Background: Occult lymph node metastasis (OLNM) is an essential prognostic factor for early-stage tongue cancer (cT1-2N0M0) and a determinant of treatment decisions. This, accurate prediction of OLN can significantly impact the clinical management and outcomes of tongue cancer patients. The aim of this study was to develop and validate a multiomics-based model to predict OLN in patients with early-stage tongue cancer.

Methods: The data of 125 patients diagnosed with early-stage tongue cancer (cT1-2N0M0) who underwent primary surgical treatment and elective neck dissection was retrospectively analyzed. A total of 100 patients were randomly assigned to the training set and 25 to the testing set. The preoperative contrast-enhanced computed tomography (CT) and clinical data of these patients were collected. Radiomics features were extracted from the primary tumor region of interest (ROI) on CT images, and correlation analysis and LASSO were used to identify the most relevant features. A SVM classifier was constructed and compared with other machine learning algorithms. Using the same method, a clinical model was built and the peri-tumoral and intra-tumoral images were selected as the input for the deep learning model. Stacking ensemble technique was used to combine the multiple models. The predictive performance of the integrated model was evaluated on the basis of the accuracy, sensitivity, specificity, and the area under the receiver operating characteristic curve (AUC-ROC), and compared to expert assessment. Internal validation was performed using a stratified 5-fold cross-validation approach. **Results:** Of the 125 patients, 41 (32.8%) showed OLN on postoperative pathological examination. The integrated model achieved higher predictive performance compared to the individual models, with accuracy of 84%, sensitivity 100%, specificity 76.5%, and AUC-ROC 0.949 (95% CI 0.870-1.000). In addition, the performance of the integrated model surpassed that of younger doctors and was comparable to the evaluation of experienced doctors.

Conclusions: The multiomics-based model can accurately predict OLNМ in early-stage tongue cancer patients, and may serve as a valuable decision-making tool to determine the appropriate treatment and avoid unnecessary neck surgery in patients without OLNМ.

A CT-based Integrated Model for Preoperative Prediction of Occult Lymph Node Metastasis in Early Tongue Cancer

Running title: Prediction of OLNLM in Tongue cancer

Abstract

Background Occult lymph node metastasis (OLNM) is an essential prognostic factor for early-stage tongue cancer (cT1-2N0M0) and a determinant of treatment decisions. This, accurate prediction of OLNLM can significantly impact the clinical management and outcomes of tongue cancer patients. The aim of this study was to develop and validate a multiomics-based model to predict OLNLM in patients with early-stage tongue cancer.

Methods: The data of 125 patients diagnosed with early-stage tongue cancer (cT1-2N0M0) who underwent primary surgical treatment and elective neck dissection was retrospectively analyzed. A total of 100 patients were randomly assigned to the training set and 25 to the testing set. The preoperative contrast-enhanced computed tomography (CT) and clinical data of these patients were collected. Radiomics features were extracted from the primary tumor region of interest (ROI) on CT images, and correlation analysis and LASSO were used to identify the most relevant features. A SVM classifier was constructed and compared with other machine learning

algorithms. Using the same method, a clinical model was built and the peri-tumoral and intra-tumoral images were selected as the input for the deep learning model. Stacking ensemble technique was used to combine the multiple models. The predictive performance of the integrated model was evaluated on the basis of the accuracy, sensitivity, specificity, and the area under the receiver operating characteristic curve (AUC-ROC), and compared to expert assessment. Internal validation was performed using a stratified 5-fold cross-validation approach.

Results: Of the 125 patients, 41 (32.8%) showed OLNМ on postoperative pathological examination. The integrated model achieved higher predictive performance compared to the individual models, with accuracy of 84%, sensitivity 100%, specificity 76.5%, and AUC-ROC 0.949 (95% CI 0.870-1.000). In addition, the performance of the integrated model surpassed that of younger doctors and was comparable to the evaluation of experienced doctors.

Conclusions: The multiomics-based model can accurately predict OLNМ in early-stage tongue cancer patients, and may serve as a valuable decision-making tool to determine the appropriate treatment and avoid unnecessary neck surgery in patients without OLNМ.

Keywords: tongue cancer, deep learning, radiomics, computed tomography, lymph node metastasis

Introduction

Tongue cancer affects the oral and maxillofacial area, and is more common in men due to higher frequency of tobacco and alcohol consumption. Treatment for early-stage tongue cancer usually involves surgery, radiation therapy, or a combination of both (Coletta et al., 2020, Ansarin et al., 2019, Pfister et al., 2020). Cervical lymph node metastasis is a major concern in the early stage of tongue cancer, and can reduce patient survival by almost half. It is currently the primary prognostic factor for tongue cancer (Ren et al., 2022, Imai et al., 2017, Li et al., 2023). Occult lymph node metastasis (OLNM) is diagnosed when pathological examination after neck dissection indicates micrometastasis in the lymph nodes but the results of palpation, ultrasound, CT, MRI, and other imaging tests are negative (Baba et al., 2020). About 20%-40% of patients in the early stages of oral cancer have OLNМ (Almangush et al., 2014, Greenberg et al., 2003). In addition, patients without pathological lymph node metastasis (pN0) who undergo neck dissection must bear unnecessary intraoperative risks and postoperative complications such as shoulder dysfunction. On the other hand, lack of effective treatment in patients negative for clinical lymph node metastasis (cN0) but with OLNМ may lead to cervical lymph node metastasis or even extracapsular spread during follow-up, resulting in worse prognosis (Wang et al., 2022). Therefore, early detection and accurate prediction of OLNМ are critical for planning the optimal treatment and improving patient outcomes.

In recent years, radiomics and deep learning techniques have helped identify early signs of metastasis, and predict the likelihood of cancer recurrence (Gillies et al., 2016, Leger et al., 2017, Shen et al., 2017). Radiomics involves extraction of quantitative features from medical images to identify subtle patterns that are not visible to the naked eye (Aerts et al., 2014, van Griethuysen et

al., 2017, *Lambin et al.*, 2012). Deep learning refers to training deep neural networks, such as conventional convolutional neural network (CNN), on large datasets and fine-tuning them on smaller datasets to improve predictive ability(*Shen et al.*, 2017, *Hosny et al.*, 2018). It uses an optimization algorithm called back-propagation to adjust its internal parameters for the best image output prediction.

Combining radiomics with deep learning techniques can help improve the accuracy of the prediction models for lymph node metastasis in early tongue cancer(*Gillies et al.*, 2016, *Leger et al.*, 2017, *Shen et al.*, 2017). Machine learning algorithms can identify patterns indicative of metastasis by analyzing radiomics features, such as texture, shape and intensity(*Aerts et al.*, 2014, *van Griethuysen et al.*, 2017, *Lambin et al.*, 2012). Furthermore, deep transfer learning can automatically extract more meaningful features from medical images to avoid massive engineering of radiomics, leading to more accurate predictions in shorter duration, and achieve good performance(*Shen et al.*, 2017, *Hosny et al.*, 2018).

Previous studies have utilized this approach on the intra-tumoral region without considering the peritumoral area. However, there is evidence that peritumoral features can improve diagnostic efficiency(*Huang et al.*, 2016, *Sun et al.*, 2018, *Zhou et al.*, 2018). Huang et al demonstrated that a radiomics signature including peritumoral features can predict disease-free survival in early-stage non-small cell lung cancer patients with high accuracy(*Huang et al.*, 2016). Sun et al used peritumoral radiomics features to assess tumor-infiltrating CD8 cells and the response to immunotherapy(*Sun et al.*, 2018). In addition, Zhou et al generated a radiogenomics map for non-small cell lung cancer to illustrate the relationship between molecular and imaging phenotypes(*Zhou et al.*, 2018).

The aim of this study was to combine radiomics and deep transfer learning to predict OLNLM in patients with early-stage tongue cancer on the basis of contrast-enhanced CT images. The peritumoral region was incorporated into the radiomics-based model to improve the predictive accuracy. In a clinical setting, this model can minimize decision-making errors by surgeons and reduce the risk of unnecessary surgery. The workflow of the study is shown in Figure 1.

Materials and Methods

Patients

A retrospective study was conducted using data of patients diagnosed with tongue cancer between 2015 and 2022. 125 patients were randomly divided into the training set (100 cases) and test set (25 cases). The study was approved by the ethics committee of Zhengzhou Central Hospital (202336) and conducted in line with the Declaration of Helsinki. Due to the retrospective nature of the study, the need for informed consent was waived by the committee.

The inclusion criteria were as follows: (1) pathological diagnosis of tongue squamous cell carcinoma, (2) planned surgery and elective neck dissection, (3) clinical diagnosis of cT1-2N0M0 based on palpation and imaging tests, (4) contrast-enhanced CT scans of the head and neck area performed within 30 days prior to surgery, and (5) availability of complete clinical information. Patients with a history of previous malignancy, or with unidentifiable lesions or

artifacts-induced radiological interference on CT scans were excluded. The baseline characteristics including gender, sex, T stage, tumor size, smoking history, and alcohol consumption were retrieved from the hospital database.

Region of interest segmentation and preprocessing

Two radiologists blinded to the clinicopathological information of the patients independently conducted tumor segmentation on the CT dataset using ITK-SNAP version 3.8.0 (<http://www.itksnap.org>). A senior radiologist verified and corrected all delineation tags. Since the images came from two CT scanners with different parameters, resampling was done before the features could be extracted from the ROI of the CT. The image space was normalized to 1x1x1. Inter-observer reliability and intra-observer repeatability of the extraction of radiomic characteristics are generally evaluated using inter- and intra-class correlation coefficients (ICCs). Features with ICC > 0.75 were retained for good consistency. The extracted image features were then normalized by adjusting the distribution of all features to the same range. The data was standardized according to the formula: $Z = (X - \mu) / \sigma$, where μ is the feature mean and σ is the feature standard deviation.

Feature extraction and selection

The radiomics features were classified into three groups to describe different aspects of the tumors: (I) geometry - three-dimensional form of the tumor; (II) intensity - first-order statistical distribution of the voxel intensities within the tumor; (III) texture - the patterns, or second- and high-order spatial distributions of the intensities. The neighborhood gray-tone difference matrix, the gray-level co-occurrence matrix, gray-level run length matrix, gray level size zone matrix, and other techniques were used to extract the texture features (Figure 2A).

The radiomic features with p values less than 0.05 in the Mann-Whitney U test were screened. The correlation between these features was analyzed by Spearman's method, and those with a correlation coefficient > 0.9 were selected. A greedy recursive deletion technique was used for feature filtering, wherein the feature with the highest level of duplication in the current set is removed each time in order to preserve the ability to display features as fully as possible. Finally, 115 features were retained and subjected to least absolute shrinkage and selection operator (LASSO) regression with the scikit-learn package in Python using 10-fold cross validation with minimum criteria. The features with non-zero coefficients in the regression model were used to construct a radiomics signature, and a linear combination of retained features weighted by their model coefficients was used to calculate the radiomics score for each patient (Figure 2B, C, D).

To construct deep transfer learning models, the most representative images were identified. The images were processed through three steps: M1: Assuming that the image background would create interference, the background pixels were removed and the primary lesion area was extracted along with the area surrounding the tumor. M2: The largest ROI was selected from the CT images and enlarged outward by 5 pixels. M3: In the 3D image, the tumor area was expanded

evenly by 2 voxels to obtain the peritumoral region, and the image with the largest ROI was selected (Figure 2E).

Development of different models

Radiomics model: The final features were input into various machine learning models such as SVM, KNN, RandomForest, ExtraTrees, XGBoost, LightGBM, MLP, and LR to construct a radiomics model (Cortes and Vapnik, 1995, Geurts et al., 2006, Chen and Guestrin, 2016, Ke et al., 2017).

Clinical model: The preoperative clinical data included age, gender, T stage, tumor size, drinking and smoking history. The same methodology as above was used to construct the clinical model.

Deep transfer learning model: Based on literature review and preliminary experimental testing, ResNet50 (He et al., 2016) was selected as the deep transfer learning model, and three datasets were incorporated for training. The SGD optimizer was utilized with a learning rate of 0.001 and 100 epochs. A fully connected layer, followed by a dropout layer with a 0.5 drop rate, was employed to prevent overfitting. The optimal dataset was selected for training, and the structured data was extracted from the average pooling layer (i.e., the penultimate layer). The deep learning model was then constructed using the same methodology as mentioned above. Finally, the three meta-models were fused using stacking strategy to obtain the integrated model.

Statistical analysis

Student's t-test or the Mann-Whitney U test were used to compare continuous variables, and the chi-squared test was used for categorical variables. All statistical tests were two-tailed and $P < 0.05$ was considered statistically significant. Python 3.7 was used for statistical analysis.

Results

Clinical data

A total of 125 patients met the inclusion criteria, of which 100 were randomly assigned to the training set and 25 to the test set. The clinical features of the patients are summarized in Table 1.

Performance of the different models

The LightGBM model demonstrated the best performance and was selected to construct the radiomics signature, which achieved AUC values of 0.896 (95%CI 0.825 – 0.967) and 0.824 (95%CI 0.658 – 0.989) in the training and testing datasets respectively (Figure 3A). The confusion matrix for LightGBM is shown in Figure 3B. The AUC of the clinical signature was 0.728. In the deep learning models, the performance of M3 was significantly higher than that of the other datasets, with AUC of 0.826 in the training cohort and 0.674 in the test cohort (Figure 4). Subsequently, the deep transfer learning model trained on the M3 dataset was selected as the deep signature.

Once the base models were trained, we used stacking to combine their predictions (Džeroski and Ženko, 2004). The dataset was split into training and testing sets, and the predictions generated

from each base model on the testing set were used as input features to train a meta-model for optimally combining the predictions of the three base models. Logistic regression was used as the meta-model due to its simplicity and interpretability. Our integrated model demonstrated improved performance compared to individual models, achieving an accuracy of 95%, sensitivity 100% and specificity 92.5% in the training dataset, and 84% accuracy, 100% sensitivity and 76.5% specificity in the testing dataset (Table 2). The AUC of the integrated model was 0.949 (95% CI: 0.870 – 1.000), which was higher than the AUCs of the radiomics (0.893), clinical (0.728), and deep learning models (0.798)(Figure 5A, B).

The performance of the integrated model was also evaluated by the DeLong test and decision curve analysis (DCA). The DeLong test indicated that the integrated model had a higher AUC compared to the individual models (nomogram vs clinical: 0.002; nomogram vs radiomics: 0.073; nomogram vs deep learning: 0.035), demonstrating its superior discriminative ability. The DCA further showed that our integrated model yielded a greater net benefit compared to other models across the majority of practical threshold probabilities (Figure 6). The nomogram of the integrated model is shown in Figure 7.

Comparison of the integrated model with clinical assessment

The performance of the integrated model was compared to that of clinical experts. Three clinicians with varying levels of experience in oral diseases, i.e., less than 5 years (D1), less than 10 years but longer than D1 (D2), and more than 15 years (D3), were asked to interpret imaging and clinical data. The decisions of the three clinicians were compared to that of the integrated model by plotting ROC curves. As shown in Figure 8, the integrated model achieved an AUC of 0.838 compared to 0.654, 0.768 and 0.893 of clinicians D1, D2 and D3 respectively. This suggests that there are differences between the model and expert evaluations.

Discussion

OLNM is an essential prognostic factor in early-stage tongue cancer (cT1-2N0M0) and influences the treatment decisions(Kubo *et al.*, 2022, Kwon, 2022). Thus, accurate prediction of OLNMs can significantly impact clinical management and outcomes of tongue cancer patients(Baba *et al.*, 2019). In this study, we developed a decision-level fusion system for classifying CT images by integrating radiomics, clinical, and deep learning models using the stacking ensemble technique. A nomogram was employed to visualize the integrated prediction results and allow clinical interpretation.

The integrated model exhibited superior performance compared to the individual radiomics, clinical, and deep learning models in terms of the AUC values, which can be attributed to the combination of the complementary strengths of the three models that allowed diverse aspects of the data to be captured. For instance, the radiomics model extracted quantitative features from CT images and captured subtle patterns that might be overlooked by human observers, while the clinical model provided additional demographic and clinical information. We also applied deep learning to predict the presence of OLNMs in cT1-2N0 patients(Jin *et al.*, 2021). The deep

learning model based on ResNet50 can directly analyze raw medical images, and learn complex and high-level representations of the data(Yu *et al.*, 2020). However, the format of the raw images is a matter of debate. While some researchers advocate for directly incorporating 3D images into the model, others believe that the images should first undergo a flattening process before being fed into the model(Harmon *et al.*, 2020, Calabrese *et al.*, 2022, Tian *et al.*, 2020, Shi *et al.*, 2022, Cho *et al.*, 2022, Charles *et al.*, 2017). However, direct use of 3D data for deep learning training often requires significant computational resources, such as high-performance GPUs and large memory capacities, which make the training and deployment processes expensive and time-consuming. Furthermore, medical image datasets are often small and imbalanced, which may lead to overfitting when 3D data is used directly for deep learning training. Overfitting can cause the model to perform well with training data but poorly in real-world applications due to reduced generalization. Therefore, we converted the 3D CT images to 2D images, which required determination of the feature extraction range due to relatively fewer features. In order to extract more representative features, we adopted three cropping methods to obtain suitable images as input for the deep learning model. The M1 dataset was first obtained by setting pixel values of the background to zero. The largest cross-section from the 3D ROI was selected and expanded by 5 pixels, resulting in dataset M2. Finally, the 3D ROI was evenly expanded by 2 voxels around the tumor, and the largest cross-section was cropped to generate the M3 dataset. Incorporating peri-tumoral information can prevent overfitting when applying deep learning models to most small medical imaging datasets by increasing the number of features. Among the two peri-tumoral processing methods, M3 uniformly expanded a fixed length in 3D images, while M2 involved rectangular expansion in 2D images. Consequently, M3 encompassed more critical features than M2, eventually yielding superior results.

By combining the outputs of multiple base models, stacking leverages the strengths of each to achieve better predictive accuracy(Mostafaei *et al.*, 2020) and reduces overfitting by diversifying the model ensemble, leading to more robust and generalizable results. We compared the performance of our integrated model to the decision-making abilities of clinicians, and found that the integrated model had superior accuracy. As already explained, this can be attributed to the ability of the machine learning algorithms to detect subtle patterns and relationships in the data that may not be easily discernible by human experts. Our findings indicate that a targeted multi-omics integration model may help clinical practitioners, especially those with less experience, attain a performance level similar to that of experts. Clinicians often need to analyze vast amounts of information, including medical images, clinical records, and laboratory results, within limited time, which can lead to cognitive overload and increase the likelihood of errors. The integrated model can rapidly process and analyze large amount of data, thus reducing the time needed for diagnosis and treatment planning. Another benefit of the integrated model is its ability to continuously learn and adapt as new data becomes available. As medical knowledge and clinical practice evolve, clinicians need to update their knowledge and decision-making processes accordingly. However, this process can be time-consuming and challenging. The integrated model can be retrained with new data, enabling it to stay up-to-date with the latest

advancements in the field and provide more accurate predictions. While the expertise of clinicians is invaluable, personal biases and preferences can sometimes influence their decisions, potentially leading to sub-optimal patient outcomes. By providing an objective, data-driven approach, the integrated model can minimize the impact of subjectivity in decision-making, leading to more consistent and optimal patient care. The nomogram incorporated the predictions from the radiomics, clinical, and deep learning models, as well as the output from the meta-model, to provide a comprehensive and intuitive representation of the decision-level fusion process. This can enable more effective communication of the results to both clinical practitioners and researchers, facilitating better understanding and application of the model in real-world settings.

Nevertheless, there are several limitations to our study that should be acknowledged. First, the sample size used for training and validation was relatively small, which may limit the generalizability of our findings. Future studies should incorporate larger and more diverse patient cohorts to further validate the performance of the integrated model. Second, the choice of the meta-model in the stacking ensemble technique could potentially impact the results. In our study, we employed logistic regression as the meta-model due to its simplicity and interpretability. However, other meta-models, such as support vector machines or random forests, could be explored in future to assess their impact on the performance of the integrated model.

Conclusion

In conclusion, integration of radiomics, clinical, and deep learning models using the stacking ensemble technique can enable clinical decision-making based on imaging data. Furthermore, the nomogram can visualize the integrated prediction results and thus enhance the interpretability and applicability of the model. Despite the noted limitations, our integrated model could serve as a valuable tool for improving diagnosis and treatment planning, eventually leading to better patient outcomes. To the best of our knowledge, this is also the first application of an ensemble model for predicting OLN in early-stage tongue cancer.

Ethics approval

The study was approved by the ethics committee of Zhengzhou Central Hospital (202336) and conducted in line with the Declaration of Helsinki. Due to the retrospective nature of the study, the need for informed consent was waived by the committee.

Figure legends

Figure 1. The workflow of this study.

Figure 2. Features selection process. (A). Number and ratio of handcrafted features; Nonzero coefficients were selected to establish the Rad-score with a LASSO logistic regression model. (B). Coefficients and (D). MSE (mean standard error) of 10 folds validation; (C). The histogram of the Rad-score based on the selected features. (E). Deep learning datasets based on different methods (M1, M2, M3)

Figure 3. Development of radiomics model. (A). The ROC curves of the radiomics model; (B). The confusion matrix of predicting lymph node metastasis

Figure 4. The ROC curves of M3.

Figure 5. The ROC curves of the clinical model, radiomics model, Deep learning model and combined model in the training cohort(A) and validation cohort (B). The integrated model demonstrated significantly higher AUCs in the training and validation cohorts (AUCs of 0.989 and 0.949) than the clinical model (AUCs of 0.815 and 0.728), the radiomics model (AUCs of 0.896 and 0.893) and the deep learning model (AUCs of 0.980 and 0.798)

Figure 6. The DCA of the clinical model, radiomics model, Deep learning model and combined model.

Figure 7. The development of the nomogram for clinical use.

Figure 8. The ROC curves of the integrated model and diagnostic results of each radiologist in the test cohort. The integrated model reached a high AUCs (AUC: 0.838), doctor1 acquired 0.654 of AUC, the AUC of doctor2 was 0.768 and doctor3 demonstrated the highest with 0.893.
