

# A crab swarm at an ecological hotspot: patchiness and population density from AUV observations at a coastal, tropical seamount

Jesús Pineda, Walter Cho, Victoria Starczak, Annette F. Govindarajan, Héctor M. Guzman, Yogesh Girdhar, Rusty C Holleman, James Churchill, Hanumant Singh, David K Ralston

A research cruise to Hannibal Bank, a seamount and an ecological hotspot in the coastal eastern tropical Pacific Ocean off Panama, explored the zonation, biodiversity, and the ecological processes that contribute to the seamount's elevated biomass. Here we describe the spatial structure of a benthic anomuran red crab population, using submarine video and autonomous underwater vehicle (AUV) photographs. High density aggregations and a swarm of red crabs were associated with a dense turbid layer 4-10 m above the bottom. The high density aggregations were constrained to 355-385 m water depth over the Southwest flank of the seamount, although the crabs also occurred at lower densities in shallower waters (~280 m) and in another location of the seamount. The crab aggregations occurred in hypoxic water, with oxygen levels of 0.04 ml/l. Barcoding of Hannibal red crabs, and pelagic red crabs sampled in a mass stranding event in 2015 at a beach in San Diego, California, USA, revealed that the Panamanian and the Californian crabs are likely the same species, *Pleuroncodes planipes*, and these findings represent an extension of the southern endrange of this species. Measurements along a 1.6 km transect revealed three high density aggregations, with the highest density up to 78 crabs/m<sup>2</sup>, and that the crabs were patchily distributed. Crab density peaked in the middle of the patch, a density structure similar to that of swarming insects

## 18 **Abstract**

19           A research cruise to Hannibal Bank, a seamount and an ecological hotspot in the coastal  
20 eastern tropical Pacific Ocean off Panama, explored the zonation, biodiversity, and the  
21 ecological processes that contribute to the seamount's elevated biomass. Here we describe the  
22 spatial structure of a benthic anomuran red crab population, using submarine video and  
23 autonomous underwater vehicle (AUV) photographs. High density aggregations and a swarm of  
24 red crabs were associated with a dense turbid layer 4-10 m above the bottom. The high density  
25 aggregations were constrained to 355-385 m water depth over the Southwest flank of the  
26 seamount, although the crabs also occurred at lower densities in shallower waters (~280 m) and  
27 in another location of the seamount. The crab aggregations occurred in hypoxic water, with  
28 oxygen levels of 0.04 ml/l. Barcoding of Hannibal red crabs, and pelagic red crabs sampled in a  
29 mass stranding event in 2015 at a beach in San Diego, California, USA, revealed that the  
30 Panamanian and the Californian crabs are likely the same species, *Pleuroncodes planipes*, and  
31 these findings represent an extension of the southern endrange of this species. Measurements  
32 along a 1.6 km transect revealed three high density aggregations, with the highest density up to  
33 78 crabs/m<sup>2</sup>, and that the crabs were patchily distributed. Crab density peaked in the middle of  
34 the patch, a density structure similar to that of swarming insects.

## 35 **Background**

36           Seamounts are distinct oceanic habitats found in all oceans (Wessel et al. 2010), yet key  
37 first-order ecological processes are not well understood (Clark et al. 2010). Communities of  
38 benthic species on seamounts are regionally isolated, with elevated, shallow rocky habitat  
39 patches surrounded by deep sedimentary plains. These two environmental axes, type of substrate  
40 (hard vs. soft), and depth (gradients in food, light, and oxygen), create horizontal and vertical  
41 patterns in faunal zonation (Pitcher et al. 2008; Thresher et al. 2014). These patterns are likely  
42 determined regionally by circulation and larval dispersal, and vertically by physical factors and  
43 biological interactions. In the pelagic environment, the trapping and concentration of pelagic  
44 planktonic biomass around seamounts, due to hydrodynamic and behavioral processes, result in  
45 local increase of predators -such as fish and marine mammals (Klimley et al. 2005; Morato et al.  
46 2010; Morato et al. 2008). Thus, seamounts are ecological hotspots in the sense that many  
47 biological and physical processes combine to produce high benthic and pelagic biomass, and  
48 higher biodiversity. Seamounts are productive – their shallow summits have been fished for  
49 centuries and the biomass of zooplankton is unusually high, but debate remains over the  
50 mechanism of pelagic biomass enrichment. A commonly cited hypothesis is that zooplankton  
51 and fish productivity result from phytoplankton growth due to topographic induced upwelling of  
52 nutrients to euphotic waters, but the importance of this mechanism has been recently challenged  
53 (Genin & Dower 2007). Seamounts harbor valuable yet slow growing resources, such as reef-  
54 building corals (e.g., scleractinians), black corals (e.g., antipatharians), soft-corals (e.g.,  
55 gorgonians), and fish, some of which can live over 100 years (e.g., orange roughy) (Koslow  
56 1997). These habitats, however, have been under-sampled and under-studied, with less than 1%

57 of all seamounts explored (Clark et al. 2010). The occurrence of seamounts in open oceans  
58 beyond national jurisdiction, and advances in deep-sea fishing practices have resulted in severe  
59 anthropogenic pressure on seamount populations, which due to their life history characteristics  
60 are amongst the least resilient populations in the marine environment (Koslow 1997; Schlacher  
61 et al. 2010).

62 *Pleuroncodes planipes* (Stimpson, 1860) adult crabs, also known as red crabs, tuna crabs  
63 and “langostilla”, occur in pelagic waters and in deep continental shelf and continental slope  
64 benthic habitats. Larvae and small individuals ( $\sim$  2.6 cm standard carapace length) tend to  
65 dominate the pelagic fraction off western Baja California, with larger organisms occurring  
66 exclusively in the benthos (Boyd 1967). Large individuals reproduce, but observations of pelagic  
67 ovigerous females and their larvae in waters over bathyal and abyssal depths ( $\sim$ 2000 – 3500 m)  
68 suggests that a fraction of the pelagic population can reproduce as well (Longhurst & Seibert  
69 1971). *P. planipes* can be extremely abundant, with accounts of dense pelagic patches up to 7 -  
70 10 km (Gómez-Gutiérrez et al. 2000). (See also the casual account of a 16 km patch by B.  
71 Shimada, quoted in Boyd 1967.) Off Baja California *P. planipes* is the main prey of large pelagic  
72 predators such as yellowfin tuna and skipjack tuna (Alverson 1963). *P. planipes* is well adapted  
73 to its pelagic lifestyle, where it can feed both on phytoplankton, by specialized filtration, and on  
74 small zooplankton (Longhurst et al. 1967). On benthic habitats, galatheid crabs are deposit  
75 feeders and scavengers (Lovrich & Thiel 2011; Nicol 1932). Benthic *P. planipes* ingest  
76 particulate organic matter (detritus associated with sediments), phytoplankton cells, and small  
77 crustaceans, foraminiferans and radiolarians (Auriolles-Gamboa & Pérez-Flores 1997). When

78 feeding on bottom sediments with diatoms, detritus and small organisms, galatheid crabs' "third  
79 maxillipeds... act as brooms" (Nicol 1932), which would disturb and resuspend fine sediment.

80 Most studies on *Pleuroncodes planipes* have been done in pelagic waters, and have  
81 provided little information on the benthic habitat. Boyd (1967) found that benthic *P. planipes*  
82 ranged from ~100 to 300 m water depth off western Baja California, with smaller individuals  
83 found in shallower bottoms, and population densities up to 11/m<sup>2</sup>. These distributions correlated  
84 with oxygen minima waters, with oxygen levels below 0.5 ml/l. Boyd (1967) and Robinson and  
85 Gómez-Gutiérrez (1998) found that some benthic individuals tend to migrate from the bottom to  
86 the upper water column. The typical northern geographic endrange of *P. planipes* is somewhere  
87 in Baja California. Intermittently, particularly during the El Niño phase of the El Niño Southern  
88 Oscillation (ENSO), its geographic range expands northward to California (Longhurst 1966;  
89 Smith 1985). The southernmost geographic endrange of *P. planipes* appears to be somewhere in  
90 Costa Rica (Wicksten 2012), where it is thought to overlap with the southern range of  
91 *Pleuroncodes monodon* (Macpherson et al. 2010; Wehrmann et al. 2010; Wicksten 2012). The  
92 center of abundance of pelagic *P. planipes* is in western Baja California (Brinton 1979; Gómez-  
93 Gutiérrez et al. 2000; Longhurst 1968). The distribution and abundance of benthic *P. planipes* is  
94 not well documented, particularly south of Baja California.

95 We present findings from a research cruise to Hannibal Bank, a coastal seamount in the  
96 Gulf of Chiriquí, Eastern Tropical Pacific coastal ocean off Panama (Fig. 1). This cruise  
97 explored the mechanisms that contribute to high densities of benthic and pelagic organisms in an  
98 ecological hotspot and examined the seamount biodiversity and the benthic community zonation

99 along the depth gradient. Work included (a) submarine dives to collect, film and observe  
100 firsthand the benthic habitats, with DNA extractions of collected organisms performed onboard,  
101 (b) autonomous underwater vehicle (AUV) transects to map population densities of abundant  
102 benthic fauna, and (c) hydrographic and velocity measurements over the seamount using a  
103 conductivity, temperature, depth (CTD) and oxygen profiler and a hull-mounted acoustic  
104 Doppler current profiler. Hannibal seamount and its shallow top, Hannibal Bank, are within the  
105 recently created Coiba National Park, a [UNESCO World Heritage site](#), off the Pacific coast of  
106 Panama. Hannibal Bank harbors abundant large fish sustaining artisanal fisheries, and is a  
107 destination for international sport fishermen. The flat-topped triangular shaped seamount rises  
108 from 450 m to ~40 m, occupying an area of 83 km<sup>2</sup> (Fig. 2). Proximate to the continental shelf  
109 edge, it is ~20 km west of Coiba Island, 60 km from the main coast, and centered at about 07°  
110 24' N - 82° 3' W (Cunningham et al. 2013). Hannibal seamount communities are likely  
111 influenced by several physical processes, including synoptic upwelling from December to late  
112 April (D'Croz & O'Dea 2007), low aragonite saturation state (Manzello et al. 2008), low oxygen  
113 sub-thermocline waters, low salinity from runoff and precipitation (~3 m yearly precipitation),  
114 sharp thermal stratification, large internal tides, and a 4 m tidal range (Dana 1975; Pineda et al.  
115 2009; Starczak et al. 2011).

116 On the last dive of the research cruise we observed extraordinarily high densities of  
117 anomuran galatheid crabs near the bottom of the seamount, and an associated turbid layer over  
118 the bottom. The encounter was unexpected and mesmerizing., We documented these  
119 observations with high definition video, a photo-transect, environmental water column  
120 measurements and genetic analysis of crab samples. Here we report on these observations, and

121 address the following questions: What is the distribution of the crabs along a transect? What are  
122 the patterns of variability in abundance within a patch? Is there a relationship between the turbid  
123 layer and the crab aggregations? Are the crabs observed over the Hannibal Seamount the same  
124 species as *Pleuroncodes planipes* found off of California?

## 125 **Methods**

126 The cruise onboard the M/V *Alucia* from 31 March to 20 April 2015 focused on Hannibal  
127 Seamount. Work included ecological surveys over all flanks of the seamount (Fig. 2), and fifteen  
128 submarine dives conducted with Nadir, a 3-person submarine, and 11 dives with RV2, a 2-person  
129 submarine with more robust sampling capabilities than Nadir. On most missions, the submarines  
130 surveyed starting from the bottom of the seamount and continued to the top, working in tandem,  
131 within ~150 m of each other. Twelve transects with the Seabed autonomous underwater vehicle  
132 (AUV) complemented the diving missions and surveyed similar areas, collecting benthic  
133 imagery. On a typical cruise day, submarines were deployed during the morning and the Seabed  
134 AUV in the evening. Here we focus on observations completed on 18 and 19 April 2015, when  
135 crab aggregations were detected and studied. A conductivity, temperature, oxygen and depth  
136 profile was taken from the M/V *Alucia* using a Seabird SBE19 plus CTD in the vicinity of the  
137 submarine dive and Seabed AUV transect on 18 April 2015 (Fig. 2, blue cross in inset).

### 138 ***AUV observations and density estimation***

139 Seabed AUV conducted transects on the seamount, and obtained images to estimate  
140 densities of bottom organisms. Designed specifically for optical imaging of the seafloor (Singh  
141 et al. 2004b), the Seabed AUV has been used extensively for coral reef ecology, and other high

142 resolution imaging applications (Singh et al. 2004a; Williams et al. 2014). It is equipped with  
143 high-dynamic range cameras (Singh et al. 2007) to provide species documentation via imagery  
144 that can be corrected for the nonlinear attenuation of light in the water. Seabed AUV navigated at  
145 a speed of  $\sim 20 - 25$  cm/s and mean altitude of  $3.5 - 4.5$  m above the bottom along a predefined  
146 track, adjusting its altitude using a high frequency acoustic Doppler profiler. Seabed took 1024  
147 by 1380 pixel images of the seafloor that was illuminated with a strobe, and recorded  
148 temperature, conductivity, depth, and altitude. The camera pixels are square and the field of view  
149 is  $45^\circ$  in the horizontal and  $33^\circ$  in the vertical. Image width,  $x$ , is determined from altitude  
150 (height above bottom),  $z$ , by noting that  $0.5(x/z) = \tan(45/2)$ , which gives  $x = 0.828z$ . Because  
151 the pixels are square, the image height,  $y$ , is proportional to the number of pixels; i.e.,  
152  $y = x(1024/1380)$ . AUV specific altitude is used for every image, and image area is calculated  
153 as  $x \cdot y$ .

154 The Seabed AUV was programmed to take photographs every  $\sim 4$  seconds, with image  
155 overlap. We examined every third image (12 s interval), which gave a sequence with no image  
156 overlap. The non-analyzed images were used to resolve ambiguities in identification. Images  
157 were inspected for crabs and other organisms by eye, and all organisms were counted in each  
158 image.

159 Species identification of the crabs was confirmed by DNA barcoding of individuals in  
160 our samples (described below). Images from the Seabed AUV were light-corrected and inspected  
161 for organisms and type of substrate. A catalog of organisms was created from the photographs,  
162 and each morphospecies received a code. *Pleuroncodes planipes* were easily distinguished in the

163 video recording taken from the submarine dives, and in the Seabed AUV images. To estimate  
164 crab density (#/m<sup>2</sup>), the number of crabs was divided by estimated image area in each  
165 photograph.

### 166 ***Patchiness estimate***

167 Patchiness of *P. planipes* was estimated with  $I_{\text{mod}}$  using the formula of Bez (2000)  
168 modified by Décima and Ohman (2010). This index, based on Lloyd's index, considers a transect  
169 that does not sample the entire range of the species:

$$170 \quad I_{\text{mod}} = \left[ \frac{\sum_i z_i^2}{s \left( \sum_i z_i \right)^2} \right] N$$

171 where  $z_i$  is the density of the crabs in a given image,  $s$  is the size of the sampling unit used in the  
172 survey (mean quadrat size, 8.93 m<sup>2</sup>), and  $N$  is the number of images analyzed. For comparison,  
173 we also report the patchiness index of an unidentified stomatopod that was easily detected in the  
174 photographs.

### 175 ***Seamount sample collection and genetic barcoding***

176 The submarines collected benthic organisms opportunistically, using a robotic  
177 manipulator arm, a net and a sediment scoop. (Ministerio del Ambiente de Panama permit #  
178 SE/A-18-15) Collected specimens were stored in a compartmentalized honeycomb quiver or in a  
179 larger "biobox". After the submarine dives, the sampled organisms were held in chilled seawater  
180 until they were photographed and labelled (e.g., Fig. 3b), preliminary taxa identification based on

181 morphology was made, tissue was collected, and DNA extractions were performed onboard.  
182 Here, we focus on *Pleuroncodes* crabs. DNA was extracted using the DNEasy extraction kits  
183 (Qiagen) following the manufacturer's protocol. Upon return to the laboratory in Woods Hole,  
184 we conducted a genetic barcoding analysis on the crabs. A portion of the mitochondrial  
185 cytochrome c oxidase subunit I (COI) gene was amplified by PCR using the universal HCO-  
186 2198 and LCO-1490 primers (Folmer et al. 1994). PCR conditions were: 95°C for 3 minutes; 35  
187 cycles of 95°C for 30 seconds, 48°C for 30 seconds, and 72°C for 1 minute; and 72°C for 5  
188 minutes. PCR products were visualized on agarose gels stained with Sybr Safe (Life  
189 Technologies). PCR products were purified using Qiaquick PCR purification kits (Qiagen) and  
190 sequenced in both directions (MWG Eurofins Operon). Sequences were analyzed using the  
191 Geneious v. 7.1.7 software platform (Biomatters). Because morphological and video examination  
192 suggested that the crabs were *Pleuroncodes planipes*, we also sequenced COI from crabs  
193 identified as *P. planipes* from California for comparison (collection details below). Hannibal and  
194 California crab sequences were aligned with ClustalW (Larkin et al. 2007) using default  
195 parameters. The ends of the alignment were trimmed so that the dataset was complete for all  
196 taxa. Uncorrected p and Kimura 2-parameter distances were calculated and a neighbor-joining  
197 tree was constructed in PAUP\* (Swofford 2003).

### 198 ***Sample collection in a mass stranding event***

199 From January to August 2015 there were several mass stranding events of *Pleuroncodes*  
200 *planipes* crabs on Southern California beaches, documented from news reports, the Lexis-Nexis  
201 database, and informal surveys (J. Pineda, pers. obs., Table 1, *Supplemental Materials*). In June  
202 2015, crabs were observed in a San Diego beach (S. Searcy, Univ. San Diego, pers. com., and J.

203 Pineda, pers. obs.), and most of the crabs on the beach were still alive. At False Point, La Jolla  
204 (32°48' 28.51"N, 117°15'54.96"), we collected galatheid crabs on 2-5 June 2015, and preserved  
205 them in ethanol to provide reference specimens for DNA barcoding of seamount crabs.

## 206 **Results**

### 207 *Submarine observations and AUV mission*

208 On the last diving mission of the cruise, 18 April 2015, the two submarines dived to the  
209 bottom by the westward flank of the seamount (Fig. 2). Upon approaching the bottom, a very  
210 dense cloud of sediment was encountered; on no other submarine or AUV dive had such a dense  
211 cloud been observed (Fig. 3a). Altitude soundings from the submarine indicated that the turbid  
212 cloud extended 4 to 10 m over the ocean floor. As the submarine approached the bottom, a large  
213 number of galatheid crabs were encountered. RV2 took 13 min and 40 sec high-definition video  
214 of the crabs. A few still photographs and other video were taken from within the Nadir.

215 The video clips and photographs show that crabs were sometimes interacting among  
216 themselves (e.g., facing each other pulling out a dead crab) and with other organisms, including a  
217 sand eel. In some footage, crabs were sparsely distributed, and appeared to be sedentary. In other  
218 footage, benthic crabs were very dense, touching adjacent crabs, with most crabs moving broadly  
219 in the same direction (Fig. 3c and d) as a swarm (Video S1, Supplemental Materials). In this  
220 footage, some crabs jumped and swam a few 10's of cm and landed in another spot. A crab  
221 outside of the patch moved towards, and merged with the main patch (Fig. 3d). Sand eel, small  
222 pelagic fish, shrimp, and a few stomatopods were in close proximity to the crab aggregation.

223 The population observed in the footage was composed of relatively large crabs, with no  
224 visible smaller individuals, i.e.,  $\sim < 2.3$  cm carapace length. (See Fig. 3b for typical crabs, with  $\sim$   
225 2.7 cm carapace length; carapace length as measured by Gómez-Gutiérrez et al 2000). For most  
226 of the footage, the submarine hovered 2-3 m above the bottom, and the submarine and its lights  
227 did not appear to affect the behavior of the crabs. The high turbidity immediately above the  
228 bottom extended horizontally for at least 10's of m, and the turbid cloud appeared to be  
229 associated with the crab patch. As the submarine moved up the seamount slope and abandoned  
230 the patch, the density of crabs decreased abruptly, and the turbid cloud disappeared (Fig. 3d).

231 On 19 April 2015, the Seabed AUV was programmed to complete a photo-transect in the  
232 same region as the crabs seen on 18 April. The AUV dived to about 325 m, and then completed a  
233 1,610 m transect which included a set of turns to avoid potential high risk areas (e.g., rocky  
234 pinnacles) (Fig. 2., inset) Mean image width and length for this transect were 3.46 and 2.57, m,  
235 yielding a mean area per image of  $8.93 \text{ m}^2$  ( $n = 580$ ). Mean AUV altitude and speed was 4.18 m,  
236 and 0.23 m/s. The 580 analyzed photos were taken at 12 s intervals, and consecutive images had  
237 a gap of  $2.78 - 2.57 = 0.21 \text{ m}$ . (See Fig. 4 for an image from the AUV, with the highest density  
238 of crabs detected in the transect,  $77.2 \text{ individuals / m}^2$ ).

### 239 ***Pleuroncodes planipes* abundance**

240 *Pleuroncodes planipes* were detected in 12.2% of the Seabed AUV photographs. Images  
241 with counts of *P. planipes* tended to center around 365-m water depth (Fig. 5). Crabs were rare  
242 in the shallowest and deepest images, with bins centered at 305 and 405 m, although the number  
243 of images from these depths was low. Peak densities, with up to  $72.2 \text{ crabs/m}^2$ , occurred at 360

244 – 380 depths (Fig. 7). Three high-density patches were constrained to depths between 362 and  
245 381 m (Fig. 8, top panel), and were separated from each other by over 100's of meters along the  
246 northing (latitudinal) axis (Fig. 8, lower panel). The distribution of abundance in these peaks  
247 indicates that densities were low at the periphery, and that the maxima densities occur near the  
248 middle of the patch (Fig. 9). The distribution of crabs along the transect was very patchy, with  
249  $I_{\text{mod}} = 5.34$ . Unidentified stomatopods that always occurred as singletons in the images had  $I_{\text{mod}} =$   
250 3.54. The turbid layer was not apparent in the Seabed AUV images.

### 251 ***Galatheid crabs DNA barcode ID***

252 We obtained COI sequences for 6 specimens from Hannibal seamount and 4 specimens  
253 from the *Pleuroncodes planipes* stranding in California. Sequences were deposited in GenBank  
254 (Hannibal, KU179422-26, KU179431; La Jolla, KU179427-30). Five out of the 6 Hannibal  
255 specimens were obtained from the main crab swarm on 18 April 2015. The 6<sup>th</sup> specimen was  
256 obtained on 3 April 2015, at a depth of 278 m, when crabs were observed on the bottom at the  
257 Northeast flank of the seamount (near 7° 21.21' N, 82° 1.37' W) at low densities. The final  
258 alignment for the combined seamount and California dataset was 595 base pairs. Inspection of  
259 the amino acid translation indicated that the sequences did not represent pseudogenes. Sequences  
260 differed from each other by between 1 to 8 base pairs. Uncorrected p and Kimura 2-parameter  
261 distances were similar to each other and ranged from 0.00168 – 0.01363. There were no shared  
262 haplotypes and the mean pairwise distance (for both metrics) between Hannibal specimens was  
263 greater than the mean distance between Hannibal and California specimens (Table 1, Fig. 6).

## 264 ***Water properties***

265           The CTD cast revealed strong temperature, salinity, and oxygen stratification (Fig. 10).  
266   The temperature profile showed a sharp thermocline in the upper 40 m, with a temperature drop  
267   from 28.5°C at the surface to 17.4°C at 40 m, and a near-bottom temperature of 11.1 °C at ~365  
268   m. A halocline was also observed, with a salinity drop from 33.4 psu at the surface to 34.8 psu at  
269   40 m. Maximum salinity occurred at mid depths (34.9 psu at 180 m), with a slight freshening  
270   with increasing depth (to 34.8 psu at 365 m).

271           Oxygen concentration decreased rapidly with depth, from over 4.8 ml/l at the surface to  
272   1.1 ml/l at 50 m, and was less than 1.0 ml/l deeper than 250 m. The lowest oxygen value, 0.04  
273   ml/l, was obtained from the deepest measurement, 365 m, ~15 m above the bottom. Thus, *P.*  
274   *planipes* maximum densities occurred at depths where waters were oxygen depleted. The vertical  
275   gradients of temperature and oxygen concentration changed abruptly at about 238 m, with larger  
276   gradients seen below 238 m. The vertical salinity also changed at around 238 m, but more subtly.  
277   Beam attenuation data from the SBE CTD revealed a turbid layer around 365 m depth in which  
278   optical attenuation tripled.

## 279 **Discussion**

280           Based on DNA barcoding, the Hannibal seamount crabs appear to be the same species as  
281   *Pleuroncodes planipes* from California. COI is the most typically used species barcode gene  
282   (Bucklin et al. 2011), and sequence comparisons are frequently based on Kimura 2-parameter  
283   (K2P) distances (da Silva et al. 2011). K2P distances may not necessarily be the best distance  
284   metric for a given taxon (Collins & Cruickshank 2013; Srivathsan & Meier 2012), other metrics

285 may not necessarily perform better and the use of this metric permits straightforward  
286 comparisons with K2P distances from studies. Uncorrected p distances were similar to the K2P  
287 distances, and in both metrics, the mean distance between individuals at Hannibal Seamount was  
288 greater than the mean distance between Hannibal Seamount and California. Pairwise  
289 mitochondrial COI distances fell within the range of typical intraspecific distances for galatheids  
290 (da Silva et al. 2011). The southern range limit of *P. planipes* is considered poorly known  
291 (Hendrickx & Harvey 1999), although researchers have suggested Costa Rica (Wicksten 2012),  
292 and our observations here, supported by DNA sequences, may be the southernmost record.

293       Species have distinct patterns of variation in abundance over space, and understanding  
294 the factors that determine these patterns and their diversity is a central goal in ecology. Spatial  
295 distribution patterns may reflect individual and population processes, including settlement,  
296 dispersal, migration (Roa & Tapia 2000) and behavior. For example, gregarious behavior and  
297 swarming in insects may produce characteristic spatial patterns of abundance (Okubo & Chiang  
298 1974). Whereas practically all organisms have patchy distributions at some spatial scale of  
299 observation, the causes and consequences of patchiness can reflect fundamental ecological and  
300 life history characteristics (Marquet et al. 1993). For example, patchiness can be species specific  
301 and vary ontogenetically (Décima et al. 2010; Hewitt 1981), and species that face different  
302 degrees of patchiness may have evolved different life history strategies (e.g. Dagg 1977).  
303 Patchiness, may be driven by external (“vectorial”, environmental), reproductive, social (e.g.  
304 behavioral) and competitive (“coactive”) processes (Hutchinson, 1953). Physical–biological  
305 interactions, such as the swimming up response of zooplankton and larvae to downwelling

306 currents (Scotti & Pineda 2007), might also produce patchiness (e.g., aggregation at fronts), and  
307 explain why only certain taxa aggregate in particular hydrodynamic settings.

308         The distribution of *Pleuroncodes planipes* was highly patchy, similar to other galatheid  
309 populations (Freire et al. 1992; Roa & Tapia 2000), and  $I_{\text{mod}}$  values were higher than those of a  
310 stomatopod that occurred at smaller densities than *P. planipes*. The high *P. planipes* densities  
311 were constrained to a narrow subset of regions and depth ranges on Hannibal seamount. From  
312 the 26 submarine dives (15 missions to distinct sites) and the 12 AUV transects, we observed  
313 dense aggregations of crabs in only one region, the northwestern flank of the seamount, and  
314 these aggregations were constrained to ~355 – 385 m water depths. The AUV survey detected  
315 three peaks in abundance (*a-c*, Fig. 9), and in peak *b*, the observed density was 77 individuals /  
316  $\text{m}^2$ , one of the highest that have been measured for galatheid crabs (Lovrich & Thiel 2011, Table  
317 6.1). Our sampling protocol cannot resolve whether these density peaks are discrete patches or  
318 whether aggregations were connected. It is unlikely, however, that crabs in density peak *c* were  
319 connected to crabs in peak *b*, because crab distributions were observed to be constrained to 355-  
320 385 m, and the crabs in *b* and *c* were separated by shallower depths (Figs. 2 and 8).

321         The density distribution within each of the three abundance peaks detected in the survey  
322 is consistent with a pattern where density increases toward the center of distribution (Fig. 9).  
323 However, we do not know whether the AUV surveyed the center of the patch. The two high-  
324 density peaks at ~480 and 1440 m along the transect (Figs. 9a and 9c) each have an adjoining  
325 lower-density peak. These lower-density peaks may represent budding, small aggregations that  
326 have split from the main aggregation, and might grow into larger patches, or they might merge

327 into the larger, adjacent patch. These density distribution patterns are likely due to aggregation  
328 driven by the crab's gregarious behavior, and coordinated movement of the aggregation, a  
329 phenomenon that has been called swarming. Okubo et al. (2001) describe swarming as a  
330 phenomenon where a group of organisms move together. Swarms are arguably one of the few  
331 ecological phenomena that possess emergent properties, where the characteristics of the  
332 aggregation cannot be simply explained by adding the individual's behaviors (Parrish &  
333 Edelstein-Keshet 1999). In these complex systems, a focus on individual behavior is unlikely to  
334 explain the properties of the swarm. Whether all emergent properties in swarms are functional or  
335 not, is an open question (Parrish & Edelstein-Keshet 1999). The increase in density towards the  
336 center is consistent with other organisms that form swarms and aggregations (e.g., insects, krill  
337 and schooling fish, Okubo & Chiang 1974; Okubo et al. 2001), and patterns of abundance in  
338 other gregarious benthic populations where density increases towards the middle of the  
339 distribution might reveal a swarming behavior. Two other galatheid species have patterns where  
340 density increases towards the middle of the patch (Freire et al. 1992) but in these European  
341 *Munida* spp. species, the scale of the patches is a few tens of kilometers, compared to the ~100 m  
342 scale observed in our study. It is unclear whether the abundance structure of these *Munida* spp.  
343 and *Pleuroncodes planipes* patches are caused by the same processes. Dense benthic  
344 aggregations of other species of anomuran and brachyuran crabs (king crabs, spider crabs, tanner  
345 crabs, lyre crabs) have been observed, and some were related to reproduction (DeGoursey &  
346 Auster 1992; Powell & Nickerson 1965; Stevens et al. 1992; Stevens et al. 1994).

347 Crabs densities appeared to be higher and more clumped in the submarine video  
348 observations than in the AUV images (compare submarine video still frame Fig. 3 with AUV

349 Fig. 4). The submarine video still frames in Fig. 3 were taken when *Pleuroncodes planipes* were  
350 moving as a group, a swarm, and most organisms appeared to be oriented in the same direction.  
351 In the AUV images, a consistent crab orientation and the swarm motion were not obvious.  
352 Moreover, the turbid cloud observed from the submarine (Fig. 3) was not seen in any of the  
353 AUV images. The turbidity cloud was most likely produced by *Pleuroncodes planipes* activities,  
354 as the turbidity disappeared at the edge of the patch, and was not observed outside of the patch or  
355 in any other submarine dive or AUV missions. Diurnal patterns of activity might explain the  
356 differences in turbidity. Submarine observations were early in the day, whereas the AUV survey  
357 was done in the evening. However, another possibility is that crabs observed from the submarine  
358 were in a location with finer, and hence more easily suspended sediments than those surveyed by  
359 the AUV survey. However, the locations not far from each other (Fig. 2).

360         The resuspension of sediment initiated by crab activity may affect the benthic  
361 environment over the northwest seamount flank. Feeding of king crabs in waters ~3m deep off  
362 Kodiak Island, Alaska, resulted in a dense cloud of turbid water (Bradley & Stephen 2014), and  
363 Yahel (2008) found that bottom fish activity was an important mechanism for sediment  
364 resuspension and remineralization of organic matter between water depths of ~ 60 and 140-m in  
365 Saanich Inlet (Vancouver Island, BC, Canada).

366         *Pleuroncodes planipes* occurred at water depths with very low oxygen (0.04 ml/l at ~15  
367 m above the bottom where the crabs were observed). The affinity of some galatheids to low  
368 oxygen waters, and *P. planipes* in particular, is known (Boyd 1967; Lovrich & Thiel 2011).

369 Depth distribution of *P. planipes* and other galatheids might be related to these low oxygen  
370 levels (discussed by Lovrich & Thiel 2011), but more study is needed to test this hypothesis.

371 *Pleuroncodes planipes* occurs in very high densities in the pelagic environment, and this  
372 species mass strands yearly in shallow water and intertidal beaches near the center of its pelagic  
373 abundance, Bahía Magdalena, Baja California (Auriolles-Gaamboa et al. 1994), and more  
374 occasionally on California beaches (Table 1, Longhurst 1966; Smith 1985). While we were on  
375 hydrographic stations over Hannibal seamount and surrounding areas, we occasionally observed  
376 organisms that appeared to be pelagic red crabs swimming swiftly by the stern of the boat at  
377 night, illuminated by the vessel lights. Despite multiple attempts, we were not able to capture a  
378 specimen to assess its identity, so the occurrence of *P. planipes* in the water column above  
379 Hannibal seamount is unknown.

380 Our observations in Panama were conducted at roughly the same time when mass  
381 stranding events were registered in Southern California (Table 1, *Supplemental Material*), and  
382 the Hannibal and Californian individuals appear to be the same species based on their mtCOI  
383 sequences. Mass stranding of *Pleuroncodes planipes* in Southern California beaches had been  
384 linked to El Niño (Smith 1985). A full El Niño had not been declared for January-June 2015,  
385 when many stranding events were reported (Table 1, *Supplemental Material*). On the other hand,  
386 an unusually large pool of warm water developed in late 2013 and early 2014 in the coastal  
387 temperate eastern Pacific, and persisted through much of 2015 (Bond et al. 2015), apparently  
388 unrelated to El Niño. The current forecast (November 2015, by NOAA [Climate Prediction](#)  
389 [Center](#)), indicate that the anomalous warm-water pool condition has been followed by an El

390 Niño, and that a full El Niño is now in progress. The “pool or warm water” conditions in  
391 January-June 2015 may be related to anomalously warm waters observed in Southern  
392 California’s nearshore in fall 2014 (Reyns, Pineda, and Lentz, unpub.). These conditions may  
393 help explain the appearance of *P. planipes* in Southern California, as speculated by some news  
394 outlets. Whereas it is unlikely that that our observations of benthic aggregations at Hannibal are  
395 connected with the California mass stranding events, it is significant that *P. planipes* can be  
396 simultaneously abundant at the two distant locations and at two different habitats. The high  
397 densities of *P. planipes* likely impacted local pelagic, intertidal, and deep seamount food webs.

398         Allochthonous supply of biomass, where resources from one habitat or ecosystem  
399 subsidizes another system, influences local population community and dynamics (Polis et al.  
400 1997). Moreover, the episodic availability of large quantities of biomass to benthic and pelagic  
401 organisms and marine mammals, including the supply of terrestrial material and whale carcasses  
402 to benthic deep sea communities, the mass stranding of pelagic organisms in shallow habitats,  
403 and the sudden availability of a new resource, represent an opportunistic yet important source of  
404 nutrition to the “receiving” communities (Polis et al. 1997), and can influence food web structure  
405 and demographic rates (Watt et al. 2000). The massive availability of *Pleuroncodes planipes*  
406 might influence diverse food webs.

407         Because of its pelagic and benthic lifestyle, and its abundance, *Pleuroncodes planipes*  
408 likely plays an important role in some seamount, continental shelf and shallow water food webs  
409 in the subtropical and sub temperate eastern Pacific. Several authors have noticed the key role of  
410 *P. planipes* in the pelagic environment, by virtue of its abundance and trophic role (Alverson

411 1963; Gómez-Gutiérrez et al. 2000; Longhurst 1966; Longhurst et al. 1967; Robinson et al.  
412 2004). *P. planipes* was patchy but very abundant at Hannibal, and it might represent an important  
413 resource for pelagic predators at the seamount. More research is needed to assess the distribution  
414 and abundance of benthic *P. planipes*, as well as its potentially key role in semitropical and sub-  
415 temperate eastern Pacific seamount and continental shelf habitats.

## 416 **Acknowledgements**

417 We would like to express gratitude for the help and logistical support of the Captain and  
418 the crew of the M/V *Alucia*, the *Alucia*'s submarine team, Jeff Anderson, for programming and  
419 running the AUV operations, and keeping it safe, Alex Bocconcelli and WHOI's Marine  
420 Operations office support, the Ministerio del Ambiente de Panama for providing the research and  
421 export permits, including # SE/A-18-15, and the US State Department for cruise permit support.

602 **Tables**

603 Table 1. Pairwise distance comparisons for uncorrected p and K2P distance metrics. Minimum  
604 and maximum pairwise distances (for all comparisons) and the mean distances for pairs within  
605 and between sampling localities are shown.

	Minimum	Maximum	Within - Hannibal mean	Within - California mean	Hannibal - California mean
Uncorrected p	0.00168	0.01513	0.01042	0.00336	0.00732
K2P	0.00168	0.01536	0.01055	0.00337	0.00734

606

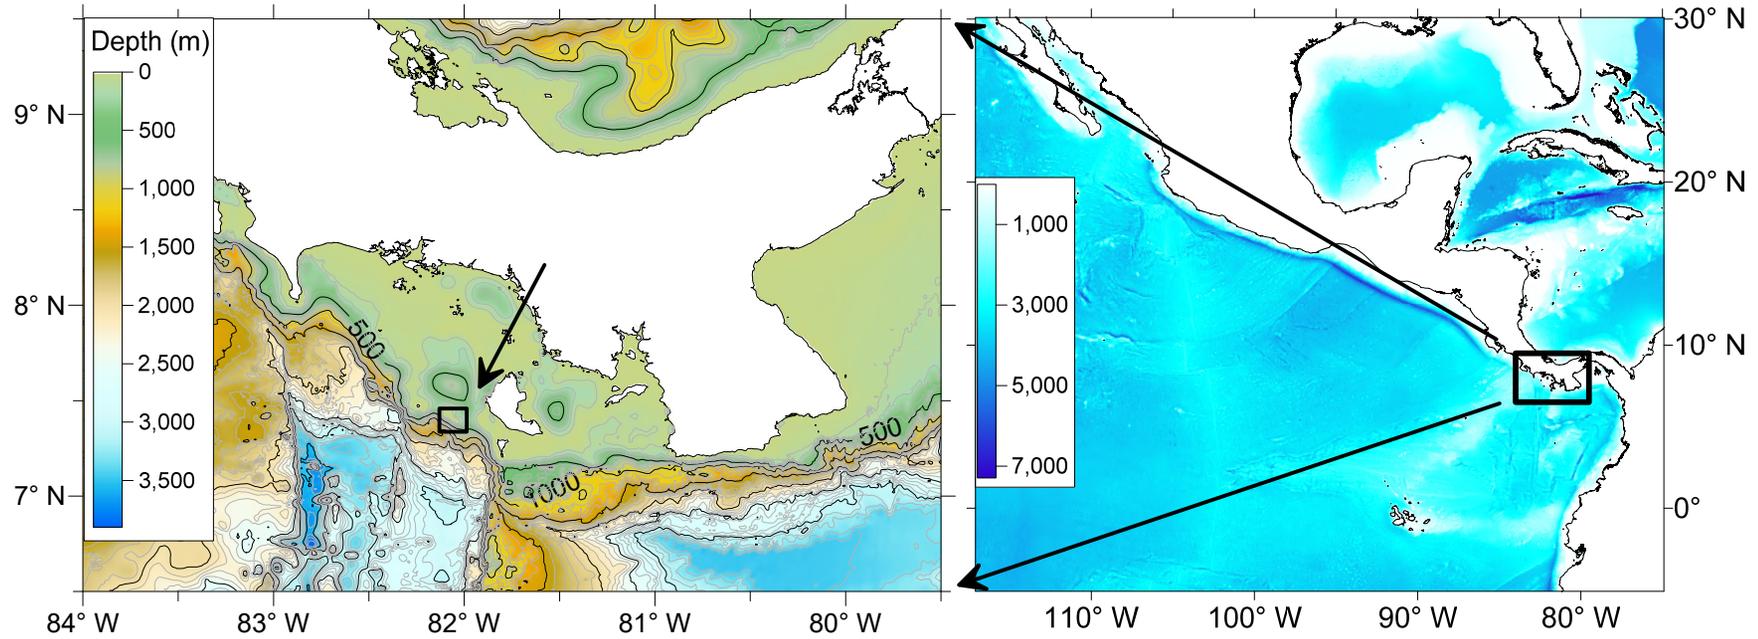

Fig 1. Map of the study area. Box in the right panel encloses the left panel, and the small box in the left panel encloses Hannibal Seamount. Bathymetry data from GEBCO.

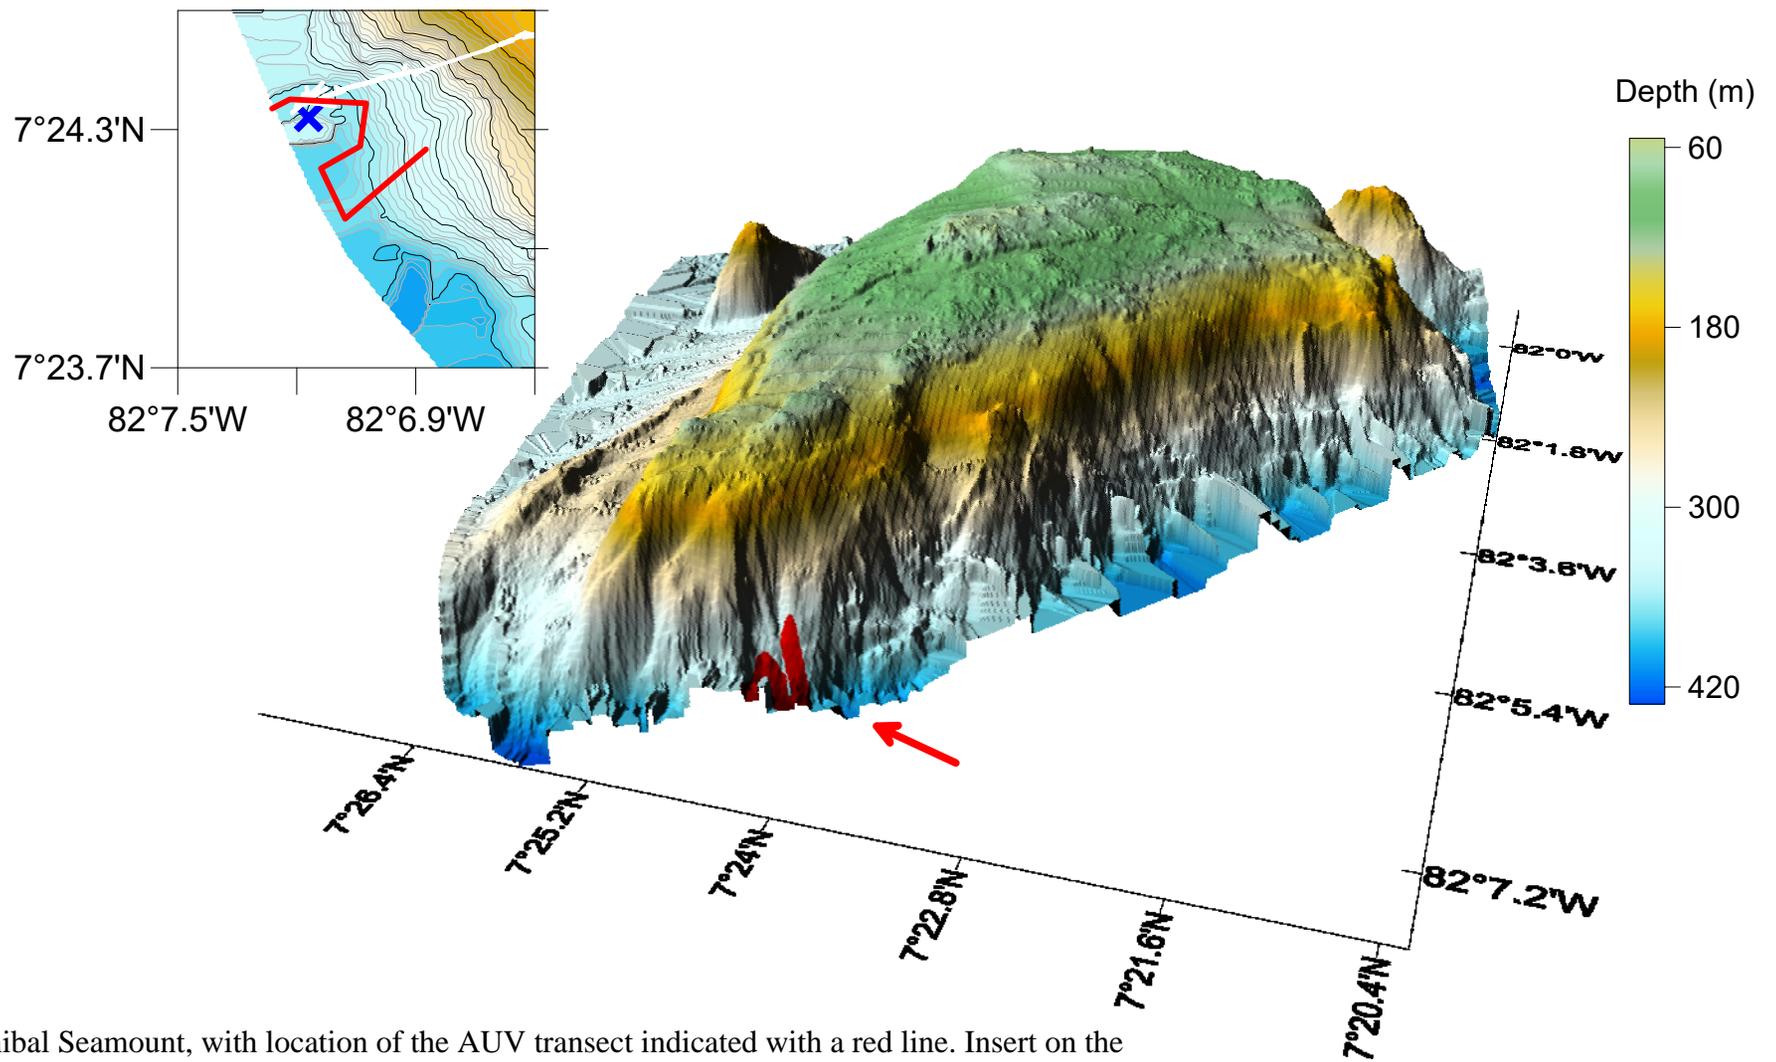

Fig. 2. Hannibal Seamount, with location of the AUV transect indicated with a red line. Insert on the left delineates AUV transect, with end of transect near the blue cross. The blue cross indicates the location of the CTD cast, and the submarine positions are in white. Depth data from Cunningham et al. (2013).

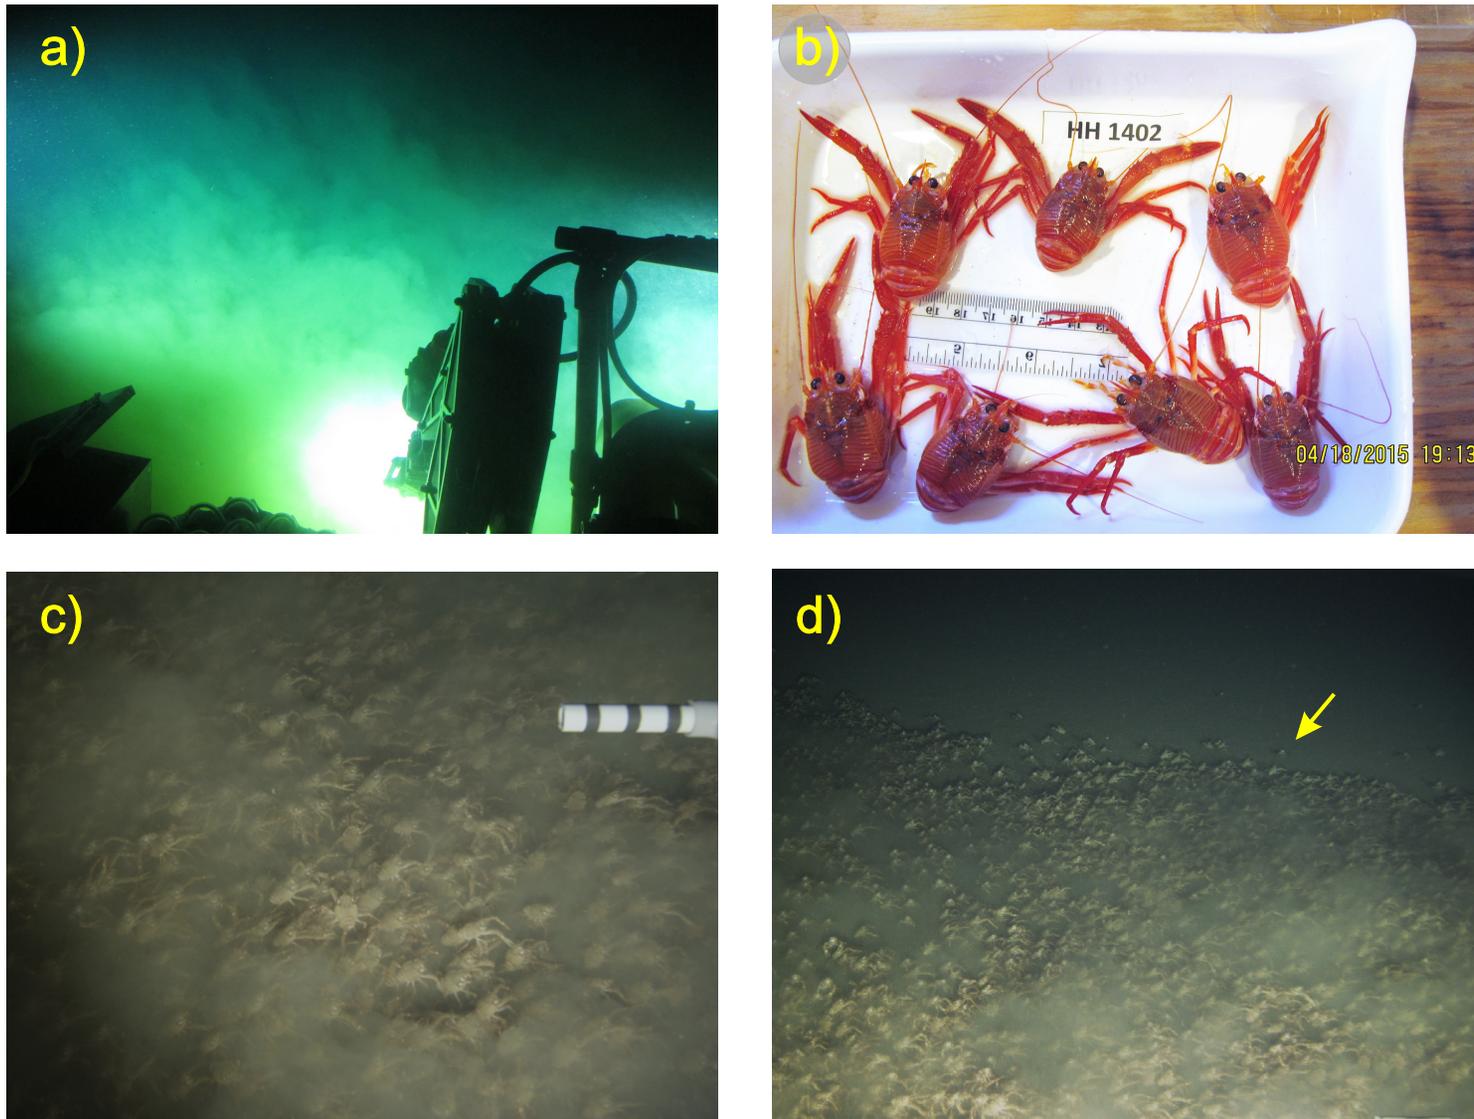

Fig. 3. Photographs and video still frames of *Pleuroncodes planipes* and its environment. a) Image taken within Nadir as it approached the bottom, from about 6 m above the bottom, where *P. planipes* aggregations were first found. b) *Pleuroncodes planipes* collected from the aggregation, with ruler scale in cm and English units. c) Still frame from HD video of a dense patch of *P. planipes* on the bottom. The white PVC segment is about 20.5 cm long d) Nearbed turbidity dropped at the edges of the *Pleuroncodes* patch. In the video the crabs were moving on the bottom towards the right, with a few crabs found beyond the boundary of the patch lagging behind the main aggregation. The crab marked with a yellow arrow was separate from the large patch and then merged into the patch by advancing in a direction perpendicular to the direction of patch movement.

Fig. 4. AUV photograph with the highest density of *Pleuroncodes planipes*.

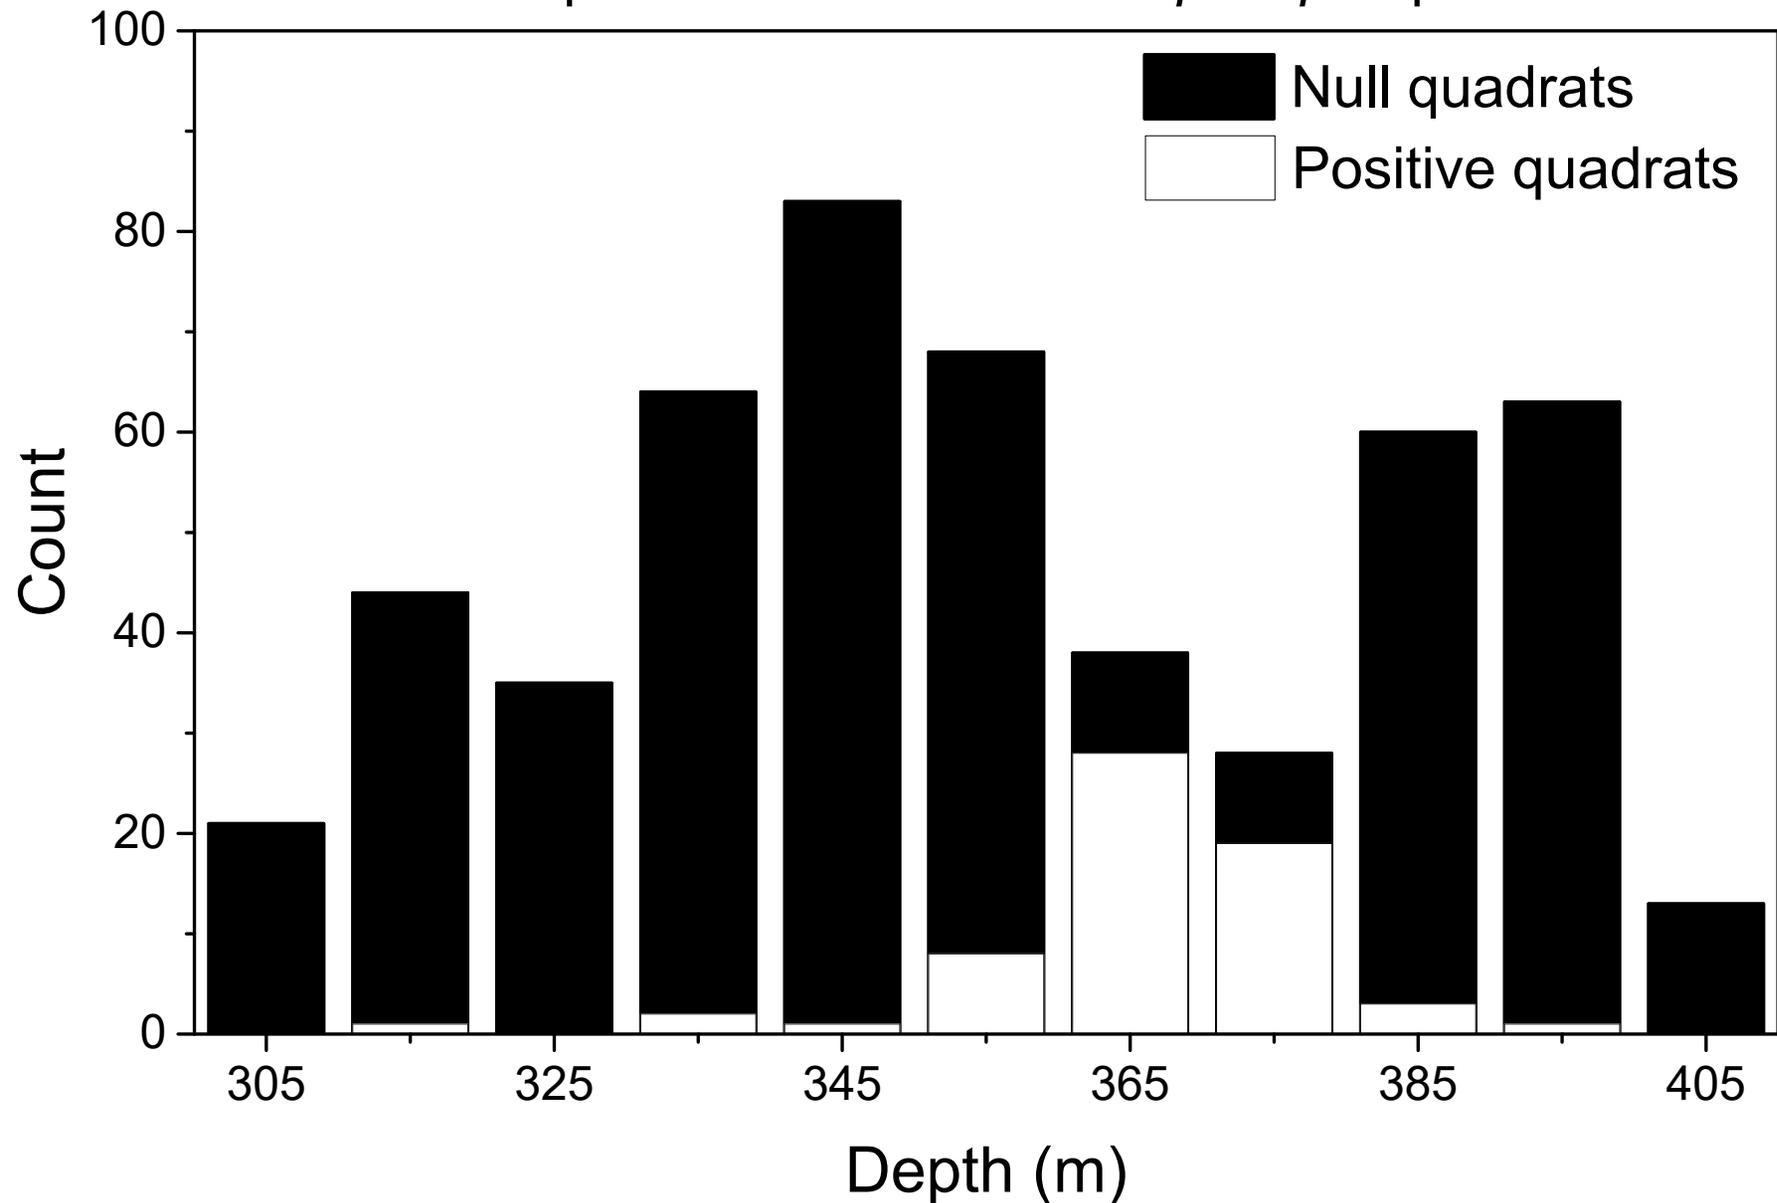

Photo quadrats: *Pleuroncodes planipes* presence

Fig. 5 Frequency distribution of quadrats with null and positive *Pleuroncodes planipes* counts. No *P. planipes* occurred in null quadrats, whereas positive quadrats are those in which at least one *P. planipes* was observed.

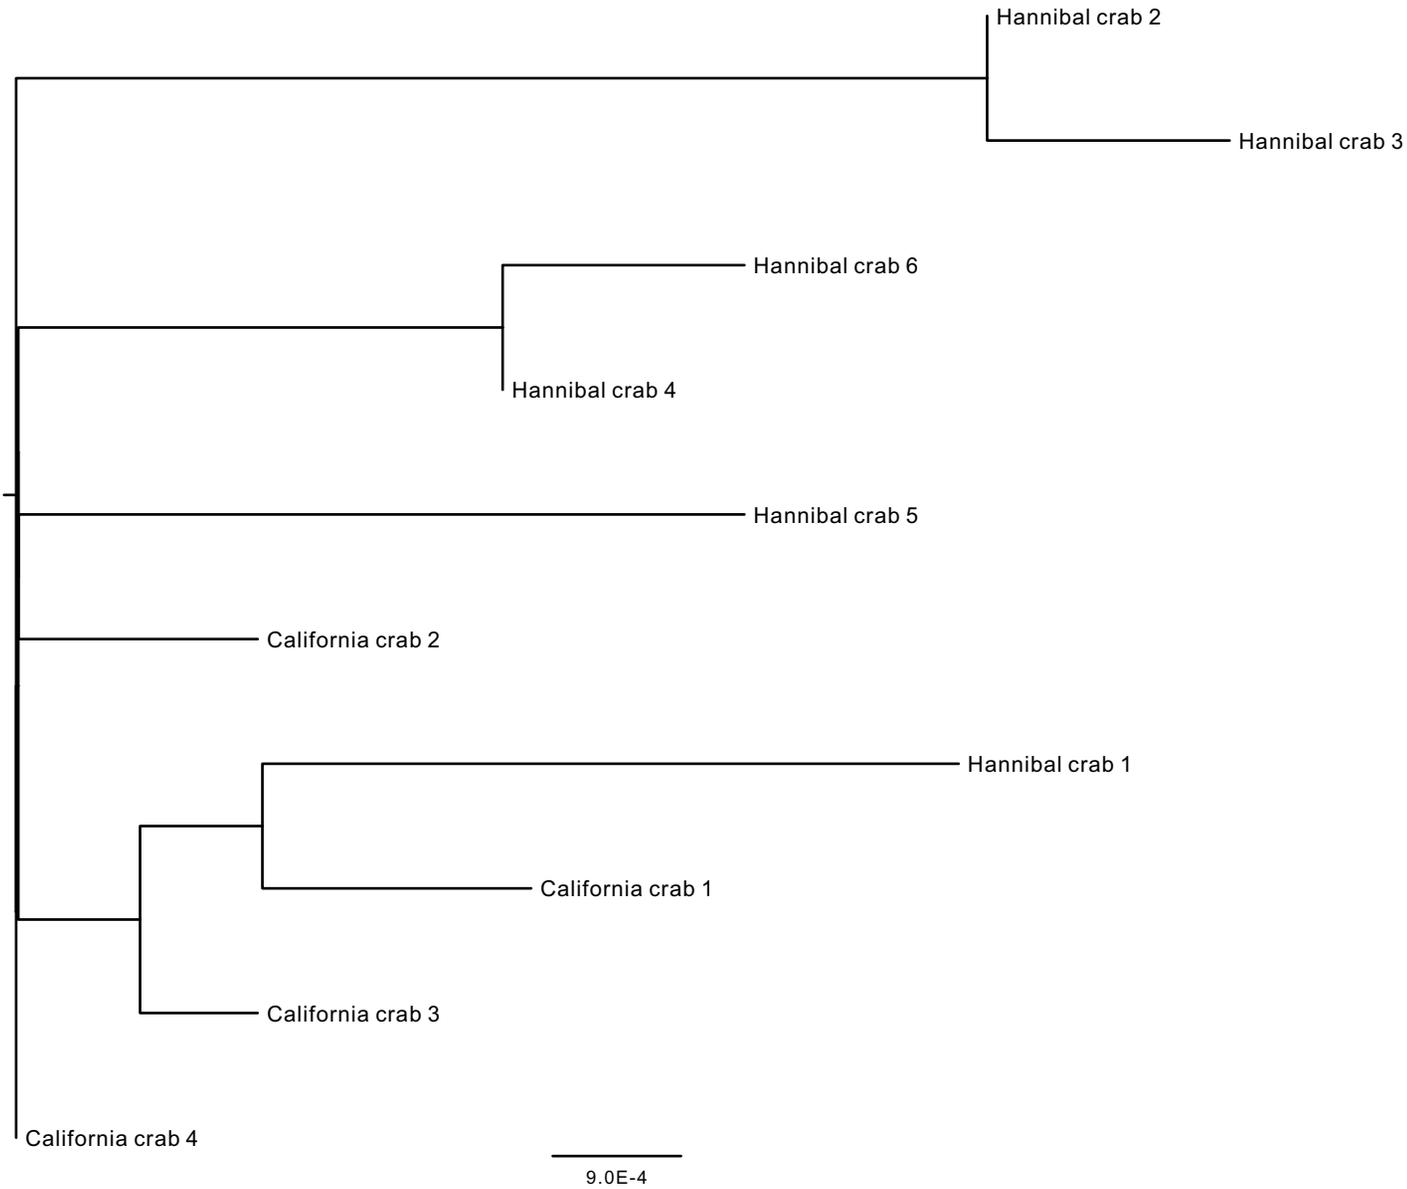

Fig. 6. Midpoint-rooted neighbor-joining topology based on mt COI Kimura 2-parameter distances. Crab number 5 was found on 3 April at another location on Hannibal seamount, and was not in an aggregation.

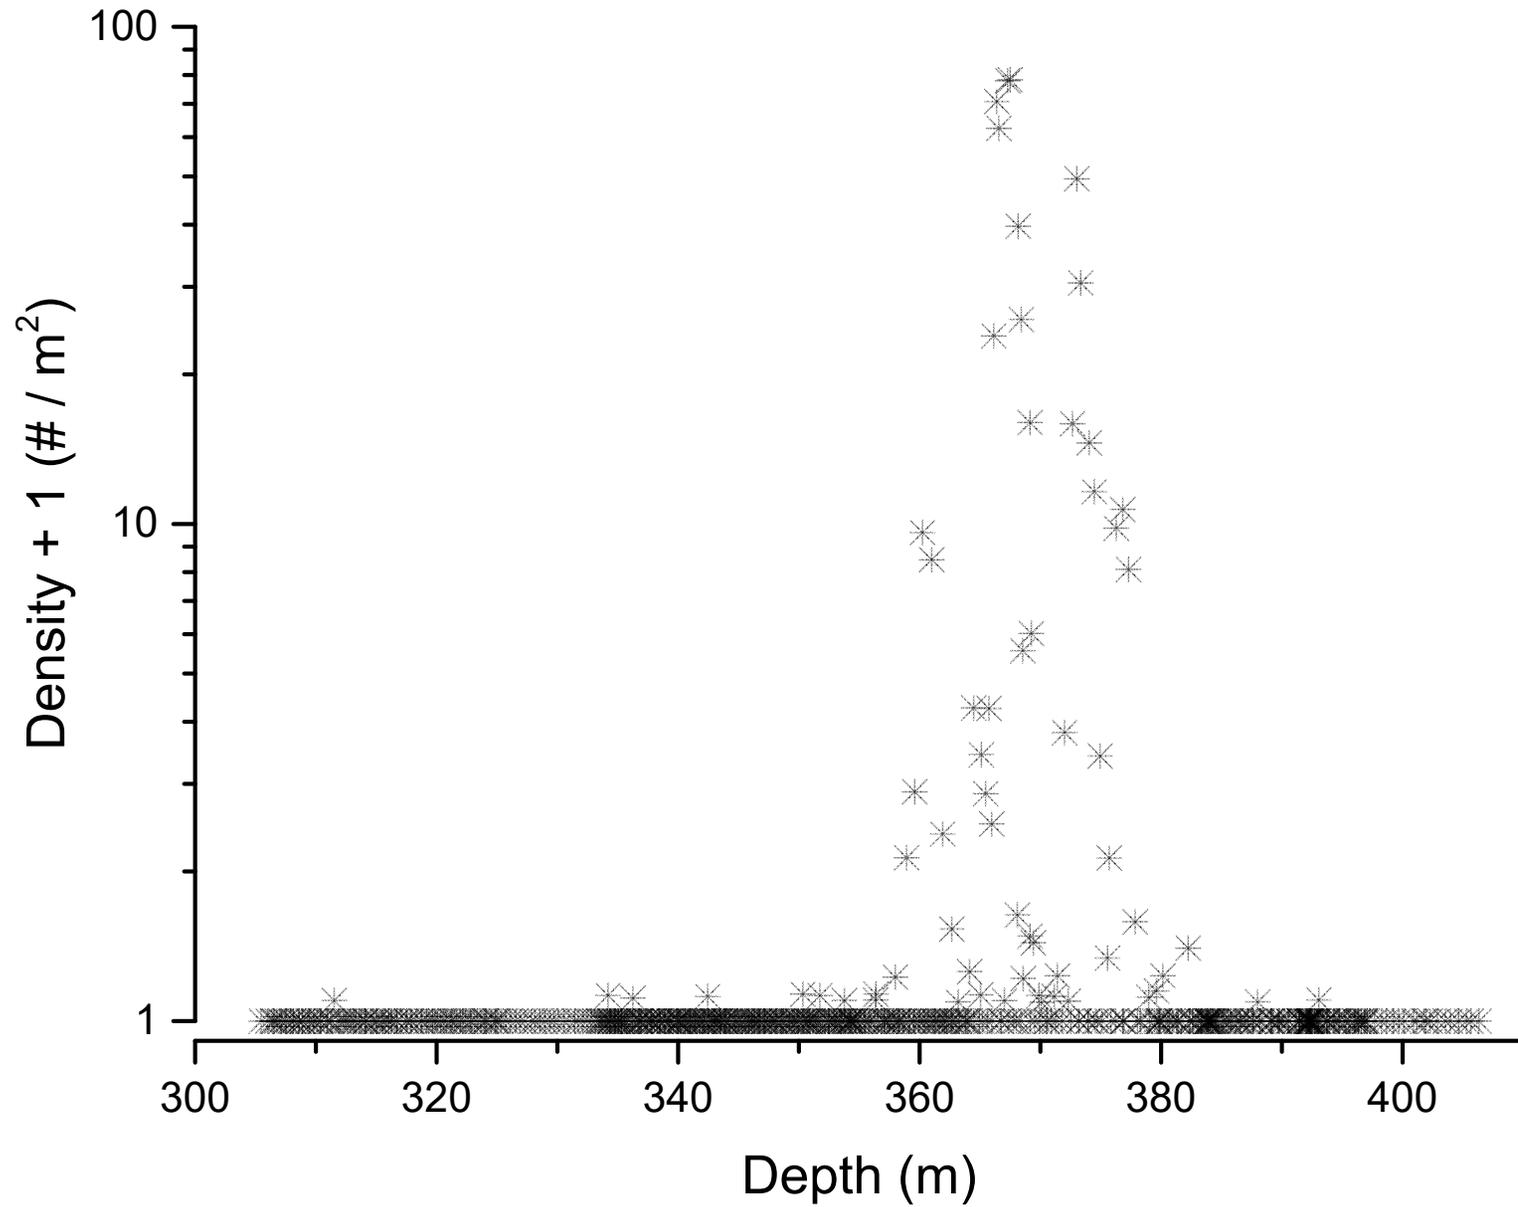

*Pleuroncodes planipes* density with depth

Fig. 7. *Pleuroncodes planipes* density with depth.

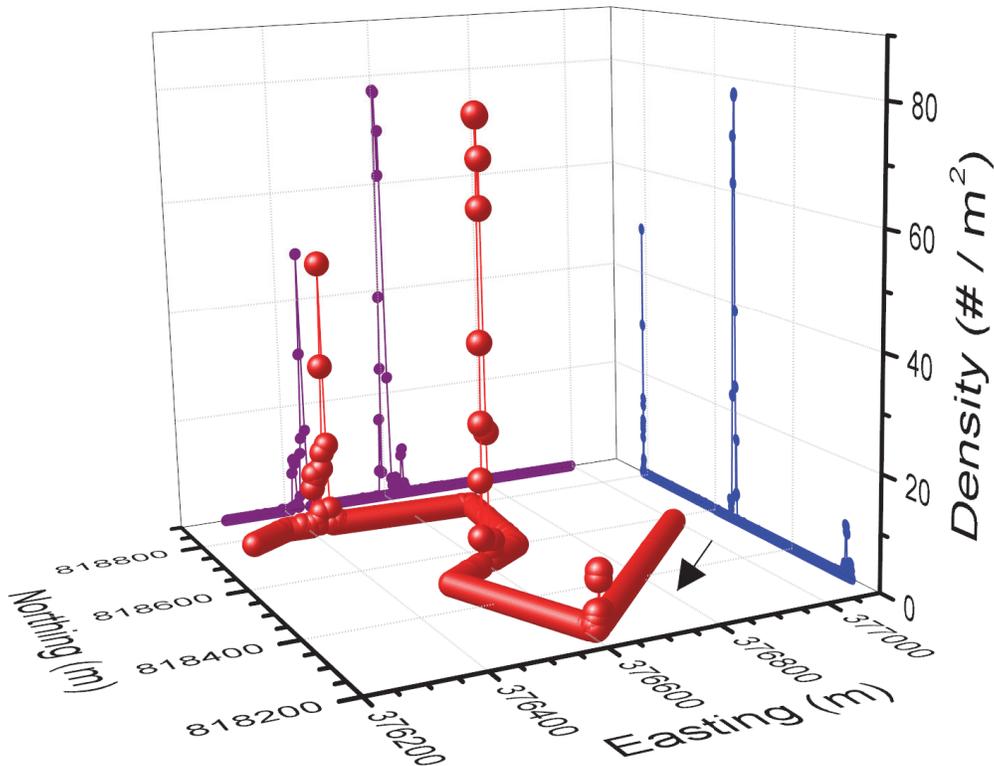

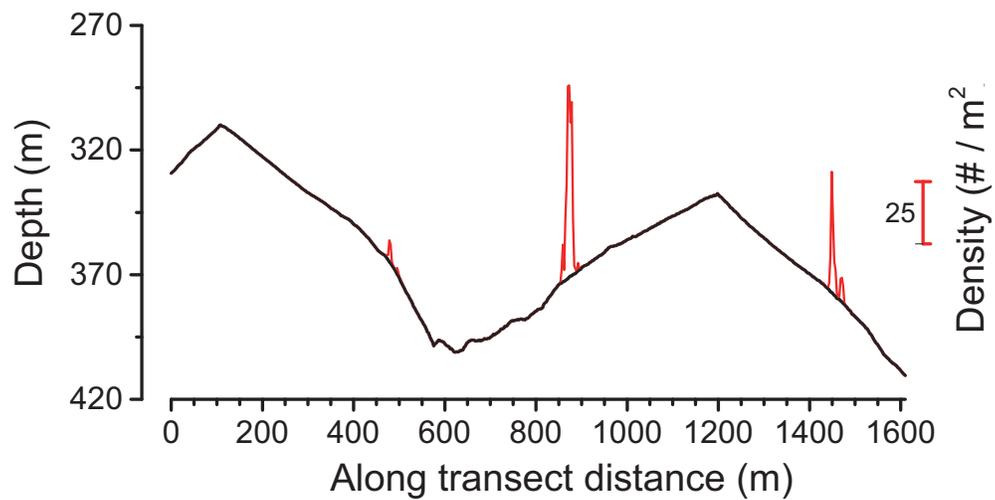

Fig. 8. Along transect *Pleuroncodes planipes* density on depth (top panel), and 3-d plot of density with latitude and longitude.

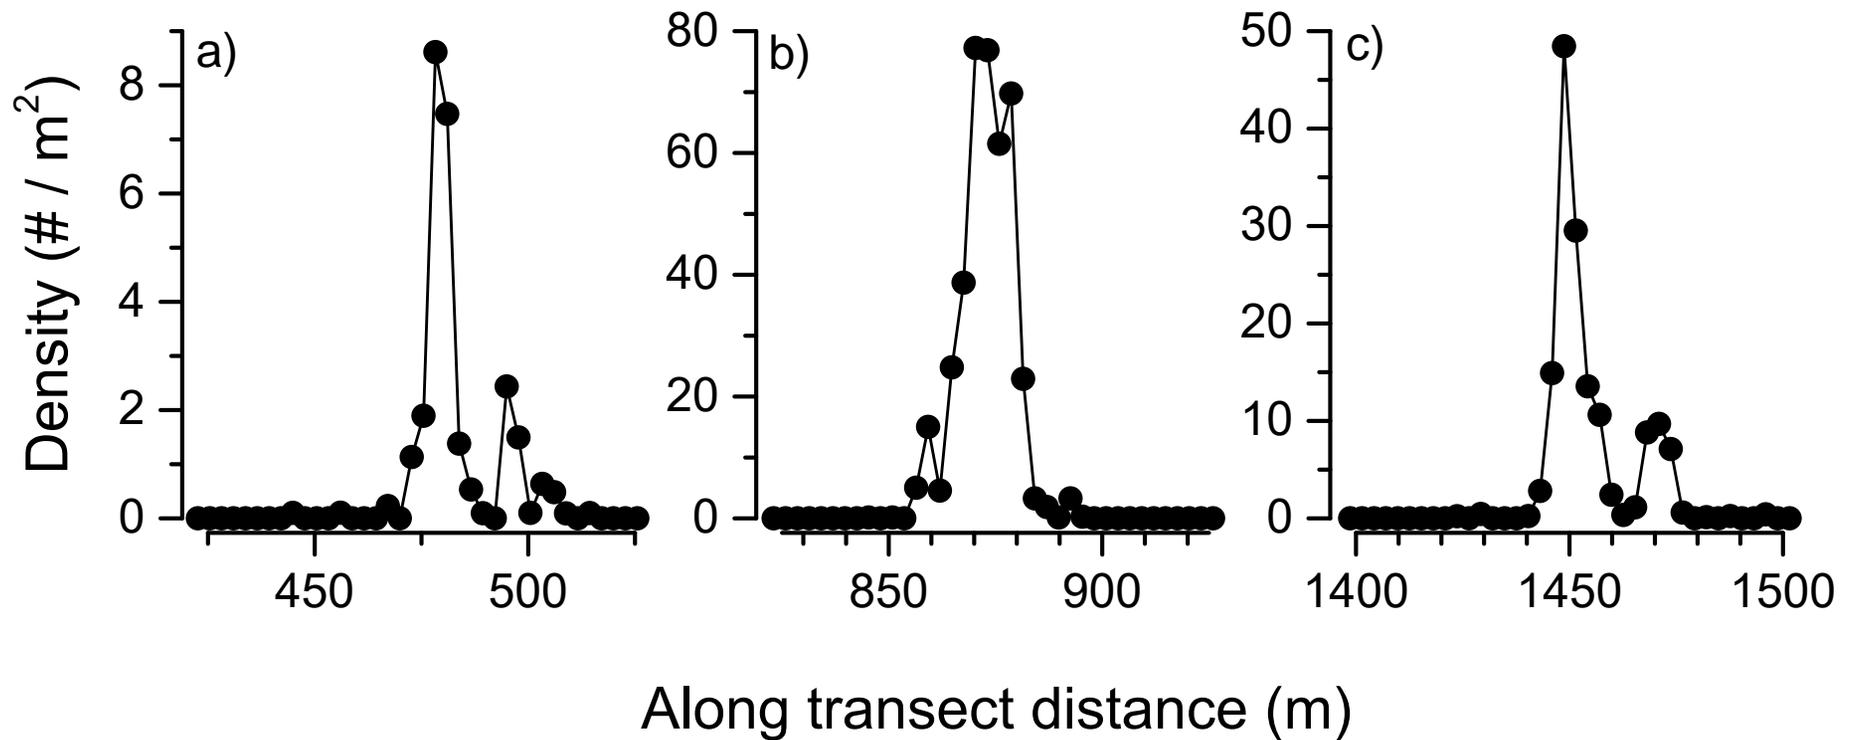

Fig. 9. *Pleuroncodes planipes* abundance distribution in each one of the three density peaks in Fig. 8. For peak correspondence, see along transect distance and maximum density.

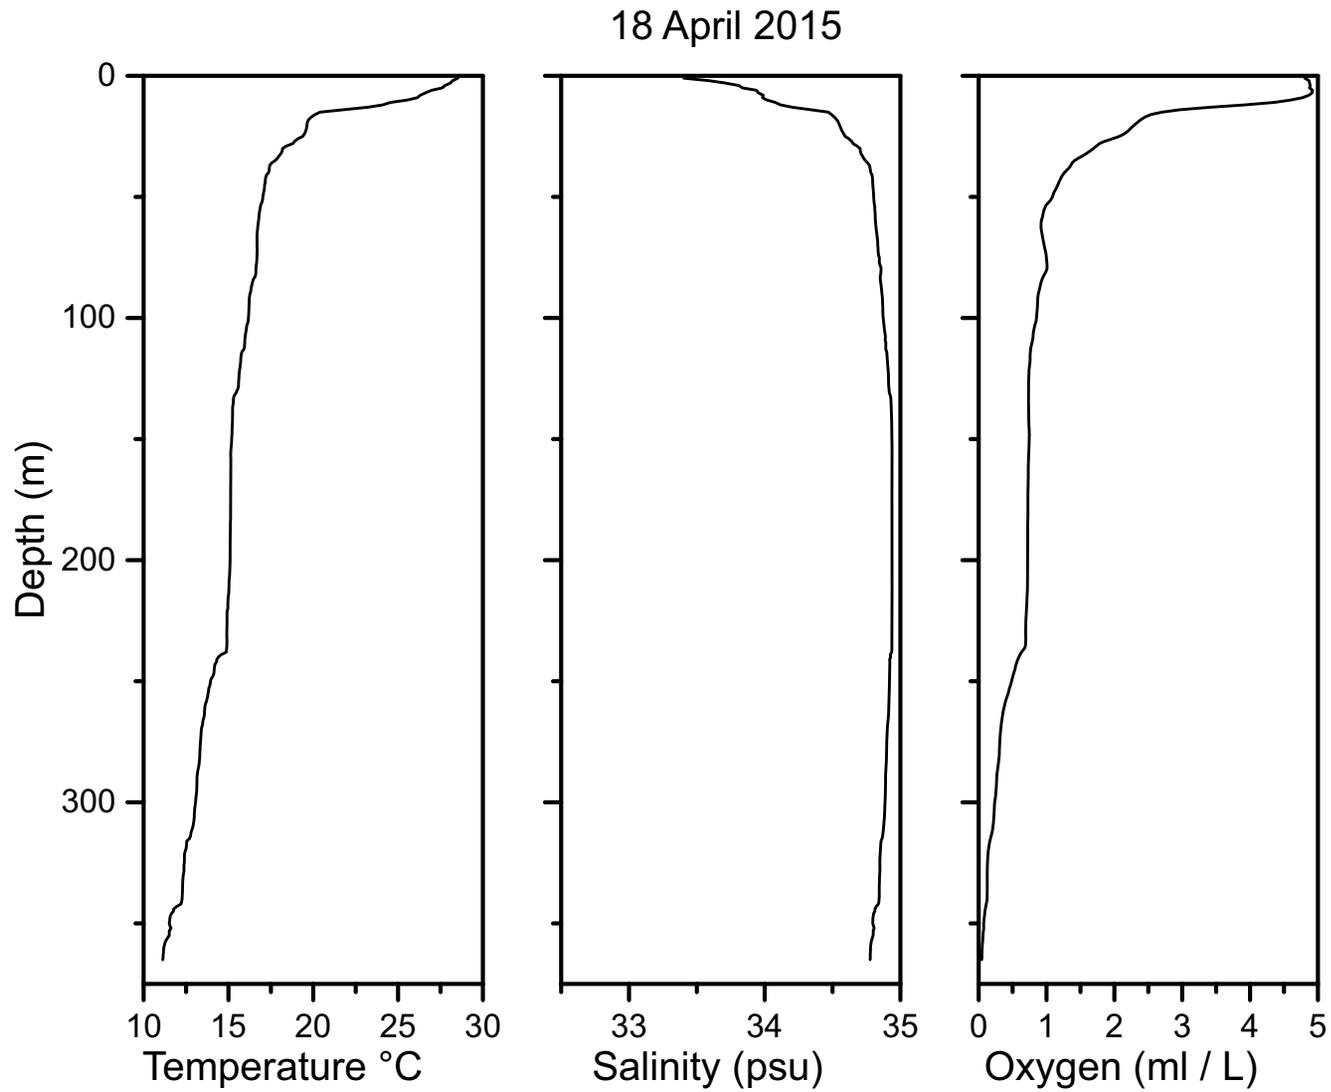

Fig. 10. Temperature, salinity and oxygen profile measurements taken with a CTD on 18 April 2015 at a station a few tens of meters from the Seabed AUV transects.
