Abstract

Plants growing along wide elevation gradients in mountains experience considerable variations in environmental factors that vary across elevations. The most pronounced elevational changes are in climate conditions with characteristic decrease in air temperature with an increase in elevation. Studying intraspecific elevational variations in plant morphological traits and biomass allocation gives opportunity to understand how plants adapted to steep environmental gradients that change with elevation and how they may respond to climate changes related to global warming. In this study, phenotypic variation of an alpine plant *Soldanella carpatica* Vierh. (Primulaceae) was investigated on 40 sites distributed continuously across a 1,480-m elevation gradient in the Tatra Mountains, Central Europe. Mixed-effects models, by which plant traits were fitted to elevation, revealed that on most part of the gradient total leaf mass, leaf size and scape height decreased gradually with an increase in elevation, whereas dry mass investment in roots and flowers as well as individual flower mass did not vary with elevation. Unexpectedly, in the uppermost part of the elevation gradient overall plant size, including both below- and aboveground plant parts, decreased rapidly causing abrupt plant miniaturization. Despite the plant miniaturization at the highest elevations, biomass partitioning traits changed gradually across the entire species elevation range, namely, the leaf mass fraction decreased continuously, whereas the flower mass fraction and the root:shoot ratio increased steadily from the lowest to the highest elevations. Observed variations in *S. carpatica* phenotypes are seen as structural adjustments to environmental changes across elevations, by means of plastic, environmentally induced responses and/or genetic differences among locally adapted populations, that increase chances of plant survival and reproduction at different elevations.

Introduction

Elevation gradients in mountains are characterised by rapid environmental changes over very short distances and increasing elevation in temperate seasonal zones is associated with changes in many factors crucial for plant growth, survival and reproduction (Körner, 2021). As elevation increases there is a decrease in temperature, atmospheric pressure, CO₂ content and length of the growing season, whereas precipitation, solar radiation, as well as number of weather-related extreme events, for example, frequencies of strong winds and frost during growing season, increase with an increase in elevation (Billings, 1974; Nagy & Grabherr, 2009; Takahashi, 2014;

Körner, 2021). Moreover, at high elevations soil depth, microbial activity, nutrients availability, soil resource competition and herbivory pressure are generally lower (Rasman et al., 2014; Körner, 2021), whereas competition for pollinator services increases with elevation because the number and activity of pollinators declines in low temperature environment of high elevations (Maad, Armbruster & Fenster, 2013; Zhao & Wang, 2015; Arroyo, Pacheco & Dudley, 2017). Therefore, elevation is an important indicator of abiotic and biotic variations which influence plant performance and survival and may significantly alter functional characteristics of a plant species (Hautier et al., 2009; Scheepens & Stöcklin, 2013; He et al., 2017; Trunschke & Stöcklin, 2017; Kiełtyk, 2018; Miljković et al., 2019; Paudel et al., 2019; Kiełtyk, 2021a; Kiełtyk, 2021b; Rathee et al., 2021; Ahmad et al., 2023).

The intraspecific elevational variation observed in many plants can result from their adaptive plasticity (Dai et al., 2017; Hamann et al., 2017; Henn et al., 2018) and/or their genetic adaptation to local conditions (Byars, Papst & Hoffmann, 2007; Gonzalo-Turpin & Hazard, 2009; Hirano, Sakaguchi & Takahashi, 2017; Morente-López et al., 2020) because the environment selects for the optimal phenotype adapted to local resource availability and habitat conditions (Midolo et al., 2019). To alleviate stress levels and increase the uptake of the limiting resources or reduce the need for these limiting resources, plants can respond to variation in the environment by adjusting their physiology, morphology and biomass allocation (Nicotra et al., 2010; Freschet et al., 2018). Hence, different elevational stresses across elevation gradients may select for different ecological strategies among individuals of the same species that are reflected in distinct patterns of morphological variation and biomass allocation along elevational gradients (Seguí et al., 2018).

Allocation of dry matter to different plant structures implies existence of investment trade-offs, because resources allocated to one organ or function are unavailable for other organs or functions (Weiner et al., 2009). For example, in herbaceous perennials much allocation to stem and leaves is advantageous for competition for photosynthetic light capture but less allocation to belowground parts is disadvantageous for water and nutrients acquisition as well as for assimilates storage (Takahashi & Matsuki, 2017). According to the optimality theory the relationship between dry mass allocation in below- and above-ground organs (the root:shoot ratio) varies with range of resource supply and plants allocate more of their dry mass to organs that capture the most limiting resource (Reich et al., 2014; Blume-Werry et al., 2018). There is a

prediction that plants growing in cold and low nitrogen availability environments, should invest more of their biomass to below ground organs, as compared to plants growing at low elevations, where temperatures are higher and soil richer in nutrients (Bloom, Chapin & Mooney, 1985; McConnaughay & Coleman, 1999). The resource-retentive or the stress-tolerant life strategy demonstrated by increased below ground allocation, particularly in storage organs (Grime, 2001), can increase the chance of plants survival and population persistence in abiotically stressful and unpredictable environments of high elevations, by provisioning plants with stored reserves in particularly severe years when the amount of assimilated carbohydrates is not sufficient for year-to-year survival (Chapin, Schulze & Mooney, 1990; von Arx, Edwards & Dietz, 2006; Guo et al., 2012). Conversely, the opposite pattern of allocation is expected for plants growing in denser and taller vegetation at low elevations, where climatic conditions are milder but competition for resources, particularly for light, is stronger (Callaway et al., 2002; Read et al., 2014). In such environment selection should promote more the resource-acquisitive strategy manifested in increased plant growth that results from higher allocation in aboveground parts, namely, stem and leaves (Grime, 2001). Other important life-history adjustment in plants growing along elevation gradients is associated with variations in flower size and floral allocation (Arroyo, Pacheco & Aguilera, 2013; Dai et al., 2017; Basnett, Ganesan & Devy, 2019). In entomophilous species, increasing flower size can be correlated with higher reproductive success. It is expected, that at high elevations where pollinators are scarce and competition for pollinator services increase (Malo & Baonza, 2002; Maad, Armbruster & Fenster, 2013; Zhao & Wang, 2015; Arroyo, Pacheco & Dudley, 2017) plants produce larger flowers because they are preferred by insect pollinators (Malo & Baonza, 2002; Maad, Armbruster & Fenster, 2013; Totland, 2001; Totland, 2004). And this, in turn, increases the chances of pollen deposition and producing viable seeds, and finally, achieving reproductive success (Arroyo, Primack & Armesto, 1982; Ohara & Higashi, 1994; Bingham & Orthner, 1998). However, other selective pressures can promote opposite adjustment in flower size across elevations. In fact, it has been suggested that producing smaller flowers as found in some species can be advantageous in resource limited and climatically severe environment of high elevations because smaller flowers have lower cost of their structural development and physiological maintenance (Herrera, 2005). Consequently, different selective pressures, abiotic and biotic, can influence plant phenotypes along elevation gradients and studying variations in plant

morphology and dry mass allocation is important to understand environmental adaptations of plants (Takahashi & Matsuki, 2017). Accordingly, common trends in plant intraspecific variations with increasing elevation include, among others, reduced overall size, height and biomass (Alexander et al., 2009; Zhu et al., 2010; Maad, Armbruster & Fenster, 2013; He et al., 2017; Paudel et al., 2019; Kiełtyk, 2021a; Kiełtyk, 2021b), reduced leaf size (Byars, Papst & Hoffmann, 2007; Kiełtyk, 2018; Miliković et al., 2019; Paudel et al., 2019) and leaf mass (Kiełtyk, 2021a; Kiełtyk, 2021b), lower number of flowers (Kelly, 1998; Baret et al., 2004; Št'astná, Klimešová & Doležal, 2012; Maad, Armbruster & Fenster, 2013; Gabel, Sattler & Reisch, 2017), increased flower size and mass (Kudo & Molau, 1999; Malo & Baonza, 2002; Herrera, 2005; Maad, Armbruster & Fenster, 2013; Kiełtyk, 2021b), and increased seed mass (Kudo & Molau, 1999; Alexander et al., 2009; Wu et al., 2011; Qi et al., 2015). However, the opposite patterns with decreases in flower size (Totland, 2001; Zhao & Wang, 2015; Hattori et al., 2016) and seed mass (Totland, 2004; Wirth et al., 2010; Gabel, Sattler & Reisch, 2017) with an increase in elevation have also been reported for some species. Furthermore, in the Asteraceae family a shift in floral allocation patterns was observed in some species despite steady gross dry mass investment in flowers across elevation gradients. Namely, plants growing at high elevations had smaller numbers of larger flower heads with larger numbers of flowers as compared to low-elevation plants that had larger numbers but smaller flower heads with smaller numbers of flowers (Takahashi & Matsuki, 2017; Kiełtyk, 2021b). Overall, the variety of elevational adjustments reported for different plant species suggests, that there are no general patterns of plant intraspecific elevational variations, but plant phenotypic responses to elevation may be species specific and context dependent (e.g. Olejniczak et al., 2018).

Patterns of intraspecific phenotypic variation in plants growing along elevation gradients in mountains are drawing increased research interest (e.g. Halbritter et al., 2018; Olejniczak et al., 2018; Basnett, Ganesan & Devy, 2019; Paudel et al., 2019; Cruz-Maldonado et al., 2021; Rathee et al., 2021; Rixen et al., 2022; Ahmad et al., 2023; Khatri et al., 2023; Spitzer et al., 2023). Studying variations in morphology and biomass allocation among plant organs across elevations provides relevant insights for understanding plant adaptive responses to biotic and abiotic variations along steep environmental gradients. Moreover, knowledge on life-history adjustments in steep climatic gradients as found along mountain slopes contributes to our understanding of how plants may cope with present and predicted future climate changes (e.g. Frei et al., 2014;

Pfennigwerth, Bailey & Schweitzer, 2017; Blume-Werry et al., 2018; Midolo et al., 2018; Rixen et al., 2022).

The current study concerns variation in the alpine herb *Soldanella carpatica* Vierh. (Primulaceae) across a 1,480 m elevation gradient in the Tatra Mts. The large elevation range of the species in this region provides a good opportunity to look at the effects of elevation on plant morphological variation and biomass allocation pattern. The aim of this study was to reveal the overall effects of elevation on variations in set of fitness-related vegetative and reproductive traits of *S. carpatica*. In particular, the following questions were addressed: (1) does plant size expressed by plant dry mass and leaf size decrease with increasing elevation?, (2) do total flower mass as well as individual flower mass change with elevation?, (3) does increasing elevation is positively correlated with the root : shoot ratio?

Material & Methods

Study species

S. carpatica is a herbaceous perennial plant endemic to the West Carpathians. The scape of *S. carpatica* is erect, (3)5–15(20) cm tall, not leafy, with (1)2–5- violet insect-pollinated flowers gathered at the top inflorescence (Pawłowska, 1972). Suborbicular leaves are gathered in a basal rosette (Fig. 1). Leaf blade is 8-50 mm wide, dark green, usually violet beneath with basal sinus narrow and shallow (Pawłowska, 1963). The species blooms from April to September and fruits from May to October (Zhang & Kadereit, 2002). *S. carpatica* is common in the Tatra Mountains growing on various habitats along wide elevation gradient from lower montane forest floor vegetation to scattered vegetation on rocky substrate in high elevations of subnival belt (Pawłowska, 1963).

Study area

The research was conducted along the 890–2,370 m a.s.l. elevation gradient in the Tatra Mountains, southern Poland, within the protected area of the Tatra National Park (Fig. 2). Permission for the study was obtained from the Tatra National Park (Bot/380 DBN.503/28/18). The Tatra Mountains, located in the centre of the Western Carpathians, constitute the highest mountain massif within the Carpathian Range. The general elevational range in the Polish Tatras extends from ca. 900 m to 2,500 m a.s.l. and crosses five climatic-vegetation belts. These are:

lower montane forest (up to 1,200 m a.s.l.), occupied by beech-fir forest, with temperate cool climate (mean annual air temperature - MAT from +4 to +6 °C); upper montane forest (1,200–1,550 m a.s.l.), dominated by spruce forest, with cool climate (MAT from +2 to +4 °C); dwarf pine (=subalpine) belt (1,550–1,800 m a.s.l.), with very cool climate (MAT from 0 to +2 °C); alpine belt (1,800–2,250 m a.s.l.), occupied by high-mountain grasslands, with temperate cold climate (MAT from 0 °C to –2); subnival belt (above 2,250 m a.s.l.), characterized by scattered poor vegetation, with cold climate (MAT from –2 to –4 °C) (Mirek, 1996).

Field sampling and traits measurements

The flowering plants of *S. carpatica* were collected in 2018, from the end of April to the beginning of July, from 40 sites distributed from 890 m a.s.l. to 2,370 m a.s.l. (Table 1). The elevation at each site was determined in the field using a GPS receiver with built-in barometric altimeter (Garmin GPS MAP 76s, Olathe, USA). An attempt was made to sample entire elevational range of the species in the area and ensure that the sampled sites were distributed approximately evenly along the species elevational range. At each site, 9-10 plants in blossom peak with single stalk were sampled and carefully excavated with roots. To ensure that the sampled plants were separate genets, the minimal distance between the sampled plants was 2 m. Sampled individuals were well-developed and did not show restriction in growth and reproductive function as well as symptoms of fungal infection nor herbivory damages. Roots were roughly cleaned of soil and plants were preserved as dry material for laboratory analyses. Scape height was assessed as a distance between the plant base just below rosette leaves and the top of inflorescence; during the measurement the scape was straightened. Leaf blade diameter, the trait that assess size of photosynthetically active leaf part, was averaged for two largest plant leaves; on each leaf blade width was measured in two perpendicular directions and averaged per plant. In the next step plants were separated into four fractions, namely roots, scape, leaves and flowers, and final cleaning of roots was performed over a 0.6 mm mesh sieve under running water. Next, all the fractions were dried for 48 h at 80 °C in a laboratory drying oven with natural air circulation (Pol-Eko-Aparatura SLN 240, Wodzisław Śląski, Poland) to obtain the dry matter content (Pérez-Harguindeguy et al., 2013) by weighing on an analytical balance (Radwag AS 60/220.X2 PLUS, Radom, Poland). All weight measurements were carried out immediately after the samples were removed from the oven.

Statistical analyses

All analyses were conducted in the statistical programming environment R version R-4.1.1 (R Development Core Team, 2021). Elevational variations in traits of *S. carpatica* (Table 2) were analysed with the linear mixed-effect models (Field, Miles & Field, 2013) using the *lmer()* function in the *lme4* package (Bates et al., 2015). In these analyses, elevation was used as a continuous fixed effect and sample site was set as a random model component. Because preliminary data analysis revealed that above 2,000 m a.s.l. there were considerable rapid changes in values of some traits that could heavily influence the overall elevational variations, analyses were run for two elevation ranges independently; the first model for each trait was constructed for the full investigated elevation gradient 890–2,370 m a.s.l. (mod₂₃₇₀), whereas the second model, constructed for elevation gradient 890–1,980 m a.s.l. (mod₁₉₈₀), did not contain plants from the highest sites above 2,000 m a.s.l. To account for non-straight-line responses of traits to elevation two mixed-effect models were constructed and evaluated for the both examined elevation ranges. The first model included elevation as a linear fixed effects ($Y = a + b_1 \times (\text{elevation})$, where a denotes an intercept and b_1 regression coefficient) while the second model included elevation and elevation with quadratic term ($Y = a + b_1 \times (\text{elevation}) + b_2 \times (\text{elevation})^2$, where a denotes an intercept and b_1 and b_2 denote regression coefficients). Comparison of these models allowed to determine whether plant traits had a linear or nonlinear relationship with elevation. Fits of these two models to the data were evaluated based on a likelihood ratio test and *Chi-Squared* statistic where a significant $P_{\text{model selection}}$ value at 0.05 significance level (Table 3) indicated significant improvement in the straight-line model upon addition of the quadratic term for elevation (Dalgaard, 2008). Comparisons of model fit were carried out using the *anova()* function from the base R installation.

Results

Elevational variation in morphological traits

Models of traits elevational variations fitted to the 890–1,980 m a.s.l. and the 890–2,370 m a.s.l. ranges (Table 3) differed considerably between these both ranges for many morphological traits indicating significant change in *S. carpatica* morphology occurring at the highest sites located at elevations 2,085–2,370 m a.s.l (Fig. 3). In the 890–1,980 m a.s.l. range aboveground plant mass

($P_{1980} = 0.0436$, Fig. 3A), total leaf mass ($P_{1980} = 0.0201$, Fig. 3C), scape height ($P_{1980} = 0.0144$, Fig. 3G) and leaf blade diameter ($P_{1980} = 0.0001$, Fig. 3H) decreased with an increase in elevation, whereas root mass ($P_{1980} = 0.8583$, Fig. 3B), scape mass ($P_{1980} = 0.8536$, Fig. 3D), total flower mass ($P_{1980} = 0.9112$, Fig. 3E) and individual flower mass ($P_{1980} = 0.4336$, Fig. 3F) did not vary across elevations. However, in the 890–2,370 m a.s.l. range all the traits had significant relationship with elevation (Table 3). Aboveground plant mass ($P_{2370} = 0.0067$, Fig. 3A), root mass ($P_{2370} = 0.0270$, Fig. 3B), total leaf mass ($P_{2370} = 0.0275$, Fig. 3C), scape mass ($P_{2370} = 0.0009$, Fig. 3D), total flower mass ($P_{2370} < 0.0001$, Fig. 3E) and individual flower mass ($P_{2370} = 0.0001$, Fig. 3F) did not have elevational trend or slightly decreased from 890 m to ca. 2,000 m a.s.l., whereas above 2,000 m a.s.l. values of these traits decreased very considerably. Scape height ($P_{2370} < 0.0001$, Fig. 3G) decreased in a straight-line manner with an increase in elevation in the 890–2,370 m range, whereas leaf blade diameter ($P_{2370} = 0.0059$, Fig. 3H) decreased slightly from 890 m to ca. 2,000 m a.s.l., and above 2,000 m a.s.l. values of this trait were reduced more considerably.

Generally, all traits reduced considerably their values with an increase in elevation from 890 m a.s.l. to 2,370 m a.s.l. (Table 4). In this range aboveground plant mass decreased with an increase in elevation by 77.5%, total leaf mass decreased by 78.9%, scape mass decreased by 73.6%, total flower mass decreased by 68.5%, individual flower mass decreased by 46.3%, scape height decreased by 37.2% and leaf blade diameter decreased by 56.4% (Table 4).

The reductions in size of plant organs occurred almost merely at the highest elevations above 2,000 m a.s.l., at sites located at elevations 2,085–2370 m a.s.l., which constitutes ca. 20 % uppermost portion of the investigated elevation gradient. From 890 m to 1,980 m a.s.l. total leaf mass decreased by 2.7%, leaf blade diameter decreased by 2.3%, aboveground plant mass decreased by 2.1% and plant height decreased by 1.8% per every 100 m increase in elevation. Percent changes in other traits in this elevation range were small and models used to their calculations were statistically not significant (Table 4). Contrary, from 1,980 m to 2,370 m a.s.l. rates of changes in all traits were very considerable; aboveground plant mass decreased by 12.1%, root mass decreased by 11.3%, total leaf mass decreased by 11.2%, scape mass decreased by 16.2%, total flower mass decreased by 15.0%, individual flower mass decreased by 9.1%, scape height decreased by 3.6% and leaf blade diameter decreased by 7.2% per every 100 m increase in elevation (Table 4).

Elevational variation in dry mass allocation traits

Overall, *S. carpatica* plants allocated on average 39.8% of their total dry mass to root, 45.2% to leaves, 10.4% to scape, and 4.7% to flowers. Of the aboveground plant mass, 74.7% was allocated to leaves, 17.3% to scape and 8.0% to flowers.

All the dry mass partitioning traits were significantly fitted to elevation by straight-line models (Table 3, Fig. 4). Models constructed for both elevation ranges, the 890–1,980 m and the 890–2,370 m a.s.l. were almost identical for these traits. The root:shoot ratio increased with increasing elevation ($P_{1980} = 0.0022$, $P_{2370} < 0.0001$, Fig. 4A), whereas leaf mass fraction decreased with an increase in elevation ($P_{1980} = 0.0001$, $P_{2370} < 0.0001$, Fig. 4B). Moreover, flower aboveground mass fraction increased with an increase in elevation ($P_{1980} = 0.0029$, $P_{2370} = 0.0009$, Fig. 4C).

Within the entire elevation range from 890 m to 2,370 m a.s.l. the root:shoot ratio increased by 61.0%, leaf mass fraction decreased by 24.3%, and flower aboveground mass fraction increased by 42.8% (Table 4). The rates of these traits changes per 100 m increase in elevation had similar values in the 890–1,980 m a.s.l. and 1,980–2,370 m a.s.l. elevational ranges. In the 890–1,980 m a.s.l. range the root:shoot ratio increased by 3.4%, leaf mass fraction decreased by 1.7% and flower aboveground mass fraction increased by 3.3% per 100 m increase in elevation. Concurrently, in the 1,980–2,370 m a.s.l. range the root:shoot ratio increased by 5.3%, leaf mass fraction decreased by 1.5% and flower aboveground mass fraction increased by 2.2% per 100 m increase in elevation (Table 4).

Discussion

Soldanella carpatica varied across the elevation gradient adjusting its morphological and dry mass traits to environmental factors correlated with elevation. Along most part of the studied elevation gradient, from the base at 890 m a.s.l. to 2,000 m a.s.l., total dry mass of photosynthetic tissue, leaf size and scape height decreased steadily in a clinal manner with an increase in elevation, whereas dry mass investment in roots and flowers as well as individual flower mass did not vary with elevation. However, at the highest elevations considerable changes occurred in most of the traits leading to abrupt plant miniaturization. Accordingly, plants growing at elevations above 2,000 m a.s.l. were distinctly smaller in size, had lower aboveground dry mass,

reduced leaf size and mass, reduced root, scape, total as well as individual flower mass, as compared to plants from sites at elevations below 2,000 m a.s.l.

Elevational variation in aboveground vegetative organs

Maintaining relatively unchanged phenotype by *S. carpatica* across a wide 1,100-m elevation range from 890 m to 2,000 m a.s.l. that corresponds approximately to ca. 6 K decrease in mean annual temperature with an increase in elevation suggests that this species is particularly well adapted to live across wide elevation gradients. Such specialised adaptations were found recently in a closely related alpine species *Soldanella pusilla* that grows in the European Alps. *S. pusilla* is a species extremely adapted to tissue formation and growth under conditions of very low temperatures (Körner et al., 2019). That species resumes growth in mid-winter being at the time covered by a 2-3 m thick snowpack and develops its entire flowering shoot under snow at 0 °C. Moreover, *S. pusilla* has an enormous carbohydrate reserves, mainly stored in below ground tissue, that would support basic metabolism for at least two entire years under snow (Körner et al., 2019). Although no similar studies are available for *S. carpatica*, it can be assumed that this species due to its phylogenetic and ecological relatedness to *S. pusilla* (Zhang & Kadereit, 2002) has similar physio-ecological characteristics and its growth is not significantly limited by low temperatures across the studied elevation gradient. Therefore, reductions in leaf size and total leaf mass in *S. carpatica* as observed from low to high elevations can represent rather adaptation to environmental conditions that change across elevations rather than restriction in growth caused by harsh environment of high elevations. Accordingly, reduction of alpine plant size with an increase in elevation is a well-known elevational trend (e.g. Alexander et al., 2009; Zhu et al., 2010; Maad, Armbruster & Fenster, 2013; He et al., 2017; Paudel et al., 2019; Kiełtyk, 2021a; Kiełtyk, 2021b) that contrasts with high metabolic capacity of tissues, especially leaves (Körner, 2021). The fact that root, stem and flowers of *S. carpatica* were unresponsive to the 1,100-m elevation gradient from 890 m to ca. 2,000 m a.s.l. despite continuous reduction in dry mass of photosynthetically active tissue could be explained by increased photosynthetic leaf tissue efficiency that guarantees adequate assimilates supply for producing and maintaining unchanged rest of plant organs in harsher climatic conditions associated with increasing elevation. It could be therefore assumed, that because reduced photosynthetic organ size and mass at higher elevations fully satisfy plant demand for products of photosynthesis and plant produces and

stores enough assimilates for growth, reproduction and year-to-year survival due to high metabolic efficiency of leaf tissue, there is no advantage in allocation in high elevations as much of dry mass to leaves as in low elevations, where inter-specific competition for light is stronger (Wepppler & Stöcklin, 2005; Callaway et al., 2002; Read et al., 2014) and where increased investment in photosynthetically active tissue may be essential for capture and utilization of sufficient light quantity. Moreover, the reduction in plant aboveground size with an increase in elevation, that in *S. carpatica* is caused by reduction in leaf size and mass, can be advantageous adaptation to decreased nutrients availability in soils (Sveinbjörnsson et al., 1995) and climatic constraints at high elevations because smaller plants have lower resource requirements, as proposed by the ‘resource-cost compromise’ hypothesis (Herrera, 2005; Zhao & Wang, 2015). Additionally, the smaller are plants with smaller leaf rosettes growing close to the ground the more they decouple their climate from the ambient due to reduction in surface area that is exposed to cold air (Körner, 2021). Being closely attached to the ground also increases plant resistance to environmental factors such as strong winds as well as to freezing events due to heat accumulation by the leaf canopy close the ground (Fabbro & Körner, 2004; Cruz-Maldonado et al., 2021). Therefore, decreasing plant aboveground size with an increase in elevation can represent adaptive adjustment allowing local populations to efficiently use limited resources under increasingly less favourable climatic conditions associated with increasing elevation.

Elevational variation in reproductive organs

Dry mass investment in flowers as well as flower size expressed by mean flower mass were not affected by elevation along a 1,100-m elevation gradient ranging from 890 m a.s.l. to 2,000 m a.s.l. Despite increasingly more growth limiting conditions due to reduced temperature and resource limitation with an increase in elevation, *S. carpatica* retained steady dry mass investment in flowers across the wide elevation range. Similar pattern of elevational variation in flower mass was found in *Bellidiastum michelii*, where flower head mass, total flower mass as well as individual flower mass did not change considerably along ca. 900-m elevation gradient and decreases in these traits were visible only at the highest elevations of the species range (Kiełtyk, 2021a). Furthermore, unchanged floral mass investment across the wide 950-m elevation gradient was found in total mass of *Senecio subalpinus* flower heads, however, at the level of an individual flower head both total tubular flower mass as well as total ligulate flower

mass increased toward high elevations (Kiełtyk, 2021b). Maintaining unchanged total mass of *S. carpatica* flowers along with reduction in total leaf mass with an increase in elevation in the 890–2,000 m elevation range resulted in the increase in flower aboveground mass fraction. Meanwhile, the increased portion of dry mass allocated to flowers may suggest that reproductive investment is increasingly important strategy for local *S. carpatica* populations persistence with an increase in elevation.

The plant height, a trait being related with species competitiveness for light in species with leafy stems, that is often used as a proxy for plant size, was commonly found to decrease with an increase in elevation in studies on intraspecific plant variations (e.g. He et al., 2017; Paudel et al., 2019; Kiełtyk, 2021b). However, in case of *S. carpatica* plant height as expressed by the scape height is not related to plant size nor competitive ability for light because the species has all its leaves gathered in basal rosette and the only function of scape is to give support for flowers and eventually fruits clustered at the top of scape. Thus, height of scape in *S. carpatica* defines elevation on which flowers are positioned above the ground, and functionally this trait is related to reproductive process by exposing flowers above the ground to attract pollinators and support fruits when dispersing seeds. With an increase in elevation from 890 m to 2,000 m a.s.l. height of *S. carpatica* scape decreased steadily, whereas amount of dry mass allocated to scape remained unchanged, what resulted in producing thicker and tougher scapes with flowers elevated lower above the ground toward higher elevations. Because height of leaf canopy of surrounding vegetation generally also decrease with an increase in elevation (Leuschner & Ellenberg, 2017) reduced scape height prevents flowers to protrude too high into well-stirred cold air above the calm aerodynamic boundary layer created by leaf canopy (Dietrich & Körner, 2014). It has been shown in the alpine environment that the closer the ground the higher air temperatures are whereas wind speed rises logarithmically with distance from the ground (Körner, 2021). Therefore, reducing the scape height toward higher elevations follows the general vegetation trend of reduced foliage layer height and can enhance decoupling flowers from the colder free atmosphere. Meanwhile, it has been shown that warmer flowers can more efficiently attract pollinators as pollinators besides flower colour are also sensitive on flower temperature (Creux et al., 2021), in colder climates preferring warmer flowers (Norgate et al., 2010). Additionally, warmer flowers have thermal benefits during maturation of sexual organs, pollen germination and pollen tube growth (Dietrich & Körner, 2014) and it has been found that experimentally

increased temperature and sheltering from wind of alpine plant *Ranunculus acris* resulted in increased seed production (Totland & Eide, 1999). Thus, decreasing scape height in *S. carpatica* with an increase in elevation can be a selective advantage of developing flowers in milder micro-climate closer to the ground as maintaining higher floral temperatures in cool alpine environment is often critical for the successful reproduction of high-mountain plants (Dietrich & Körner, 2014).

Elevational variation in root mass

Elevational variation in root mass of *S. carpatica* was analogous to that in flower mass as there was no significant change in root mass in a wide range of elevations between 890–2,000 m a.s.l. whereas above 2,000 m a.s.l. this trait decreased significantly. Steady root mass investment across ca. 1,100-m elevation range accompanied by decrease in total leaf mass with increasing elevation resulted in increasing the root:shoot ratio from low to high elevations. Because plants can adjust their morphological traits such as root length, density, branching as well as proportion of fine to coarse roots (Weemstra et al., 2021) to micro-mosaics of belowground conditions such as water and nutrient availability or soil rockiness, the increased *S. carpatica* belowground mass fraction toward high elevations may indicate an increased importance of resource acquisition and/or assimilates storage in resource limited and climatically more growth restricting and unpredictable environmental conditions of high elevations. Moreover, the decreased availability of nutrients may result not only from decreasing soil nutrients content toward high elevations (Körner, 2021) but also from increased belowground competition between plants for limited resources. It has been suggested that in abiotically severe environments of high elevations competition strength decreases as a result of reduced number of species that withstand unfavourable conditions as well as due to restrictions in resource acquisition by plants caused by severe physical conditions (Callaway, 1998). This relation may characterize aboveground plant competition for space and light as height of leaf canopy decrease and vegetation becomes less dense with increasing elevation (Nagy & Grabherr, 2009). However, because soil nutrients content and soil depth generally decrease with an increase in elevation (Sveinbjörnsson et al., 1995; Körner, 2021) nutrients availability for plants also decreases what can result in increasing belowground resource competition. Thus, dry mass investment in roots can be increasingly important for resource foraging with an increase in elevation as evidenced by unreduced *S.*

carpatica root mass from 890 m to 2,000 m a.s.l. despite accompanying continuous reduction in aboveground plant mass. Furthermore, increasing the root:shoot ratio with an increase in elevation supports the hypothesis that in colder and harsher environments plants tend to allocate greater portion of their mass in belowground organs (Bloom, Chapin & Mooney, 1985; McConnaughay & Coleman, 1999). Increased root mass fraction may be advantageous adjustment in *S. carpatica* to acquire and/or store enough resources for growth, survival and completing its life history cycle in high elevation environments.

Plant miniaturization at the highest elevations

The most pronounced pattern of elevational variation in *S. carpatica* is abrupt plant miniaturization on sites located in the 20% uppermost part of the studied elevation gradient. Rapid reduction in overall plant size may suggests that this species encounters considerably more growth limiting conditions above 2,000 m a.s.l. as compared to lower elevations. Similar pattern of rapid change in plant size across elevations was found in alpine taxon of the *Solidago virgaurea* L. complex, where plants growing at the highest elevations had distinctly lower plant height and rosette diameter (Takahashi & Matsuki, 2017) as well as lower number of flower heads (Sakurai & Takahashi, 2017) as compared to plants from lower elevations. The reduction in *S. carpatica* size cannot be explained merely by plant response, by means of phenotypic plasticity and/or genetic adaptation, to limiting climatic conditions of high elevations because climate factors change gradually with an increase in altitude (Nagy & Grabherr, 2009), as exemplified by mean annual temperature decrease by 0.55 K per every 100 m increase in elevation in mountains of temperate regions (Körner, 2021). Therefore, it could be other than climatic factors alone that trigger off morphological changes in *S. carpatica* at the highest elevations of the studied gradient. It is likely that the plant miniaturization above 2,000 m a.s.l. was related to changes in orography, i.e. increased steepness and rockiness of mountain slopes toward high mountain tops. The five highest sites on which size of *S. carpatica* was considerably reduced were located at elevations 2,085–2,370 m a.s.l. on steep rocks of Czarny Mięguszwiecki Wierch peak (2,405 m a.s.l.). The environment of such high peaks is characterized by harsh climatic conditions and lack of accumulated snow cover in winter due to frequent strong winds and high slopes inclination. Thus, *S. carpatica* growing on rocky initial soils at the highest elevations of the studied gradient was exposed to particularly unfavourable

conditions caused by strong winds and lack of protective snowpack in winter, that was found to be important for development and growth of closely related species *S. pusilla* in the European Alps (Körner et al., 2019). Miniaturization of *S. carpatica* at the highest elevations could be, therefore, a plastic or/and genetically based response to abrupt deterioration in growing conditions caused by simultaneous interactions of climate, soil and orographic conditions.

It is important to note that environmental conditions that can cause abrupt changes in morphology of alpine plants may also hinder predictions on plants upward migrations in mountains (Frei, Bodin & Walther, 2010; Wipf et al., 2013; Steinbauer et al., 2018) as well as plant phenotypic responses to climate warming if local orographic conditions or topographic microhabitat diversity are not considered (Kulonen et al., 2018). It is likely that increased rockiness and steepness of slopes and walls at high elevations of young mountains with glacial landforms shaped by geomorphic processes of physical weathering and denudation (Kotarba, 1996) coupled with lack of snowpack during dormant season, that causes freezing stress (Körner, 2021), increased frequency of strong winds, shallow initial soils and increased patchiness of fragmented vegetation (Leuschner & Ellenberg, 2017) may not constitute suitable habitats for plant species from lower elevations migrating upward mountain slopes despite the increase in mean annual temperature as predicted by future climate warming scenarios (Engler et al., 2011; Mountain Research Initiative EDW Working Group, 2015). Moreover, diversity of microhabitats in alpine landscapes creates mosaic of micro-environmental and life conditions, with range of thermal niches that can differ in mean temperature by as much as 8 K at the same elevation, and this exceeds around twice the worst climate warming scenario for the same region, as recently shown in the European Alps by Körner and Hiltbrunner (2021). Furthermore, the difference in temperature by 8 K corresponds to ca. 1,450 m difference in elevation, what equals approximately to the differences in mean air temperature across the elevation range investigated in the present study. Such diversity of thermal conditions at given elevation may ensure availability of suitable conditions for cold adapted plants under warmed climate conditions.

This study revealed pattern of elevational variation in *S. carpatica* caused by environmental factors correlated with elevation. However, to identify drivers of elevational changes in plants analyses including set of environmental factors would be helpful. Moreover, to disentangle the contributions of plastic, environmentally induced responses, and of genetic differences among locally adapted populations, to morphological variation across elevation

gradients studies involving reciprocal plant transplantations to different elevations are required (eg. Scheepens, Frei & Stöcklin, 2010; Hamann et al., 2016).

Conclusions

Soldanella carpatica overall size, leaf size and mass, and scape height decreased gradually with an increase in elevation along most part of the elevation gradient, whereas in the uppermost part of the gradient plant size decreased rapidly causing abrupt plant miniaturization. Despite the plant miniaturization at the highest elevations, biomass partitioning traits changed gradually across the entire species elevation range, namely, the leaf mass fraction decreased continuously, whereas the flower mass fraction and the root:shoot ratio increased steadily from the lowest to the highest elevations. Thus, the abrupt changes in *S. carpatica* morphology on the highest elevation sites suggest that overall plant size as expressed by leaf size, scape height and plant dry mass traits are strongly influenced by local environmental conditions to which they respond considerably, whereas steady trajectory of dry mass partitioning changes across entire elevation gradient suggests that mass partitioning and adjustive changes in organs mass fractions in response to environmental conditions represent a stable evolutionary solution of the species. While the continuous changes in plant morphology on most part of the gradient are likely to represent plant adaptation or/and plastic phenotypic responses to gradual changes that occur in climate conditions across elevations, the rapid plant miniaturization in the highest elevations may reflect changes in orographic conditions such as increased rockiness and steepness of mountain slopes at the highest elevations. On such steep, rocky slopes, there are no steady protective snowpack during winter and plants are exposed to particularly low temperatures causing freezing stress. Therefore, when predicting plants phenotypic responses across elevations in mountains or possibility of upward plant species migrations caused by climate warming it is important to consider local dominant orographic as well as topographic conditions, e.g. slope inclination, exposition, rockiness, terrain relief, because they can substantially modify the climate conditions experienced by plants at given elevation (e.g. Graae et al., 2018).

Table 2 (on next page)

Soldanella carpatica traits used in the study.

1

Trait	Measurement details	Accuracy / significant digits
Aboveground plant mass – total dry mass of the aboveground plant parts. Calculated as sum of leaves, stalk and flowers masses weighed separately.	Plant parts weighed on an analytical balance after drying for 48 h at 80 °C.	0.0001 g
Root mass – dry mass of all plant roots.	Roots washed on the 0.6 mm sieve under running water and weighed on an analytical balance after drying for 48 h at 80 °C.	0.0001 g
Total leaf mass – total dry mass of all plant leaves.	Weighed on an analytical balance after drying for 48 h at 80 °C.	0.0001 g
Scape mass - dry mass of plant scape.	Weighed on an analytical balance after drying for 48 h at 80 °C.	0.0001 g
Total flower mass – total dry mass of all plant flowers.	Weighed on an analytical balance after drying for 48 h at 80 °C.	0.00001 g
Individual flower mass – total flower mass divided by number of flowers in the inflorescence.	–	0.00001 g
Scape height – measured from the plant base to the top of the inflorescence.	Straightened scape was measured with a ruler on herbarium specimens.	1 mm
Leaf blade diameter – mean value of the two perpendicular blade width measurements. This trait was measured and averaged for two largest plant leaf blades.	Measured with a digital calliper on herbarium specimens.	0.1 mm
Root : Shoot ratio – root mass divided by plant aboveground mass.	–	–
Leaf mass fraction – total leaf mass divided by total plant mass.	–	–
Flower aboveground mass fraction – total flower mass divided by plant aboveground mass.	–	–

2

Table 3 (on next page)

Summaries of linear mixed-effects models for fitting *Soldanella carpatICA* traits to elevation.

Elevational model range - mod₂₃₇₀: 890–2370 m a.s.l., mod₁₉₈₀: 890–1980 m a.s.l.; P_{model selection} – test between straight line and curvilinear line models; t, P – test of model significance at the significance level of 0.05.

1

	Elevational model range	P _{model selection}	Intercept a	Slope b ₁	Slope b ₂	t	P
Aboveground plant mass (g)	mod ₂₃₇₀	0.0048	7.340×10^{-2}	3.389×10^{-4}	-1.447×10^{-7}	-2.858	0.0067
	mod ₁₉₈₀	0.4402	3.368×10^{-1}	-6.000×10^{-5}	–	-2.099	0.0436

Table 4(on next page)

Fitted values of *Soldanella carpatica* traits and percentage traits changes across elevations.

All percentage changes in trait values are referred to fitted values at the base of elevational gradient at 890 m a.s.l. Trait values at 890 m a.s.l. were fitted by linear mixed-effects models constructed for the 890–1,980 m a.s.l. elevational ranges, values at 2370 m a.s.l. were fitted by models constructed for the 890–2370 m a.s.l. elevational ranges, and values at 1,980 m a.s.l. were averaged based on the fitted values from the both models; *ns* – not significant model used for fitted values estimation.

1

	Fitted value at 890 m a.s.l.	Fitted value at 1,980 m a.s.l.	Fitted value at 2,370 m a.s.l.	Change per 100 m increase in elevation in the 890– 1,980 m a.s.l. range (%)	Change per 100 m increase in elevation in the 1,980– 2,370 m a.s.l. range (%)	Total change with an increase in elevation from 890 m to 2,370 m a.s.l. (%)
Aboveground plant mass (g)	0.2834	0.1976	0.0639	− 2.1	− 12.1	− 77.5
Root mass (g)	0.1612	0.1505	0.0794	+ 0.2 <i>ns</i>	− 11.3	− 50.7
Total leaf mass (g)	0.2257	0.1459	0.0476	− 2.7	− 11.2	− 78.9
Scape mass (mg)	40.12	35.97	10.60	+ 0.2 <i>ns</i>	− 16.2	− 73.6
Total flower mass (mg)	17.58	15.79	5.54	+ 0.1 <i>ns</i>	− 15.0	− 68.5
Individual flower mass (mg)	5.58	4.97	2.99	− 0.4 <i>ns</i>	− 9.1	− 46.3
Scape height (mm)	156.7	120.6	98.5	− 1.8	− 3.6	− 37.2
Leaf blade diameter (mm)	25.4	18.2	11.1	− 2.3	− 7.2	− 56.4
Root : Shoot ratio	0.6008	0.8425	0.9671	+ 3.4	+ 5.3	+ 61.0
Leaf mass fraction	0.5025	0.4104	0.3802	− 1.7	− 1.5	− 24.3
Flower aboveground mass fraction	0.0670	0.0900	0.0958	+ 3.3	+ 2.2	+ 42.8

2

Figure 1

Soldanella carpatica habit.

Figure 2

Location of the 40 elevational sites sampled for *Soldanella carpatica* in the Polish Tatra Mts., Western Carpathians.

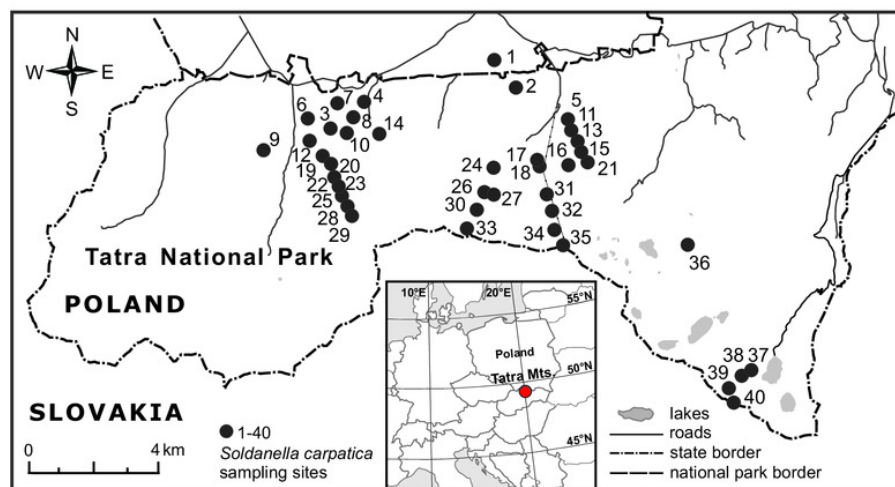

Figure 3

Elevational variation in morphological traits of *Soldanella carpatica*.

Solid lines represent the result of the mixed-effect models fitted to the 890–1,980 m a.s.l. range, interrupted lines represent models fitted to the entire 890–2,370 m a.s.l. range, the surrounding bands represent the 95% confidence intervals; P_{1980} , P_{2370} – p-value of model significance fitted for 890–1,980 m a.s.l. and 890–2,370 m a.s.l. elevation ranges, respectively; ns – non significant model at 0.05 significance level.

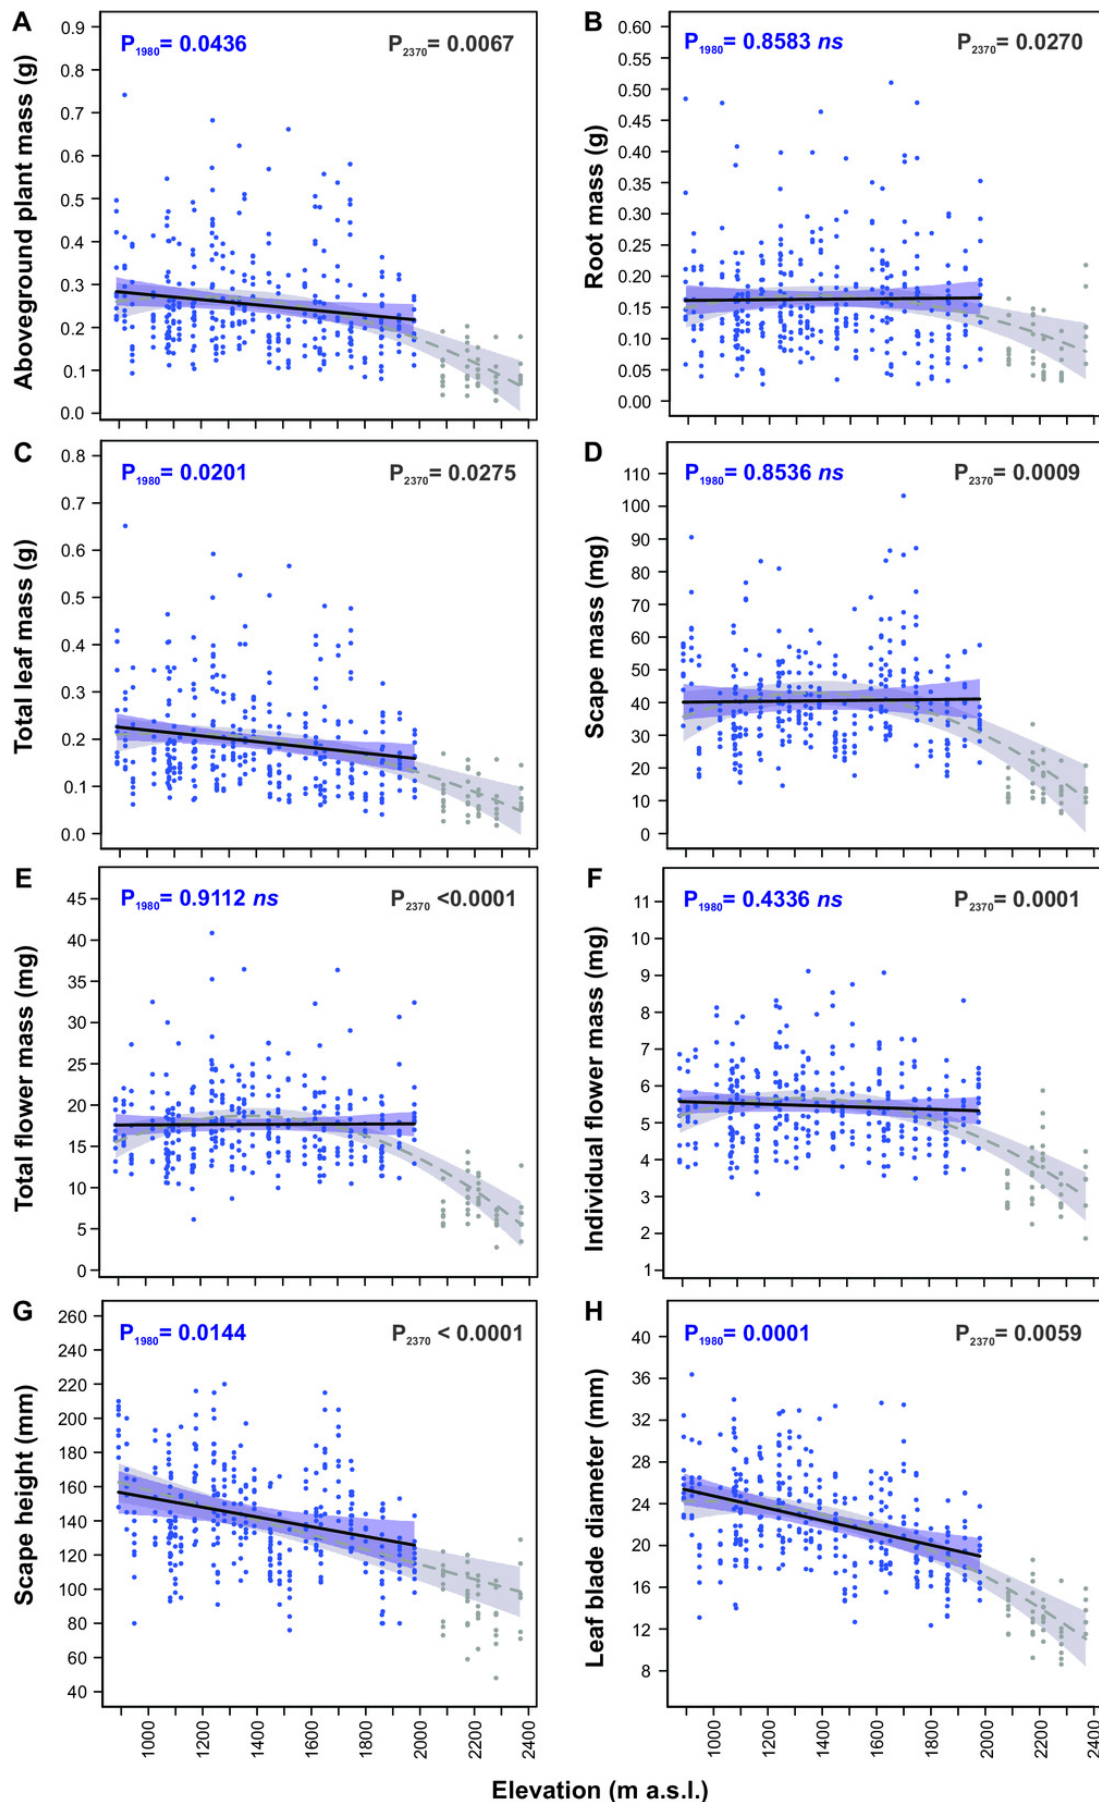

Figure 4

Elevational variation in *Soldanella carpatica* dry mass allocation traits.

Solid lines represent the result of the mixed-effect models fitted to the 890–1,980 m a.s.l. range, interrupted lines represent models fitted to the entire 890–2,370 m a.s.l. range, the surrounding bands represent the 95% confidence intervals; P_{1980} , P_{2370} – p-value of model significance fitted for 890–1,980 m a.s.l. and 890–2,370 m a.s.l. elevation ranges, respectively.
