232 the repository PUB – Publications at Bielefeld University (link and DOI to be added upon  
233 acceptance).

234

## 235 **Results**

236   We detected a total of 95 chemical substances in the preen oil of Kentish plovers, with on  
237 average 63 substances (SD = 9) per sample (on average 62 substances in females and 63  
238 substances in males). These numbers should be treated as minima, as they are based on the  
239 assumption that one peak represents one substance, but it is possible that one peak represents  
240 multiple substances (in case of coeluting substances). Most putative substances appeared to be  
241 monoesters, while no diester was detected (Table S1). About one third of the substances (32%,  $N$   
242 = 35 substances) were detected in all 20 samples, and no substance was sex-specific (i.e. detected  
243 in females only or males only).

244 We found no sex difference in preen oil composition (beta diversity) based on Bray-  
245 Curtis dissimilarities (PERMANOVA:  $P = 0.35$ ,  $R^2 = 0.11$ ). The absence of a sex difference can  
246 be seen on the NMDS plot (Fig. 2a) where the 95% confidence intervals for each sex overlap  
247 entirely. The preen oil composition of females and males also did not differ in dispersion ( $P =$   
248  $0.39$ ). In addition, no sex difference was detected in alpha diversity, neither in chemical diversity  
249 (LMM:  $\beta$  [95% CI] =  $0.09$  [ $-0.15$ ;  $0.36$ ], Fig. 2b) nor richness (LMM:  $\beta$  [95% CI] =  $5.88$  [ $-12.7$ ;  
250  $26.4$ ], Fig. 2c). Preen oil composition did not change over the course of incubation (from 1 day  
251 until 33 days after laying), neither in Bray-Curtis dissimilarities (PERMANOVA:  $P = 0.48$ ,  $R^2 =$   
252  $0.11$ ), diversity (LMM:  $\beta$  [95% CI] =  $0.00$  [ $-0.01$ ;  $0.01$ ]), nor richness (LMM:  $\beta$  [95% CI] =  $0.02$   
253 [ $-0.81$ ;  $0.86$ ]). Finally, we detected no effect of the interaction between sex and the number of  
254 days after laying, neither in Bray-Curtis dissimilarities (PERMANOVA:  $P = 0.34$ ,  $R^2 = 0.06$ ),  
255 diversity (LMM:  $\beta$  [95% CI] =  $0.00$  [ $-0.02$ ;  $0.01$ ]), nor richness (LMM:  $\beta$  [95% CI] =  $-0.32$  [ $-$   
256  $1.73$ ;  $0.93$ ]). Detailed results are available in the supplemental information (Tables S2–3).

257

## 258 Discussion

259 As predicted, we found no sex difference in the preen oil of Kentish plovers during incubation,  
260 neither in beta diversity nor in alpha diversity. This is consistent with previous findings that, in  
261 shorebirds with biparental incubation, both sexes secrete a similar preen oil during incubation  
262 (Reneerkens et al. 2007, Grieves et al. 2022). Using more advanced statistics than the classical  
263 studies on the chemistry of the preen oil of shorebirds (Reneerkens et al. 2002, 2006, 2007), we  
264 did not uncover subtle sex differences.

265 Our finding that both sexes secrete a similar preen oil during incubation may indicate a  
266 specific function of preen oil in incubation, but only if preen oil composition changes  
267 specifically during this period, as in other shorebird species (Reneerkens et al. 2002, 2006,  
268 2007). Because we sampled preen oil only during the incubation period, we could not test for  
269 such seasonal changes. We assumed that Kentish plover preen oil would follow the general  
270 pattern identified by Reneerkens *et al.* (2002) in other shorebirds, that is a switch from  
271 monoesters to diesters at the onset of incubation followed by a switch back to monoesters after  
272 incubation. It seems however that Kentish plovers do not follow this general pattern. Indeed, our  
273 putative identification of the class of substances revealed that the preen oil of incubating Kentish  
274 plovers contained predominantly monoesters, and no diesters (Table S1). Although surprising,  
275 this finding is consistent with a preliminary study (Reneerkens 2007), which found only  
276 monoesters in the preen oil of incubating Kentish plovers (as well as in incubating Northern  
277 Lapwings *Vanellus vanellus* and Eurasian dotterels *Anarhynchus morinellus*). Together, these  
278 results suggest that, in some shorebird species including Kentish plover, preen oil composition  
279 may not switch to a diester mixture during incubation, and challenge the idea that preen oil has a  
280 role in incubation in these species. However, even if the preen oil of Kentish plovers does not  
281 contain any diester during incubation, it may still undergo seasonal changes, although not as  
282 dramatic as a complete shift to diesters. For example, preen oil may consist of a mixture of  
283 monoesters year-round, but the monoesters produced during incubation may be less volatile than  
284 those secreted the rest of the year. In any case, we call for caution with these preliminary results,  
285 because the analytical methods used by Reneerkens (2007) (i.e. judging peak patterns from  
286 chromatograms) and our study (i.e. comparing mass spectrometry with the NIST library) are  
287 simplistic and prone to inaccuracies. This warrants a more accurate identification of the

288 substances in the preen oil of Kentish plovers (e.g. Rijpstra *et al.* 2007, Alves Soares *et al.* 2024),  
289 using samples collected throughout the year.

290         From our descriptive results, we can only speculate on the function of preen oil during  
291 incubation in Kentish plovers. Preen oil may have a role in olfactory crypsis at the nest, as  
292 proposed for the 26 other shorebird species studied (Reneerkens *et al.* 2006). Kentish plovers  
293 nest on the ground and are vulnerable to olfactorily searching nest predators, such as dogs, foxes,  
294 snakes and lizards (Fraga and Amat 1996, Kosztolányi *et al.* 2009). When producing a low-  
295 volatility preen oil, incubating birds (and/or their clutch or brood) may be less detectable to  
296 olfactorily searching nest predators, thereby increasing nest survival (Reneerkens 2005, Grieves  
297 *et al.* 2022). To further investigate this possibility, we should sample preen oil from Kentish  
298 plovers across several breeding stages (not only during incubation) and measure its volatility. We  
299 hypothesize that the preen oil from Kentish plovers undergoes similar shifts, from more volatile  
300 substances to less volatile volatile substances at the onset of breeding and back to more volatile  
301 substances at the end of breeding, like in the other shorebird species studied (Reneerkens *et al.*  
302 2006).

303         In addition to olfactory crypsis, preen oil may have other roles during incubation. Preen  
304 oil may protect incubating birds from feather degrading bacteria (e.g. red knots *Calidris canutus*,  
305 Reneerkens *et al.* 2008; Eurasian hoopoes, Ruiz-Rodríguez *et al.* 2009) and their clutch from  
306 eggshell bacteria (e.g. Eurasian hoopoes, Martín-Vivaldi *et al.* 2010). To test this, we should  
307 assess the antimicrobial properties of the preen oil of Kentish plovers (e.g. Shawkey *et al.* 2003).  
308 Preen oil may also have a role in chemical signalling for mate choice. Sex recognition based on  
309 preen oil odours, like in dark-eyed juncos (*Junco hyemalis*, Whittaker *et al.* 2010, 2011) and  
310 song sparrows (*Melospiza melodia*, Grieves *et al.* 2019a, b), is not likely in Kentish plovers

311 because of the absence of sex differences during incubation. To confirm this, we should also test  
312 for sex differences in preen oil before incubation, when mate choice actually occurs. Also, preen  
313 oil may have signalling roles other than sex recognition. Birds may display their genetic  
314 compatibility (e.g. major histocompatibility complex) in their preen oil odours, like in black-  
315 legged kittiwakes (*Rissa tridactyla*, Leclaire *et al.* 2014) and song sparrows (Grieves *et al.*  
316 2019c), and they may use preen oil to assess relatedness of a potential mate (Krause *et al.* 2012,  
317 Caspers *et al.* 2015a). It should be emphasized that preen oil could have a function for chemical  
318 protection and chemical signalling at the same time. Indeed, preen oil odours could signal greater  
319 protection of the offspring (e.g. against predators via olfactory crypsis, or against pathogens via  
320 antimicrobial activity) and thereby be sexually selected signals.

321         We acknowledge that our negative results (absence of sex differences) may be due to the  
322 limited sample size and thus limited statistical power (i.e. false negative, or type II error). To  
323 evaluate whether our negative results are more likely false negatives or true negatives, we can  
324 compare the effect sizes of positive results from other studies with the confidence intervals from  
325 our study (Nakagawa and Cuthill 2007). A study on the preen oil composition of blue tits found a  
326 significant sex difference in chemical richness, with females producing on average 38 substances  
327 more than males (Caspers *et al.* 2022). This effect size (38 substances) falls well outside our  
328 confidence interval ( $[-12.7; 26.4]$ ), indicating that our study would have had the power to detect  
329 such an effect. Although this does not prove that our results are true negatives, it gives us  
330 confidence that they likely are. We note that we did not focus on the volatile fraction of preen  
331 oil, which would be the most relevant to study for its putative odour-related roles, like olfactory  
332 crypsis or chemical signalling. Instead, we analysed the whole preen oil composition, which  
333 includes both volatile and nonvolatile compounds. We did so because nonvolatile compounds

334 may be precursors of volatile compounds involved in crypsis or signalling, and are thus also  
335 relevant for such studies (Mardon et al. 2011). For example, the monoesters and diesters in the  
336 preen oil of red knots *Calidris canutus* are nonvolatile but still seem to have different odours or  
337 odour levels (different detection success of monoester and diester preen oil by a dog, Reneerkens  
338 2005). Another example is the preen oil of song sparrows, where the sex differences in  
339 nonvolatile esters seem to translate into sex differences in body odour, allowing the birds to  
340 discriminate sex by smell (Grieves et al. 2019b).

341         Our results are based on a single species and a single period, and thus cannot elucidate  
342 whether preen oil has a role (and which role) in incubation. However, our study provides  
343 valuable data on sex differences in preen oil. To investigate the function of preen oil in Kentish  
344 plovers, future studies should sample preen oil at different breeding stages (notably during mate  
345 choice and non-breeding) and measure its volatility. Importantly, future studies should conduct  
346 experiments, such as antimicrobial assays to test for antiparasitic protection (e.g. Shawkey *et al.*  
347 2003, Martín-Vivaldi *et al.* 2010), detectability trials or field experiments to test for olfactory  
348 crypsis (e.g. Reneerkens 2005, Selonen *et al.* 2022), and behavioural trials to test for olfactory  
349 communication (e.g. Caspers *et al.* 2015b, Grieves *et al.* 2019b).

350

## 351 **Conclusion**

352 Sex differences in preen oil composition during incubation in Kentish plovers could not be  
353 detected during incubation in Kentish plovers, a shorebird species in which both sexes incubate.  
354 This result is consistent with previous studies, where sex differences in preen oil occurred during  
355 incubation in uniparentally incubating species more than in biparentally incubating species. The

356 similar preen oil secreted by the female and the male during incubation may have a function for  
357 olfactory crypsis, as proposed for other shorebird species, but also for protection against  
358 ectoparasites and/or olfactory communication. Importantly, to elucidate whether preen oil has a  
359 function, future studies should first test whether preen oil composition changes seasonally,  
360 specifically at the time of incubation.

# Figure 1

Representative chromatogram of the preen oil of Kentish Plovers.

The illustration depicts a female Kentish Plover with a zoom on its uropygial gland secreting preen oil.

## Figure 2

No sex difference in the preen oil composition of Kentish Plovers.

**(a)** Non-metric multidimensional scaling (NMDS) plot representing Bray-Curtis dissimilarity in chemical composition. 2D Stress measures the “goodness of fit” of the NMDS ordination, with a value  $< 0.1$  indicating a good fit. The ellipses for each sex (95% confidence intervals assuming a multivariate t-distribution) overlap entirely, highlighting the absence of a sex difference in beta diversity. Besides, no sex difference was detected in alpha diversity, namely **(b)** chemical diversity (Shannon index) and **(c)** chemical richness (number of substances) of preen oil.
