

# Disordered gamblers with risky alcohol habits benefit more from motivational interviewing than from cognitive behavioural group therapy

Henrik Josephson, Per Carlbring, Lars Forsberg, Ingvar Rosendahl

**Background.** Effective psychological treatment, including cognitive behavioural therapy (CBT) and motivational interviewing (MI), is available for disordered gambling. To advance the development of treatment for disordered gambling, it is critical to further investigate how comorbidity impacts different types of treatments. The purpose of this study was to investigate whether screening for risky alcohol habits can provide guidance on whether disordered gamblers should be recommended cognitive behavioural group therapy (CBGT) or MI.

**Methods.** The present study is a secondary analysis of a previous randomized controlled trial that compared the effects of CBGT, MI and a waitlist control in the treatment of disordered gambling. Assessment and treatment was conducted at an outpatient dependency clinic in Stockholm, Sweden, where 80 disordered gamblers began treatment. A modified version of the National Opinion Research Centre DSM-IV Screen for gambling problems (NODS) was used to assess disordered gambling. The Alcohol Use Disorders Identification Test (AUDIT) was used to screen for risky alcohol habits.

**Results.** The interaction between treatment and alcohol habits was significant and indicates that disordered gamblers with risky alcohol habits were better helped by MI, while those without risky alcohol habits were better helped by CBGT.

**Conclusions.** The results support a screening procedure including the AUDIT prior to starting treatment for disordered gambling because the result of the screening can provide guidance in the choice of treatment. Disordered gamblers with risky alcohol habits are likely to be best helped if they are referred to MI, while those without risky alcohol habits are likely to be best helped if they are referred to CBGT.

1 Disordered gamblers with risky alcohol habits benefit more from motivational interviewing than  
2 from cognitive behavioural group therapy

19

20

21 **Introduction**

22 Worldwide, 0.3 to 5.3% of adults suffer from gambling problems (Wardle et al., 2010).

23 Disordered gambling is a diagnosis described in the Diagnostic and statistical manual of mental  
24 disorders, 5th edition (DSM-5) (American Psychiatric Association, 2013), as a persistent and  
25 recurrent problematic gambling behavior leading to clinically significant impairment or distress.

26 The diagnosis shares several characteristics with substance-related disorders. Common features  
27 include preoccupation, increased tolerance, loss of control, withdrawal symptoms, and family  
28 and job disruption (American Psychiatric Association, 2013).

29

30 Meta-analyses and systematic reviews have provided evidence for the efficacy of psychological  
31 treatment for disordered gambling (Gooding & Tarrier, 2009; Hodgins, Stea & Grant, 2011;

32 Yakovenko et al., 2015). Results from a meta-analysis revealed that various forms of CBT and

33 MI showed large and significant effect sizes in the 0 – 3 month time window post treatment, with

34 enduring effects up to 24 month (or later) follow up periods (Gooding & Tarrier, 2009). Effect

35 sizes were highly significant despite variability in terms of populations being treated, severity of

36 gambling problem and type of gambling (Gooding & Tarrier, 2009).

37

38 It is well known that disordered gambling is highly comorbid with other psychiatric disorders

39 (Petry, Stinson & Grant, 2005; Lorains, Cowlishaw & Thomas, 2011; Bischof et al., 2013). Data

40 derived from a large national sample in the United States indicate that the most frequently

41 reported lifetime comorbid condition among disordered gamblers was alcohol use disorders (73.2

42 %) (Petry, Stinson & Grant, 2005), the corresponding figure in a large German study was 61.7%  
43 (Bischof et al., 2013). Results from a recent review on co-morbidity among treatment-seeking  
44 problem gamblers point in the same direction, with rates of current alcohol use disorders at  
45 21.2% (Dowling et al., 2015). Most regular video lottery terminal (VLT) gamblers (73%) said  
46 that they prefer to drink alcoholic beverages while gambling (Stewart et al., 2002), and up to  
47 80% of non-disordered gamblers reported a consumption of four to ten alcoholic drinks during  
48 their last gambling session (Baron & Dickerson, 1999). In other words, gamblers often drink  
49 while gambling, and those who do tend to engage in more risky gambling behaviors  
50 (Ledgerwood et al., 2009; Crance & Corbin, 2010). Disordered gamblers with co-occurring  
51 alcohol use disorders reported greater levels of problematic gambling (Welte et al., 2004), and  
52 were more likely to have psychiatric comorbidity compared to disordered gamblers without  
53 alcohol use disorders (Abdollahnejad, Delfabbro & Denson, 2014). In addition, gamblers with  
54 alcohol problems are at an increased risk of relapse after quitting gambling (Hodgins & El-  
55 Guebaly, 2010).

56

57 In a study that mapped the drinking patterns of disordered gamblers, entry into gambling  
58 treatment was temporally associated with reductions in alcohol use, but gamblers with risky  
59 alcohol habits were still less likely to adhere to gambling treatment (Rash, Weinstock & Petry,  
60 2011). One study suggested that alcohol problems were linked to poor compliance in individual  
61 CBT treatment for disordered gambling (Milton et al., 2002). The study reported that disordered  
62 gamblers with alcohol problems were 2.5 times more likely to drop out of treatment than  
63 disorderd gamblers without alcohol problems (Milton et al., 2002). This result has failed to be  
64 replicated in subsequent research on individual CBT (Leblond, Ladouceur & Blaszczynski,

65 2003) and multimodal CBT (Stinchfield, Kushner & Winters, 2005). However, there is a lack of  
66 research on whether different treatment forms, such as CBT and MI, differ in sensitivity to co-  
67 occurring alcohol problems. To advance the development of treatment for gambling disorders, it  
68 is critical to investigate further how comorbidity impacts different types of treatments for  
69 disordered gambling (Petry, Stinson & Grant, 2005; Hodgins, Stea & Grant, 2011; Dowling et  
70 al., 2015).

71

72 Because the presence of an alcohol use disorder is the most common comorbid condition among  
73 disordered gamblers (Petry, Stinson & Grant, 2005; Bischof et al., 2013 Dowling et al., 2015),  
74 and contributes to a loss of control over gambling (Ledgerwood et al., 2009; Crouce & Corbin,  
75 2010), greater gambling severity (Welte et al. 2004), higher rates of psychiatric comorbidity  
76 (Abdollahnejad, Delfabbro & Denson, 2014), an impaired adherence to gambling treatment  
77 (Milton et al., 2002; Rash, Weinstock & Petry, 2011), and an increased likelihood of gambling  
78 (Hodgins & El-Guebaly, 2010), it is of great clinical interest to see if the condition affects the  
79 outcome of widely used therapies, such as CBGT and MI, to different extents. The purpose of  
80 this study was to investigate whether screening for risky alcohol habits can provide guidance on  
81 whether disordered gamblers should be recommended CBGT or MI.

82

83

## 84 **Methods**

### 85 *Design*

86 The present study is a secondary analysis of a previous randomized controlled trial that compares  
87 the effects of CBGT, MI and a waitlist control in the treatment of disordered gambling  
88 (Carlbring et al., 2010).

89

#### 90 *Recruitment and Participants*

91 Between June 2005 and December 2006, 80 disordered gamblers began treatment at an  
92 outpatient dependency clinic in Stockholm, Sweden. A total of 53 trial participants were  
93 included in the present study. Reasons for exclusion were not providing baseline data ( $n = 2$ ),  
94 and not providing data at the six-month treatment follow up ( $n = 25$ ). Participants received two  
95 cinema tickets for participating in the treatment follow-up. The study was approved by the  
96 regional ethics committee in Stockholm (2005/5:5), and informed written consents were  
97 collected from the participants.

98

#### 99 *Measures*

100 The National Opinion Research Centre DSM-IV Screen for gambling problems (NODS)  
101 (Gerstein et al., 1999), modified to assess gambling at one month instead of one year, was used  
102 to assess disordered gambling. The use of the 1-month version of the instrument has not seemed  
103 to affect the instrument's reliability or validity. A comparison of the internal consistency between  
104 the NODS lifetime version, past year version and 3-month version has shown Cronbach's alphas  
105 of 0.86, 0.87 and 0.87 respectively (Wulfert et al., 2005). The total score, ranging from 0 to 10, is  
106 normally used to identify pathological gambling according to DSM-IV (scores 5 and above). The  
107 instrument was modified to assess disordered gambling according to DSM-5, by eliminating the  
108 illegal acts criterion and lowering the threshold for diagnosis to 4 criteria out of 9 possible.

109 Recent research indicates that the increased sensitivity of the DSM-5 disordered gambling  
110 diagnosis successfully identifies a broader group of gamblers with clinically significant gambling  
111 related problems (Rennert et al., 2014). Participants included in the present study were those  
112 assigned with NODS scores of 4 through 9 at baseline.

113

114 The Alcohol Use Disorders Identification Test (AUDIT) (Babor et al., 2001) was used to assess  
115 presence of risky alcohol habits. The instrument is a 10 item multiple-choice self-report  
116 inventory with a total score ranging from 0 to 40. Scores between 0 – 7 for men and 0 – 5 for  
117 women indicate low risk drinking. Scores between 8 – 15 for men and 6 – 13 for women indicate  
118 hazardous and harmful alcohol use. Scores between 16 – 19 for men and 14 – 17 for women  
119 indicate a medium level of alcohol problems with probable presence of an alcohol-related  
120 diagnosis. Finally, scores above 19 for men and 17 for women indicate a high level of alcohol  
121 problems, with probable presence of an alcohol-related diagnosis. The AUDIT accurately  
122 assesses the severity of problematic alcohol use behaviours across a wide range of contexts and  
123 populations at risk (Allen et al., 1997). When administered as part of a larger test battery in a  
124 primary care setting, the AUDIT showed a test–retest reliability at a 6-week interval with a  
125 correlation of  $r=0.88$ , and an internal consistency reliability of  $\alpha = 0.85$  (Daepfen et al., 2000) .  
126 AUDIT scores were dichotomized in the present study: scores of 8 and above for males, and 6  
127 and above for females were labelled as hazardous and harmful alcohol use.

128

### 129 *Diagnostic and data collection procedures*

130 Prior to starting treatment, all participants went through a 60 to 90-minutes in-person interview,  
131 conducted by a clinical psychologist trained in the assessment procedures. The interview

132 included demographic questions and a set of self-report measures, including the NODS and  
133 AUDIT. The participants were asked to fill out the set of self-report measures again at six-month  
134 follow-up.

135

### 136 *Treatments*

137 The CBGT treatment ( $n = 25$ ) was administered in closed groups with one 3-hour session per  
138 week for 8 weeks. The treatment was manualised (Ortiz, 2006) and each session focused on a set  
139 theme. Psychoeducation, exercises, distributing and follow up homework were included in the  
140 sessions. A recurrent feature throughout the treatment was exercises aimed at reducing the urge  
141 to gamble by imaginary exposure and response prevention. The treatment was partly focused on  
142 cognitive restructuring, and partly on encouraging clients to try alternative behavioural  
143 strategies. In addition, another important treatment component dealt with identifying personal  
144 high-risk situations for gambling, and increasing participants' skills to cope with these situations  
145 in a more functional way.

146

147 The MI treatment ( $n = 28$ ) was administered individually throughout four 50 minutes sessions.  
148 The first two sessions were one week apart, and the last two sessions were three weeks apart. In  
149 total, treatment was administered over 8 weeks – the same as the CBGT condition. The therapists  
150 used the MI approach as described by Miller and Rollick in 2002, including showing empathy,  
151 eliciting the patient's own reasons for making a change, collaboration and autonomy support,  
152 developing discrepancy between ongoing problematic behaviors and internal goals and values,  
153 and supporting the participant's confidence in their own abilities. Techniques such as asking  
154 open-ended questions and reflective listening were used throughout the sessions. If the patients

155 were ready to change, they were encouraged to make a decision about changing their gambling  
156 behaviour, and to make a change plan. The therapists had access to a semistructured manual in  
157 which these standard MI principles were described and exemplified in the context of problem  
158 gambling (Forsberg, Forsberg & Knifström, 2010).

159

#### 160 *Treatment fidelity*

161 The therapists administering the CBGT received continuous supervision. All sessions were  
162 audio taped and 20% were randomly selected for coding by an independent licensed clinical  
163 psychologist with psychotherapist training and experience in the specific treatment method.  
164 According to the treatment manual (Ortiz, 2006) a total of 375 agenda points should be covered.  
165 The coding showed 93% adherence to the manual.

166

167 To test MI treatment integrity, all sessions were audio taped and 20% of the sessions were  
168 randomly selected to be coded by independent and blinded coders using the Motivational  
169 Interviewing Treatment Integrity Code 2.0 (MITI) (Moyers et al., 2003). The MI competency in  
170 the delivered sessions was deemed acceptable using the given reference values for MI  
171 proficiency in the coding manual (Moyers et al., 2003). Supervision of the MI treatment was  
172 based on assessment of the therapists' audio-taped sessions. Results from the coding were used  
173 to facilitate specific feedback.

174

#### 175 *Statistical analyses*

176 Analyses were done using SPSS 22.0 and STATA 14.0. An independent samples *t*-test and a  
177 Chi-Square test were used to determine whether the two treatment groups differed in pre-

178 treatment characteristics. The same test statistics was also used to investigate if participants who  
179 were lost at follow-up ( $n = 25$ ) differed in pre-treatment characteristics compared to participants  
180 who completed the follow-up measurements.

181 Analysis of covariance (ANCOVA) of the NODS-scores at six-month follow-up was used with  
182 NODS score at pre-treatment as a quantitative control variable. Two categorical factors:  
183 treatment (MI vs. CBGT), and AUDIT (Risky alcohol habits vs. Not risky alcohol habits), with  
184 an interaction term were included in the model. Marginal means were calculated from the  
185 ANCOVA model and visualized via a bar-plot of the margins. To assess the difference between  
186 the CBGT and the MI treatment adjusted for alcohol habits, contrasts of discrete marginal effects  
187 were estimated and tested.

188

## 189 **Results**

### 190 *Pre-treatment variables*

191 Table 1 shows point estimates and the distribution of some basic characteristics of the  
192 participants ( $n = 53$ ). No statistically significant differences in characteristics were found  
193 between the two treatment groups.

194

---

195 **Insert Table 1 about here**

---

196

197

198

### 198 *NODS-scores at 6-months follow-up*

199 The interaction between treatment and alcohol habits in the ANCOVA-model was significant ( $F$   
200  $(1, 48) = 5.39; p = 0.025$ ), and indicates that the effect of treatment depends on the patient's

201 alcohol habits. Marginal means calculated from the ANCOVA model showed that disordered  
202 gamblers with risky alcohol habits who received MI treatment had a mean NODS score of 1.9 at  
203 six-month follow-up. As the low average NODS score suggests, a strikingly large proportion  
204 (81.8 %) of the participants in this group no longer met the criteria for disordered gambling at the  
205 six-month follow-up. For disordered gamblers with risky alcohol habits who received CBGT, the  
206 corresponding NODS score was 4.0, with a lower proportion of participants (30.0%) who no  
207 longer met the criteria for disordered gambling at follow-up.

208 The contrasts between MI and CBGT, shown in Figure 1, were significantly different between  
209 participants with no risky alcohol habits and participants with risky alcohol habits ( $t(48) = 2.32$ ;  
210  $p = 0.025$ ).

211

---

**Insert Figure 1 about here**

---

213

#### 214 *Analyses of missing data*

215 There were 25 patients, equally distributed between the two treatment groups CBGT ( $n = 13$ ) and  
216 MI ( $n = 12$ ), who did not participate in the six-month follow-up. There were no statistically  
217 significant differences in terms of sex, age, or pretreatment scores on NODS and AUDIT  
218 between those who took part in the six-month follow-up and those who did not. (no  $p$ -values  
219 lower than 0.40)

220

#### 221 **Discussion**

222 The findings in this study indicate that disordered gamblers respond differently to CBGT and MI  
223 depending on whether they have risky alcohol habits at pre-treatment or not. Disordered

224 gamblers who also have risky alcohol habits appear to have a better chance of benefitting from  
225 gambling treatment if treated with MI, and conversely, patients with no risky alcohol habits  
226 appear to have a better chance of benefitting from treatment that includes CBGT. The results are  
227 clinically relevant because they can be used to facilitate the referral of individuals with gambling  
228 problems to the treatment that will help them best.

229 The present research question was posed to empirically test the common belief that comorbidity  
230 indiscriminately affects all forms of treatments negatively. The findings raise the question why  
231 MI appears to be more efficient than CBGT when treating disordered gamblers with risky  
232 alcohol habits, and conversely, why CBGT appears to be more efficient when patients do not  
233 have risky alcohol habits.

234

235 In a recent study on the personality traits of problem gamblers with and without alcohol  
236 dependence, disordered gamblers with co-occurring lifetime alcohol dependence reported a  
237 personality style characterized by resistance to externally motivated treatment approaches  
238 (Lister, Milosevic & Ledgerwood, 2015). This resistance might be better addressed with MI than  
239 CBGT treatment because MI is a non-authoritarian, collaborative method that focuses on  
240 building intrinsic motivation (Miller & Rollick, 2013).

241 Further, the results might be partly explained by the fact that there were more opportunities to  
242 tailor treatment in the individually administered MI treatment. MI is a compassionate treatment  
243 where the patient is likely to comfortably raise personal issues (Miller & Rollick, 2013), that  
244 may pose obstacles to treatment if they are not given space. If the patient also had risky alcohol  
245 habits, this could be addressed in treatment if it would help the patient move towards the target  
246 behavior to stop or reduce gambling. The advantage of having the opportunity to address

247 multiple behaviour targets in the MI treatment may have had a significant impact on the outcome  
248 because the two addictive behaviors are likely to trigger, reinforce and maintain each other.  
249 Alcohol is usually readily available in casinos, racetracks and other gambling environments, and  
250 gambling under the influence of alcohol is associated with higher risk-taking (Ledgerwood et al.,  
251 2009; Crounce & Corbin, 2010). Conversely, events that occur during the time of gambling (e.g.  
252 winning and losing) may trigger alcohol consumption (Zack et al., 2005). Multiple behaviour  
253 targets in MI treatment have been studied in other fields of addiction, and have proven to be  
254 effective in motivating people to simultaneously reduce their usage of tobacco, alcohol and  
255 cannabis (McCambridge & Strang, 2004). In a review on smoking cessation during substance  
256 abuse treatment, Baca and Yahne (2009) concluded that targeting smoking cessation enhances  
257 outcome success.

258

259 An additional advantage to be able to address risky alcohol habits in treatment is that disordered  
260 gamblers might have the same reasons for alcohol consumption that they have for gambling  
261 (Stewart et al., 2008), and these reasons could then be highlighted and tackled from different  
262 angles .

263

264 In the CBGT treatment, on the other hand, the possibility of tailoring treatment to fit any  
265 comorbid conditions was very small because the treatment was group-based and strictly followed  
266 a manual (Ortiz, 2006). The superior effect of CBGT on patients who did not have risky alcohol  
267 habits can probably be explained by the extensive treatment that included a wide range of  
268 psychoeducative elements, exercises and homework assignments that all addressed various  
269 aspects of problem gambling (Ortiz, 2006)

270

271 *Strengths and limitations of the study*

272 The study addressed the important issue of understanding moderators of treatment effects. The  
273 two treatment arms compared were evidence-based effective treatment methods for problem  
274 gambling, and treatment outcome was measured at six-month post-treatment, which implies that  
275 the results presented were persistent. The potential moderator (risky alcohol habits) included in  
276 the analysis was selected for two main reasons. Firstly, it is the most common comorbid  
277 condition among disordered gamblers (Petry, Stinson & Grant, 2005; Bischof et al., 2013), and  
278 secondly, earlier findings indicate that the condition is an aggravating factor in treatment that  
279 correlates with an impaired adherence to treatment (Milton et al., 2002; Rash, Weinstock &  
280 Petry, 2011), and an increased risk of gambling relapse (Hodgins & El-Guebaly, 2010). The  
281 inclusion of additional potentially predictive comorbid conditions in the analysis, such as drug,  
282 mood, anxiety, and personality disorders would have been preferable. The small sample limited  
283 the number of predictor variables that could be analysed in the model.

284

285 The modified version of the NODS (assessing gambling at one month instead of one year) has  
286 not been evaluated. However, shortening the window of time from one year to 3 months doesn't  
287 appear to affect the instrument's reliability or validity (Wulfert et al., 2005). An apparent benefit  
288 of a shorter-term version of the NODS is that it can serve as a convenient treatment outcome  
289 measure. It is a limitation that it is unclear to what extent the results can be explained by  
290 different modes of treatment (individual vs. group), and to what extent it can be explained by  
291 unique factors that can be attributed to each treatment. A considerable limitation is that there  
292 was no control group. It is therefore unknown whether the participants' reported reductions of

293 symptoms of gambling disorder during the six-month post treatment follow-up were the results  
294 of the treatment or just spontaneous recovery. About one-third of individuals with gambling  
295 problems are believed to recover without formal treatment (Slutske, 2006).

296

### 297 *Generalizability*

298 There were missing data at the 6-month follow-up. However, there were no statistically  
299 significant differences between those who participated and those who did not participate in the  
300 follow-up in terms of, sex, age, severity of problem gambling and alcohol problems at baseline.  
301 It appears reasonable to conclude that it is possible to generalise the findings to gamblers seeking  
302 treatment for gambling problems extensive enough to meet the criteria for “disordered  
303 gambling.” The findings are interesting from a health-planning perspective, and are valid for  
304 both CBGT and MI, which are two commonly used evidence-based treatments for gambling  
305 disorders (Gooding & Tarrier, 2009; Hodgins, Stea & Grant, 2011; Yakovenko et al., 2015)

306

### 307 *Future research*

308 Firstly, the results from this study need to be replicated to ensure that these associations are not  
309 sample-specific. We have no obvious theoretical explanation for why treatment matching with  
310 risky alcohol habits would improve gambling outcomes. In order to confirm our results, future  
311 studies have to a priori state the hypothesis that problem gamblers with risky alcohol habits will  
312 benefit more from MI than from CBGT, and that disordered gamblers with no risky alcohol  
313 habits will be more helped by CBGT than by MI. Moreover, further research is needed to  
314 investigate how other comorbid conditions, such as anxiety and depression, affect the efficacy of

315 treatment. It would also be useful to learn more about the impact of comorbidity on individual  
316 CBT.

317

### 318 *Conclusions*

319 The results support a screening procedure including the AUDIT prior to starting treatment for  
320 disordered gambling because the result of the screening can provide guidance in the choice of  
321 treatment. Problem gamblers with risky alcohol habits are likely to be best helped if they are  
322 referred to MI treatment, while those without risky alcohol habits are likely to be best helped if  
323 they are referred to CBGT.

324
