Abstract

The activities of microbiomes in river sediments play an important role in sustaining ecosystem functions by driving many biogeochemical cycles. However, river ecosystems are frequently affected by anthropogenic activities, which may lead to microbial biodiversity loss and/or changes in ecosystem functions and related services. For example, while parts of the Atlantic Forest biome stretching along much of the eastern coast of South America are protected by governmental conservation efforts, an estimated 89% of these areas in Brazil are under threat. This adds urgency to the characterization of prokaryotic communities in this vast and highly diverse biome. Here, we present prokaryotic sediment communities in the tropical Juliana River system at three sites, an upstream site near the river source in the mountains (Source) to a site in the middle reaches referred to as Valley and an estuarine site near the urban center of Ituberá (Mangrove). The diversity and composition of the communities were compared at these sites, along with environmental conditions, the former by using qualitative and quantitative analyses of 16S rRNA gene amplicons. While the communities included distinct populations at each site, a suite of core taxa accounted for the majority of the populations at all sites. Prokaryote diversity was highest in the sediments of the Mangrove site and lowest at the Valley site. The highest number of genera exclusive to a given site was found at the Source site, followed by the Mangrove site, which contained some archaeal genera not present at the freshwater sites. Copper (Cu) concentrations were related to differences in communities among sites, but none of the other environmental factors we determined was found to have a significant influence. This may be partly due to an urban imprint on the Mangrove site by providing organic carbon and nutrients via domestic effluents.

Introduction

River ecosystems are frequently influenced by anthropogenic activities, which may lead to microbial biodiversity loss and/or changes in ecosystem functions and related services (Mansfeldt et al., 2020). Therefore, studies have been carried out to evaluate the significance of microbial community changes and how anthropogenic activities may influence such changes (Reis et al., 2020; Zhang et al., 2020b; Lee et al., 2021). However, since microbiomes remain unexplored in vast areas of the world, changes in sediment microbial communities of rivers are largely unknown at present, including in biomes that are under major threat.

One example is the Atlantic Forest extending along the Atlantic coast of South America, which is one of the most biologically diverse and most vulnerable biomes in the world (MDDA, 2010). Human activities have drastically reduced the original cover of the biome, to only 11% of its pre-Columbian size on Brazilian territory (Ribeiro et al., 2009; Silva & Nolasco, 2015). One of the largest remaining fragments of the Atlantic Forest is located within the limits of the Pratigi Environmental Protection Area in the southern part of Bahia State, Brazil (MMA, 2004). Since its creation in 1998, the area has been subject to various environmental assessments, which have shown the effectiveness of the conservation efforts in the area (Ditt et al., 2013; Lopes, 2011; Mascarenhas et al., 2019), with the exception of a few local disturbances (de Santana et al., 2021b).

The aim of the present study was to determine the diversity and composition of bacterial and archaeal sediment communities along a tropical river in the Atlantic Forest of Brazil from the headwaters to the mouth.

Materials & Methods

Study area

Three sites were chosen along the Juliana River in the southeastern part of Bahia State, Brazil. The river drains the most important watershed in the region in terms of size and economic and ecological significance. Currently, the Juliana River is located entirely within a legally protected area, the Environmental Protection Area of Pratigi (Figure 1). Its basin comprises an area of 299.8 km^2, through which the river runs almost linearly over 47 km. The source is in the Papuã Mountains. Several tributaries join the river along its way to the Serinhaém estuary (Mascarenhas et al., 2019; Ditt et al., 2013), where the city of Ituberá is located, a small urban area with less than 30,000 people and tourism as the main economic activity (IBGE, 2020). Ituberá has been constructed within a mangrove forest, which has been retained along urban waterways and mudflats (de Santana et al., 2021b). In contrast, most of the upstream reaches enable the observation of minimally impacted environments, because the upper portions of the watershed are considered to be highly conserved, lending themselves to ecological, hydrological and biogeochemical research. This includes studies on the biodiversity and ecology of microbial communities in river sediments (de Santana et al., 2021a).

The Juliana River basin is subdivided into three administrative sections, I, II and III. Section I corresponds to the highlands of the Papuã Mountains. A site located there has been designated the Source site for the purpose of the present study. Section II corresponds to the downstream Valley region, which is mostly dominated by primary

forest, interspersed with a few agroforestry systems. Section III is the lowermost part of the hydrographic basin, hosting ecosystems ranging from tropical forest fragments to mangroves (Mascarenhas et al., 2019), including in and near Ituberá City close to where the sediments were collected. Nevertheless, this area still experiences little direct impacts by industrial development. Family farming predominates land use (Pereira et al. 2022).

The field study presented here was approved by the state governmental Fundação De Amparo à Pesquisa do Estado da Bahia (project number: FAPESB/CNPq nº 794014/2013; permit number: 794014/2013). Portions of this text were previously published as part of a doctoral thesis (de Santana 2020).

Sampling and genomic analyses

Sediments were collected in February 2019 at the three sites selected in the Juliana River (Source, Valley, and Mangrove). At each site, 3 random collection points at least 1.5 m apart from one another were chosen in the margin of the river where water depth exceeded 10 cm. Sediments were collected with a cylindrical core sampler, taking precautions to avoid disrupting rhizospheres associated with vegetation. The top 10 cm of the three replicate samples at each site were combined to a composite sample of surface sediments. Plant litter and other coarse particulate organic matter was

manually removed from the core before placing the sediment samples in plastic bags on ice in thermal boxes and immediately transporting them to the laboratory for chemical and genomic analyses.

Physical-chemical parameters such as temperature, pH, conductivity, and dissolved oxygen in the water column were measured at each site using a multiparameter probe (YSI model 85, Yellow Spring Instruments Inc., Yellow Springs, OH, USA). Additional environmental variables such as concentrations of Pb, Zn, Cu and Cd at each site have been previously reported (Pereira et al. 2022; Mascarenhas et al., 2019; Supplemental Table 1). Since Cd concentrations were below detection limit at all sites, this variable was not included in the data analysis. In the laboratory, an aliquot of each sediment core was frozen at -20°C for subsequent DNA extraction, while the remainder of the sample was used to measure organic matter (O.M.) content.

The total genomic DNA was extracted from 0.25 g of sediment using the PowerSoil DNA Isolation Kit (Qiagen, Carlsbad, CA, USA) and stored at -80 ºC before analysis. After DNA extraction, the samples were sent on dry ice to Novogene Bioinformatics Technology Co. Ltd. for amplification of bacterial 16S rRNA genes, using the 515F and 806R primers (Supplemental Table 2), followed by Illumina NovaSeq 6000 paired-end (2x250) sequencing (Thompson et al., 2017). Since sequencing of one of the samples from the Valley site failed, analyses were limited to the two remaining replicates.

Trimmomatic (Bolger, Lohse & Usadel, 2014) was used to filter and trim the demultiplexed sequences (ILLUMINACLIP:TruSeq3-PE.fa:2:30:10 LEADING:3 TRAILING:3 SLIDINGWINDOW:4:15 MINLEN:100). All reads were subsequently

denoised using DADA2 (Callahan et al., 2016) in QIIME2 (Bolyen et al., 2019), merged using QIIME2 (Supplemental File 1, Supplemental Table 3), and then clustered into amplicon sequence variants (ASVs) (Supplemental Table 4). Alpha-rarefaction was calculated using QIIME2 (Supplemental Figure 1) and set to 41,000 reads for the purpose of alpha- and beta-diversity analyses (Supplemental Figure 2, 3). All diversity analyses were performed using QIIME2's default parameters (Supplemental File 1).

Statistical analyses

Taxonomic assignment was performed using QIIME2's naive Bayes scikit-learn classifier (Bokulich et al., 2018) trained with the 16S rRNA gene sequences in the SILVA database (SILVA 138-99-515-806) (McDonald et al., 2012). The taxonomic feature table (Supplemental Table 5) was resolved to the genus level for analysis (Supplemental Table 6) using QIIME2. Classes of high relative abundances (2% of the total community per site) and phyla were identified, and a heatmap of relative genus abundances generated for each replicate sample.

Taxa resolved to the genus level were considered common across sites if they accounted for at least 0.1% of the reads per site, occurred in at least 2 replicates per site, or represented at least 1% of the reads in a single replicate. These criteria had to be met for each of the three sites (Supplemental File 4). ~~We found 87 taxa (as well as "Unassigned") which satisfied these criteria (Supplemental Table 7).~~

To determine how many taxa, resolved to the genus level, were only found at any given site, we first required each taxon to be minimally present at only one site. Minimal presence was defined as being greater than 0.001% of the total population per site, or

being, on average, greater than 0.0001% of the population per site per replicate (Supplemental File 5). ~~We found 152 taxa satisfied these criteria (Supplemental Table 8), although only one taxon was greater than 0.1% of the population per site (Supplemental Figure 5).~~

A site-specific analysis of significant differential abundances was performed using the ANCOM-BC package in QIIME2 (Supplemental Tables 9, 10, 11). We further subset these taxa to identify those that were significantly distinct to a single site, relative to the other two sites (ANCOM-BC, q-value < 0.01) and that also represented a substantial percentage of the total population at that site (> 1% total population), (Figure 3D).

The *Vegan* package (Dixon, 2003) was used to test correlations between community structure and environmental variables in R environment (version 4.2.2). Distances were calculated using metaMDS (distance used was Bray-Curtis) (Supplemental Figure 7, Supplemental Table 12, Supplemental File 7) and environmental variables were fit using envfit (Figure 4B, Supplemental Table 13, Supplemental File 8).

The sequencing data is available from NCBI BioProject PRJNA650560. The entire computational workflow is available in a GitHub repository: https://github.com/pspealman/Project_Juliana_River_basin.

After quality filtering and taxonomic assignment, the 879,453 sequences remaining displayed the following pattern: 91.0% of the reads were associated with the kingdom Bacteria, 8.3% were associated with the Archaea and 0.6% were not assigned to either of these prokaryotic kingdoms. In total, ASVs were assigned to 85 phyla, 202 classes, 457 orders, 699 families, 1089 genera and 458 species (Supplemental Table 4).

We identified 18 highly abundant classes with a mean abundance per site of at least 2% (Figure 2A). These classes constituted 9 bacterial and 2 archaeal phyla. The two archaeal phyla, Crenarchaeota and Thermoplasmatota (as well Halobacterota, which was just below the 2% cutoff), were present at all sites, although they were most frequent in the mangrove sediments. For the Bacteria domain, the three sites shared similar dominant phyla, with Proteobacteria exceeding 10% and Bacteroidota, Bacillota (Firmicutes), Chloroflexota, and Desulfobacterota accounting each for >5% at all sites. Combined, these five phyla and their 11 classes represented the majority of the prokaryotic populations (50-64%) at all sites.

This large overlap prompted us to assess how many of the more abundant genera were present at all sites (see Methods). We found 87 such taxa, 77 of which were resolved to the genus level (Supplemental Table 7, Figure 2B), which together accounted for 72% (Source) and 61% (Valley and Mangrove), respectively, of the total abundance and could thus constitute the core microbiome in sediments of the river.

community at least at one site. ~~We found several outliers at all sites, such as Sva0485 (Source), Clostridia (Valley), and Dehalococcoidia (Mangrove).~~ (**B**) Fifteen taxa that were highly abundant at all sites (>1% total per site).

Community differences among sites

ANCOM-BC analysis indicated that abundances of numerous taxa significantly differed between pairs of sites (Figure 3A, B, C; Supplemental File 6). The greatest difference occurred between the Source and Mangrove sites (Supplemental Figure 6, Supplemental Tables 9, 10, 11). Genera specific to only one of the study sites (Supplemental Figure 5) included 87 taxa that were unique to the Source site, 2 to the Valley site, and 63 to the Mangrove site. However, these taxa represent very small proportions of the total communities, with 0.65% being unique to the Source site, 0.03% to the Valley and 1.1% to the Mangrove site (Supplemental Table 8). Resolved to the genus level, some taxa were significantly more abundant at one site compared to the two others (ANCOM-BC, q-value < 0.01) and represented a notable percentage of the total abundance at that site (> 1% total population). We found 9 such taxa at the Source site and 8 at the Mangrove site (Figure 3D), whereas none were more abundant at the Valley site, although sediments at that site had more reads that could not be assigned to any taxon ('Unassigned').

Community structure, diversity and environmental variables

Prokaryotic diversity expressed as the Shannon entropy index was highest at the Mangrove and lowest at the Valley site (Figure 4A); however, sites differences were only significant in the omnibus test (p = 0.044). Similarly, differences in community composition between sites assessed by the Weighted UniFrac distance measure (Supplementary Figure 3) were only significant in the omnibus PERMANOVA (p = 0.007). Site differences among the prokaryotic communities are also shown in the PCA, which separated the Source site from the Valley and Mangrove sites along PC1 (Figure 4B), with copper (Cu) concentration as the most influential environmental variable (p = 0.011). Nearly significant differences in the concentration of lead (Zn) (p = 0.063) were primarily related to PC2, whereas temperature, dissolved oxygen, organic matter (O.M.), Ni, salinity, Cr, pH, and Pb had not detectable influence.

Figure 4. Prokaryotic community characteristics. (**A**) Shannon alpha-diversity indices of prokaryote communities at the Source, Valley and Mangrove sites. (**B**) PCA plot relating sediment prokaryote community composition to environmental variables at the three sites.

Our results suggest a shift in prokaryote diversity along the river continuum from the headwaters (Source) to the mouth (Mangrove), with a minimum occurring in the middle reaches (Valley). One potential reason for the decrease from the headwaters to the middle reaches could be increasing anthropgenic influences, including contamination, as seen in previous studies (Berg et al., 2012; Chen et al., 2018). However, given the conservation status of the Julian River and the limited number of sites and samples in the present study, this tentative conclusion remains speculative, since a range of other factors may have influenced the prokaryotic sediment communities. Moreover, given the differences observed in both communities and environmental variables at the Mangrove site, it remains unclear to what extent the increase in diversity at this urban site was due to factors not determined in our study, including local anthropogenic impacts.

Previous studies of sediment microbial communities along river-estuary continua have found a decreasing downriver trend of microbiome diversity (Wang et al., 2012; Behera et al., 2019; Zhang et al., 2020a; Santana 2020). Variables such as temperature, salinity and trophic state were strongly related to the taxonomic and functional composition of microbial communities in those studies, in contrast to the present study where only Cu concentrations were significantly related with to differences in the prokaryotic communities among sites.

Diversity is expected to decrease with increasing habitat harshness (Statzner & Moss, 2004), which is frequently associated with environmental disturbances. Accordingly, we expected the community in our mangrove sediments to be less diverse than the freshwater sediments, but we observed the opposite trend in that the mangrove

site displayed the highest prokaryotic diversity. Considering that environmental conditions in mangrove sediments differ fundamentally from characteristics at freshwater sites, prokaryote diversity is expected also to differ between those sites. Additionally, wastewater discharge may have an influence by supplying labile organic matter and nutrients, which may override adverse effects of habitat harshness on prokaryotic diversity (de Santana et al., 2021a).

Gammaproteobacteria were well represented within the phylum Proteobacteria, including an uncultured genus in the Steroidobacteraceae that was both common across sites and frequent. Steroidobacteraceae have been recognized as key taxa in aquifers (Abiriga et al. 2022) and have also been found in association with Rhizobiales in plant rhizospheres (Sakai et al., 2014). Presence of the phylum Bacteroidota in sediments has been related to environmental characteristics such as trophic state and temperature (Huang et al., 2017; Dai et al., 2016), suggesting that resource availability and environmental conditions were conducive to this group along the river continuum. Another highly abundant phylum was Sva0485. Recently reported but not well characterized, this group has been related to environmental conditions such as pH (Zhang et al., 2023). Interestingly, Sva0485 has also been reported from active sulfate-reducing repertoires where it is thought to play an important role in the sulfur cycle of freshwaters (Chen et al., 2023).

The prevalence of Proteobacteria and Firmicutes in the sediments of all our study sites is in general agreement with literature reports from soils and sediments (Tveit et al., 2013; Jost, 2007; Yadav et al., 2015; Andreote et al., 2012; Imchen et al., 2018; Su et al., 2018) and has been ascribed mainly to the high morphological and physiological

diversity of these groups that enable the colonization of diverse habitats. However, aside from the majority of generalists, we also found some level of site-specificity, with some taxa showing preference and even exclusivity for the Source, Valley or Mangrove sites. In general, we found preferences for the Mangrove site for groups which are prevalent in coastal environments, such as the archaeal phyla Thermoplasmata, Halobacterota, and Crenarchaeota (Thiele et al., 2017). Many of the characterized groups of Crenarchaeota are thermophilic, have a preference for anaerobic environments, such as sediments, and may also be acidophilic (Leigh & Whitman, 2013; Shakir et al., 2023). Halobacteridota are known to succeed in environments with high salt concentrations and the genera we found exclusively at the Mangrove site are highly correlated with methanogenesis (Yang et al., 2022). Overall, these results suggest that although many of the taxa we identified survive in specific environmental conditions, some taxa are broadly distributed in sediments along the river continuum.

The majority of the 88 taxa unique to the Source site belonged to the Bacteria domain, with two genera of the methanogenic archaeal phylum Halobacteridota. From the bacterial groups, we found taxa with varied importance in ecological, biotechnological and in human health contexts, such as *Methylocystis*, a methane-oxidizing genus that has been studied for the purpose of mitigating methane emissions, and *Anaerococcus*, which are anaerobic species commonly found in human microbiota (Dedysh, Knief & Dunfield, 2005; Murphy & Frick, 2013). The family Sporolactobacillaceae and the genus *Microbacterium* were exclusively found in the sediments from the Valley. While *Microbacterium* is known to be quite widespread and common in a variety of environments (Evtushenko & Takeuchi, 2006), the endospore-

forming Sporolactobacillaceae are primarily known from food spoilage and biotechnological and other industrial systems (Harirchi et al., 2022).

~~Although not significant ($p = 0.12$) in our analysis, organic matter content and nutrients usually affect microbial communities in various ways. Since the characteristics of dissolved and particulate organic matter have large effects on nutrient and heavy metal concentrations, species and availability in aquatic environments (Dong et al., 2020), notable effects in aquatic microbial community are expected when these characteristics differ (Tolkkinen et al., 2020). Future work, with increased statistical power, may be able to resolve these differences.~~

Based on our earlier observation that the diversity and composition of sediment microbial communities at the three sites of the Juliana River differed significantly, the current analysis focusing on abundances revealed which taxa were most prevalent or even exclusive to each site. Several taxa were associated with anaerobic biodigestion, including vadinHA17 in the Bacteroidetes (Zhou & Xu, 2020), ADurb.Bin063-1 in the Pedosphaeraceae (Gaio et al., 2023), and Anaerolineaceae (Yamada & Sekiguchi, 2018), consistent with the observation that the Source site had the lowest dissolved oxygen concentrations (Supplemental Table 1). While several taxa we found are considered sensitive to heavy metals, including 4-29-1 which belongs to the Nitrospirota (Wang et al., 2022a) and ADurb.Bin063-1 (Chun et al., 2021), we also found taxa resistant to trace metals, such as *Syntrophorhabdus* (da Costa et al., 2023) and Subgroup 2 (GP2) of the Acidobacteriota (Wang et al., 2022b). Notably, GP2 has previously been found to be significantly associated with undisturbed tracts of the

western Amazon rainforest (Navarrete et al., 2015) and the Atlantic Forest (Catão et al., 2014), consistent with the conservation status of the Juliana river basin.

Conversely, we found the Mangrove site to be enriched in several genera associated with disturbed ecosystems. These include *GIF3* (Dehalococcoidia) observed to rapidly arise in sediments of disturbed riverbanks (López-Lozano et al., 2013), and *Desulfatiglans*, a potential polycyclic aromatic hydrocarbon (PAH) degrader in urban rivers (Li et al., 2022b). Both *Desulfatiglans* and *SEEP-SRB1* (Desulfobacterota) are associated with urban mangroves with high sulfate (SO_4^{2-}) and iron (Fe) concentrations and low nitrate (NO_3^-) and P (Li et al., 2022a) concentrations. *SEEP-SRB1* is also a syntrophic sulfate-reducing bacterium (SRB) capable of anaerobic methane oxidation (AOM) in obligate partnership with anaerobic methanotrophic archaea (ANME) (Murali et al., 2023). This could suggest a potential relationship with the of some of the unassigned Archaea observed at the site. However, many distinct environmental factors may contribute to the investigated mangrove being the most different site in the present study, especially because of the coastal tidal environment, in addition to its urbanization.

Conclusions

In this study we investigated prokaryotic communities in the sediments of three sites along the Juliana River located within the boundaries of the Pratigi Environmental Protection Area, Brazil. The results provide valuable information on the prokaryotic community composition along the river and how the taxa respond to environmental differences. A core microbiome was composed of taxa occurring at all sites, ~~and~~

~~therefore can be interpreted as having some importance for the stability of the microbiomes~~. We identified differences in community structure observed at both higher and lower taxonomic levels, indicating that the three study sites along the river had distinct taxonomic profiles. Significant differences in diversity measures indicated that the communities in sediments of the Mangrove site were most diverse, and the to be the least diverse at the Valley site, with only two unique taxonomic groups identified. More taxa were exclusive to the Mangrove sediments, possibly due to distinct environmental conditions at this site. The Source sediments had generally more bacterial taxa, whereas some archaea were unique particularly to the Mangrove site. Since impacts caused by human or natural disturbances in the sediments could also affect the availability and speciation of chemical elements and thus influence the ecosystem's resilience, it is important to consider human interferences as a factor affecting the microbial communities at the Mangrove site. Although the limited scope of the present study precludes firm conclusions, the collected data are a first step towards characterizing the poorly known microbiome of sediments along a river continuum in the Brazilian Atlantic Forest.

Page 14: [41] Commented [MG24] **Mark Gessner** **14/07/2024 12:06:00**

Not a useful trait at your study sites, I suppose?

Page 14: [42] Commented [MG25] **Mark Gessner** **14/07/2024 12:06:00**

Not the case at the Mangrove sites, I suppose.

Page 14: [43] Commented [MG27] **Mark Gessner** **14/07/2024 12:09:00**

I would rather expect sulfate reducers there and methanogenesis to be suppressed. This requires clarification/a commentary.
