

# The role of Rnf in Ion gradient Formation in *Desulfovibrio alaskensis*

Luyao Wang, Peter Bradstock, Chuang Li, Michael J McInerney, Lee R Krumholz

Rnf is a membrane protein complex that has been shown to be important in energy conservation. Here, *Desulfovibrio alaskensis* G20 and Rnf mutants of G20 were grown with different electron donor and acceptor combinations to determine the importance of Rnf in energy conservation and the type of ion gradient generated. Addition of the protonophore TCS strongly inhibited lactate-sulfate dependent growth whereas the sodium ionophore ETH2120 had no effect, indicating a role for the proton gradient during growth. Mutants in *rnfA* and *rnfD* were more sensitive to the protonophore at 5  $\mu$ M than the parental strain, suggesting the importance of Rnf in the generation of a proton gradient. The electrical potential ( $\Delta\Psi$ ),  $\Delta$ pH and proton motive force were lower in the *rnfA* mutant than in the parental strain of *D.alaskensis* G20. These results provide evidence that the Rnf complex in *D. alaskensis* functions as a primary proton pump whose activity is important for growth.

**The role of Rnf in Ion gradient Formation in *Desulfovibrio alaskensis***

# ABSTRACT

Rnf is a membrane protein complex that has been shown to be important in energy conservation. Here, *Desulfovibrio alaskensis* G20 and Rnf mutants of G20 were grown with different electron donor and acceptor combinations to determine the importance of Rnf in energy conservation and the type of ion gradient generated. Addition of the protonophore TCS strongly inhibited lactate-sulfate dependent growth whereas the sodium ionophore ETH2120 had no effect, indicating a role for the proton gradient during growth. Mutants in *rnfA* and *rnfD* were more sensitive to the protonophore at 5  $\mu$ M than the parental strain, suggesting the importance of Rnf in the generation of a proton gradient. The electrical potential ( $\Delta\Psi$ ),  $\Delta$ pH and proton motive force were lower in the *rnfA* mutant than in the parental strain of *D.alaskensis* G20. These results provide evidence that the Rnf complex in *D. alaskensis* functions as a primary proton pump whose activity is important for growth.

42 The Rnf complex was first discovered in *Rhodobacter capsulatus* and is thought to be  
 43 transcribed in one cluster of seven genes *rnfABCDGEH* (Jouanneau et al., 1998).  
 44 Evidence that depleting one subunit could destabilize others indicated the formation of a  
 45 complex (Kumagai et al., 1997) which was later shown to be a protein complex  
 46 involved in the *Rhodobacter* nitrogen fixation process (Schmehl et al., 1993). The Rnf  
 47 complex has been differentiated into three major groups based on gene organization  
 48 (Biegel et al., 2011). The first group found in *R. capsulatus*, *Pseudomonas stutzeri* (Yan  
 49 et al., 2008) and *Azotobacter vinelandii* (Curatti et al., 2005) with *rnfABCDGE*.  
 50 Another group with the gene order *rnfCDGEAB* is found in *A. woodii* (Biegel et al.,  
 51 2009) and *Clostridium kluyveri* (Seedorf et al., 2008). Lastly *rnfBCDGEA* is found in  
 52 *Chlorobium limicola*, *Bacteroides vulgatus* and *Prosthecochloris aestuarii* (Biegel et al.,  
 53 2011).

54 Rnf complex has been shown to be a novel type of ferredoxin-dependent enzyme,  
 55 catalyzing the oxidation-reduction reaction between reduced ferredoxin and  $\text{NAD}^+$   
 56 (Biegel et al., 2009; Boiangiu et al., 2005). Because of the high sequence similarity to  
 57 the  $\text{Na}^+$ -translocating NADH:ubiquinone oxidoreductase (Nqr) (Kumagai et al., 1997),  
 58 the Rnf complex in *R. capsulatus* was suggested to be involved in ion translocation  
 59 using the energy from the exergonic reduction of  $\text{NAD}^+$  coupled to the oxidation of  
 60 reduced ferredoxin (Müller et al., 2008). Based on the above similarity, Rnf was  
 61 originally proposed to be a sodium pump (Biegel et al., 2009). This theory was  
 62 strengthened after the Rnf complex in *Acetobacterium woodii* was confirmed to  
 63 generate a  $\text{Na}^+$  gradient when carrying out the redox reaction between reduced  
 64 ferredoxin and  $\text{NAD}^+$  (Biegel & Müller, 2010). However, the Rnf complex was

65 suggested to be a proton-translocating ferredoxin:NAD<sup>+</sup> oxidoreductase in *Clostridium*  
66 *ljungdahlii* (Kopke et al., 2010) and was more recently shown to produce a proton  
67 gradient (Tremblay et al., 2013). It therefore appears that Rnf may pump different ions  
68 in different bacteria (Hess et al., 2016).

69 *Desulfovibrio alaskensis* G20 encodes the Rnf complex with a unique gene  
70 arrangement (*rnf*CDGEABF); however, a similar Rnf complex is present in most  
71 sulfate-reducing bacteria for which genome sequences are available (Pereira et al.,  
72 2011). Directly preceding the operon is a decaheme cytochrome (*dhcA*) which is also  
73 present in many but not all sulfate reducing bacteria. The first gene in the *rnf* operon is a  
74 decaheme cytochrome (*DhcA*) that belongs to cytochrome c<sub>3</sub> family (Pereira et al.,  
75 2011). The final gene in the operon, *rnfF* is most similar to *apbE*, a membrane  
76 associated lipoprotein (Beck & Downs, 1999).

77 Recently, it was reported that mutants in Rnf in *D. alaskensis* are unable to grow  
78 using H<sub>2</sub> or during syntrophic growth conditions with *Syntrophus aciditrophicus* or  
79 *Syntrophomonas wolfeii* (Krumholz et al., 2015; Price et al., 2014). By investigating  
80 gene expression levels of *D. alaskensis* G20 grown in pure culture or under syntrophic  
81 conditions (Krumholz et al., 2015), it was suggested that both formate and H<sub>2</sub> can act as  
82 electron shuttles during syntrophic growth. Those experiments also showed that  
83 expression of *rnf* genes are upregulated under syntrophic conditions and during H<sub>2</sub>  
84 dependent growth confirming the role of the Rnf complex in H<sub>2</sub> metabolism.

85 In this experiment, mutants of RnfA (Dde\_0585) and RnfD (Dde\_0582) were  
86 studied and compared with the G20 parent strain to determine whether Rnf in *D.*  
87 *alaskensis* is involved in generation of a proton motive force (PMF). These two

mutants of *Desulfovibrio alaskensis* G20 were obtained by using mini Tn10 transposon (Groh et al., 2005) and identified individually during syntrophic growth with *Syntrophomonas wolfeii* (Krumholz et al., 2015).

## MATERIALS AND METHODS

**Growth of Cultures.** *Desulfovibrio alaskensis* G20 and *rnf* mutants were routinely cultured anaerobically (N<sub>2</sub>-CO<sub>2</sub>, 80:20) in basal medium with lactate-sulfate (50mM each) as the electron donor and electron acceptor, respectively and contained 0.1% yeast extract (Krumholz et al., 2015). The medium was prepared under a headspace of N<sub>2</sub>/CO<sub>2</sub> (80/20, vol/vol) with sodium bicarbonate (3.5g/L) added as a buffer. Before inoculation, the medium was reduced with 0.025% each cysteine and sulfide. Kanamycin (1050 µg/mL) was added to the mutant cultures. Inoculum consisted of 0.2 ml transferred into 10 ml of media or the same ratio for large volume cultures. Cultures were grown in the incubator at 37°C and growth of triplicate cultures was measured by optical density at 600 nm. The stock cultures were frozen in 20% glycerol at -20°C. Growth of syntrophic cocultures was as previously described (Krumholz et al., 2015).

Growth was tested with a variety of other electron donors and acceptors: lactate (50mM), pyruvate (25mM), ethanol (10mM) and formate (50mM). Sulfate was used at 50mM with lactate and 25mM with other electron donors and sulfite was added at 10mM.

The protonophore 3,3,4,5-tetrachlorosalicylanide (TCS, 5 µM or 20 µM), or the sodium-specific ionophore N,N,N',N'-Tetracyclohexyl-1,2-phenylenedioxydiacetamide (ETH2120, 20 µM) were added to media to test their effects on growth.

111

112 **Transcriptional analysis of *rnf* genes.** Total RNA was extracted from the parent strain,  
113 *rnfA*, and *rnfD* mutants using the Qiagen RNeasy kit as previously described (Krumholz  
114 et al., 2015). Purity and adequate yield was confirmed with a diode-array  
115 spectrophotometer. First-strand cDNA synthesis was performed using the Fermentas  
116 Revertaid kit with gene-specific primers covering the entirety of the *rnf* mutants'  
117 operons. Primers were designed to span the gaps between each gene in the operon  
118 (Table 1). PCR was performed with the parent strain and mutants with each primer set  
119 followed by agarose gel analysis to determine whether all genes in the operon were  
120 expressed and whether the genes were on the same transcript.

121 *Quantitative PCR analysis.* Triplicate cultures of the parent strain and *rnfA* and *rnfD*  
122 mutants were grown to mid-log phase (OD<sub>600</sub> 0.3-0.45) and harvested by centrifugation  
123 at 5,000 x g for 5 min at 4 °C. The pellet was homogenized in RNAprotect Bacteria  
124 reagent (QIAGEN) for 5 min at room temperature to prevent degradation of RNA  
125 transcripts. Excess liquid was removed by centrifugation and cell pellets were  
126 resuspended in 200ul of TE buffer containing 1mg/ml lysozyme. Total RNA was  
127 extracted using the RNeasy mini kit (QIAGEN). RNA was then treated with the  
128 Ambion Turbo DNA –free kit (Thermo) to eliminate genomic DNA contamination.  
129 RNA was quantified spectrophotometrically. cDNAs were synthesized using the First  
130 Stand cDNA synthesis kit (Fermentas) as described in the manual. Control PCR  
131 reactions were done to ensure there was no genomic DNA or non-specific  
132 amplification.

Quantitative PCR, was done in triplicate from each culture replicate using 10ng cDNA as the template and the Maxima SYBR Green qPCR master mix (Thermo) with a MyIQ Cycler (Bio-Rad). Primers were designed using Primer-BLAST (NCBI website) to specifically amplify 128- to 155-bp regions of targeted genes Dde\_587, Dde\_589, Dde\_590 (Table 2). Dde\_587 is the final gene in the *rnf* operon and the other two genes are the next two ORFs directly downstream of the operon. The 16s rRNA primers were as previously described (Li et al., 2011). Reactions used the following amplification condition: 95°C for 10 min; 40 cycles of denaturation at 95°C for 15 s and annealing/extension at 60°C for 1 min. mRNA expression was calculated using  $(E_{\text{target}})^{\Delta \text{Ct}_{\text{target}} (\text{control}-\text{mutant}) / (E_{\text{reference}})^{\Delta \text{Ct}_{\text{reference}} (\text{control}-\text{mutant})}$  (Pfaffl, 2001) The 16s rRNA gene was used for normalization.

**Washed cell experiments.** Washed cells were used to measure sulfide production under non-growth conditions. Briefly, 100 ml lactate-sulfate culture grown to mid log phase was harvested by centrifugation at 5300 x g for 15 min, washed twice in buffer containing 50 mM MOPS (pH 7.2), 5 mM MgCl<sub>2</sub> and resuspended in the same buffer. All buffers were flushed with N<sub>2</sub> for 30 min. Assays were carried out in serum tubes containing 2 ml of buffer-cell mixture incubated at 37°C on a shaker at 100rpm. The assay mixture contained the washing buffer, 5mM sodium sulfate and either 50 mM lactate, 50 mM sodium formate (N<sub>2</sub> headspace) or H<sub>2</sub> in the headspace. Between 50 and 200 µg of cell protein was added to each tube. Tubes were sacrificed by addition of 2 ml 10% Zinc Acetate at 60 min intervals for sulfide analysis. Sulfide was determined using the methylene blue assay (Cline, 1969).

155 **Measurement of proton motive force.** Triplicate cultures of *D. alaskensis* parent strain  
 156 and *rnfA* mutant were grown in lactate –sulfate basal medium until mid exponential  
 157 phase (OD<sub>600</sub> of 0.5) in a 1 liter volume and 30 ml aliquots of cells were dispensed into  
 158 100ml serum bottles under N<sub>2</sub>/CO<sub>2</sub> (80/20, vol/vol). The basal medium contains 5 mM  
 159 K<sup>+</sup>, mainly added as potassium phosphate salts. Protein concentration was determined  
 160 using the Bicinchoninic Acid Assay (Pierce BCA Protein Assay Kit).

161 Transmembrane electrical potential ( $\Delta\Psi$ ) was measured as previously described  
 162 (Tremblay et al., 2013). Briefly, cells were incubated with  
 163 [<sup>3</sup>H]tetraphenylphosphonium bromide ([<sup>3</sup>H]TPP<sup>+</sup>) (ARC, 0.1μCi/ml) for 15 min at 37°C  
 164 (Kashket & Barker, 1977; Shirvan et al., 1989). [<sup>3</sup>H]TPP<sup>+</sup> was dissolved in media and  
 165 filtered through 0.45 μm filters prior to adding to cells. Controls were incubated with  
 166 nigericin (ACROS ORGANICS, 20μM dissolved in ethanol at 200x) and valinomycin  
 167 (ACROS), 20μM dissolved in DMSO at 200x) for 15 min to eliminate the  $\Delta\Psi$ . The  
 168 combination of nigericin (proton/K<sup>+</sup> antiporter) and valinomycin (K<sup>+</sup> uncoupler) will  
 169 dissipate the proton gradient (Kessler et al., 1977). Cells were then separated from the  
 170 medium using silicone oil as described below and [<sup>3</sup>H]TPP<sup>+</sup> was determined in the  
 171 liquid scintillation counter (Packard TriCarb 2100TR). The uptake of [<sup>3</sup>H]TPP<sup>+</sup> was  
 172 corrected for extracellular contamination using the ratio of the intracellular to  
 173 extracellular volume as described below. Non-specific binding of [<sup>3</sup>H]TPP<sup>+</sup> was  
 174 corrected by subtracting the cell associated [<sup>3</sup>H]TPP<sup>+</sup> in the valinomycin/nigericin  
 175 treatment from that in the untreated cells. The  $\Delta\Psi$  was calculated with the simplified  
 176 Nernst equation ( $-2.3 [RT/F] \times \log[(\text{concentration in})/(\text{concentration out})]$ ).

177 The  $\Delta\text{pH}$  was measured by testing the distribution of  $[^{14}\text{C}]\text{benzoate}$  (ARC,  
178  $0.4\mu\text{Ci/ml}$ ) across the cell membrane after 15min incubation at  $37^\circ\text{C}$  with cells  
179 (Kashket & Barker, 1977; Shirvan et al., 1989). Cells were then separated from the  
180 supernatant as described below and  $[^{14}\text{C}]\text{benzoate}$  was measured.  $[^{14}\text{C}]\text{benzoate}$   
181 uptake was corrected for extracellular contamination using the ratio of intracellular to  
182 extracellular volume described below. Tetrachlorosalicylanilide (TCS,  $20\mu\text{M}$ ) was  
183 added to controls to eliminate the  $\Delta\text{pH}$  and was used to calculate internal pH in the  
184 absence of a  $\Delta\text{pH}$ . The external pH was measured,  $[^{14}\text{C}]\text{benzoate}$  uptake was  
185 quantified and intracellular pH was calculated with the Henderson–Hasselbach equation  
186 (Rottenberg, 1979). The proton motive force (PMF) was calculated using the  
187 equation:  $\text{PMF}=\Delta\Psi-z\Delta\text{pH}$ . At  $37^\circ\text{C}$ ,  $z$  equals to 61.48.

188 ***Measurement of intracellular volume/total volume of cell pellet.***  $^3\text{H}_2\text{O}$  ( $1\mu\text{Ci/ml}$ )  
189 was used to measure the total pellet volume while  $[^{14}\text{C}]\text{taurine}$  (PerkinElmer,  $0.5\mu\text{Ci/ml}$ )  
190 was used to measure extracellular volume and was inferred to penetrate up to the  
191 plasma membrane (Kashket & Barker, 1977). The intracellular water volume was  
192 estimated from total pellet water volume minus extracellular water volume by  
193 measuring the difference between the distribution of  $^3\text{H}_2\text{O}$  and  $[^3\text{H}]\text{taurine}$  after  
194 incubating cells for 15 min at  $37^\circ\text{C}$  with each isotope.

195 ***Separation of cells from the supernatant.*** Following the 15 minute incubation with  
196 the isotope, three 10 ml aliquots of the total 30 ml solution were put into three 15 ml  
197 Falcon tubes with 3ml of a mixture of silicone oils (25% Fluid 510, 50 centistokes, and  
198 75% Fluid 550, 115 centistokes; Dow-Corning Corp, Serva. vol/vol). Cells were then  
199 centrifuged at  $5300 \times g$  at  $4^\circ\text{C}$  for 10min. The aqueous layer and the silicone oil was

200 removed with a Pasteur pipette connected to a vacuum line. The bottom of the falcon  
201 tube containing the cell pellet was cut off and moved into the scintillation vial and the  
202 cell pellet was re-suspended with 200µl distilled-water. Liquid scintillation cocktail  
203 (PerkinElmer, Ultima Gold) was added prior to scintillation counting.

204 **Statistical analysis.** Statistical analysis used either the t-test or a one-way analysis of  
205 variance (ANOVA) with the Tukey's Range test.

## 206 RESULTS

207 **Mutants in the *rnf* operon.** In a previous study, a Tn10 mutant library of *D.*  
208 *alaskensis* G20 was screened for the ability to grow on butyrate in coculture with  
209 *Syntrophomonas wolfei* (Krumholz et al., 2015). Seventeen mutants were obtained  
210 that were deficient in syntrophic growth. Of these, two mutants had the transposon  
211 insertions within a putative *rnf* operon. This operon is composed of 8 genes located on  
212 the genome as shown in Table 3 and genes appear to be co-transcribed. They are  
213 separated from the nearest upstream transcribed region by 185 bps and from the nearest  
214 downstream transcribed region by 342 bps. The two syntrophy mutants had  
215 transposon insertions within *rnfA* and *rnfD* as determined using Arbitrary PCR  
216 (Krumholz et al., 2015). Both genes encode integral membrane proteins likely located  
217 in the cytoplasmic membrane. RnfD has been previously shown to bind a flavin  
218 (Biegel et al., 2011).

219 **Transcriptional analysis of the *rnf* operon.** The complete transcriptional analysis for  
220 strain G20 under lactate-sulfate, H<sub>2</sub>-sulfate and under syntrophic growth conditions has  
221 been previously published (Krumholz et al., 2015). Here we present a summary of  
222 normalized values for transcription of each subunit within the *rnf* operon (Table 3).

223 Transcription of all genes in the operon including *dchA* are similar under each condition  
 224 and are affected similarly by growth condition. The most highly expressed genes are the  
 225 first two in the operon, the gene for the cytochrome c family protein and *rnfC*, both of  
 226 which have 1.5-2 fold higher levels of expression than genes for the other subunits.  
 227 Expression was also enhanced approximately 2-fold when cultures were grown on H<sub>2</sub>,  
 228 relative to lactate, indicating the importance of this protein for H<sub>2</sub> dependent growth.  
 229 Syntrophic cultures had enhanced expression of all eight genes compared to  
 230 lactate/sulfate growth with similar levels of expression in the *S. aciditrophicus* coculture  
 231 to H<sub>2</sub>-grown cells and higher levels of expression observed in the *S. wolfei* coculture,  
 232 indicating the importance of this protein complex under syntrophic conditions. Similar  
 233 effects on transcription provide evidence that all eight genes are located in one operon.

234 ***Expression analysis of rnf operons in mutants.*** To determine whether the  
 235 transposon insertion eliminated downstream expression of genes in the *rnf* operon, gap  
 236 analysis was performed where all intergene regions were amplified except the region  
 237 between *rnfB* and *rnfA* using cDNA prepared using mRNA. All of the intergene  
 238 regions were amplified for the parent and the two mutants (Fig. S1) confirming that  
 239 all 8 genes form an operon and indicating that the mutants likely have intact transcripts  
 240 of the interrupted operon. In this operon, the insertions are likely only affecting the one  
 241 interrupted gene.

242 We carried out RT-PCR analysis of the terminal gene in the operon, Dde\_587 (*rnfF*)  
 243 as well as the two genes that followed that operon, Dde\_589 (*uspA*) and Dde\_590 (*cls*)  
 244 to be certain that downstream expression was not affected by the insertions.  
 245 Expression of the terminal gene in the operon was impacted in the mutants with a

246 4 fold decrease in expression in the *rnfA* mutant and a 2 fold increase in the *rnfD*  
 247 mutant (Table 4). The following 2 genes were minimally impacted indicating that  
 248 the insertions present in the mutants likely do not affect downstream expression.

249 ***Growth and sulfate reduction by rnf mutants.*** The two mutants exhibited similar  
 250 growth rates to that of the parent strain when lactate was the electron donor with sulfate  
 251 (Fig. 1A) or sulfite as electron acceptor (Fig. 1B). When pyruvate was the donor,  
 252 growth yields were reduced for the mutants (Fig. 1C). We previously reported that *rnf*  
 253 mutants grew poorly (*rnfD*) or not at all (*rnfA*) on H<sub>2</sub> (Krumholz et al., 2015) and a  
 254 recent study has reported that *rnf* mutants grow poorly or not at all with sulfate as the  
 255 electron acceptor on malate, fumarate, ethanol, hydrogen, and formate, but growth is  
 256 not affected in lactate and pyruvate (Price et al., 2014). Here, it is shown that the *rnfD*  
 257 mutant has a long lag phase with formate as the donor, but eventually grew to a similar  
 258 OD to the parent strain (Fig. 1D). The *rnfA* mutant did not grow on formate or H<sub>2</sub>  
 259 clearly indicating the involvement of Rnf in formate/H<sub>2</sub>-dependent growth. We also  
 260 confirmed that the *rnfA* mutant will not grow on ethanol (Fig. S3).

261 ***Sulfide production by washed cells.*** Washed cells were used to determine if the role for  
 262 *rnf* was linked to biosynthesis, as mutants were able to grow better on more complex  
 263 carbon compounds. Incubations of washed cells of the parent strain and the *rnfA*  
 264 mutant produced 0.57 and 0.17  $\mu\text{mol sulfide.hr}^{-1}.\text{mg}^{-1}$  protein respectively with lactate  
 265 as electron donor. Addition of either 5  $\mu\text{M}$  TCS to the washed cells of the parent  
 266 strain prevented 95% of the sulfide production and addition of 20 $\mu\text{M}$  to washed cells  
 267 inhibited sulfide production by 100%, suggesting TCS directly disrupts the proton  
 268 gradient needed for respiration. With H<sub>2</sub> as the electron donor, parent strain cells

269 produced 0.30  $\mu\text{mol sulfide.hr}^{-1}.\text{mg}^{-1}$  protein whereas the *rnfA* mutant did not have any  
270 detectable activity. To further test whether the lack of growth on  $\text{H}_2$  was due to the  
271 mutant's inability to biosynthesize carbon intermediates, we attempted to grow the  
272 mutant and the parent strain with  $\text{H}_2$  as the electron donor with 0.1% Casamino acids  
273 added to the media. The mutant would still not grow (Fig. S4), providing further  
274 evidence that the role for RNF was not directly linked to biosynthesis.

275 **Growth curves with ionophores.** The sodium ion ionophore ETH 2120, tested at 20  
276  $\mu\text{M}$ , did not have a significant influence on the growth of the parent strain or the *rnf*  
277 mutants with lactate as the electron donor whether sulfate or sulfite were present as  
278 electron acceptors (Fig S5,S6). Interestingly, the protonophore, TCS, at 5  $\mu\text{M}$   
279 differentially inhibited cultures (Fig. 2). TCS partially inhibited the growth of the parent  
280 strain and completely inhibited the growth of *rnf* mutants on lactate-sulfate (Fig. 2A and  
281 Fig. S5). Growth on lactate sulfite was then tested and 5  $\mu\text{M}$  TCS was shown to have  
282 a smaller but still significant inhibitory effect on growth in the parent strain (Fig. 2B)  
283 and again completely inhibited the *rnfA* mutant (Fig. 2B, S6). A higher level of TCS  
284 was then tested and it was shown that 20  $\mu\text{M}$  TCS almost completely inhibited the  
285 growth of the parent strain on lactate-sulfite (Fig. 2B) and again completely inhibited  
286 the mutants (Fig. S7).

287 **Measurement of  $\Delta\Psi$ ,  $\Delta\text{pH}$  and PMF.** To determine whether the Rnf complex is  
288 involved in the formation of a proton gradient, the transmembrane potential ( $\Delta\Psi$ ),  $\Delta\text{pH}$   
289 and proton motive force (PMF) were measured in cells of the G20 parent strain and the  
290 *rnfA* mutant growing on lactate-sulfate. The  $\Delta\Psi$  and  $\Delta\text{pH}$  were both reduced in the  
291 mutant (Table 5), which led to a significantly lower PMF in the *rnfA* mutant relative to

the G20 parent strain. The lower  $\Delta pH$  and PMF in the *rnfA* mutant shows that the Rnf complex clearly had an impact on the energy conservation system by affecting the proton gradient.

## DISCUSSION

The Rnf complex has previously been shown to catalyze the oxidation-reduction reaction between ferredoxin and  $NAD^+$  (Biegel et al., 2009; Boiangiu et al., 2005). The redox potential of bacterial ferredoxin can vary, but has been reported within the range of -385 to -460 mV (Smith & Feinberg, 1990). That is more negative than that of  $NAD^+/NADH$  couple ( $E' = -280\text{mV}$ ) and therefore the transfer of electrons by Rnf from reduced ferredoxin to  $NAD^+$  releases sufficient energy to generate either a proton or a sodium ion potential (Buckel & Thauer, 2013). Given that recent studies have demonstrated both proton (Tremblay et al., 2013) and  $Na^+$  translocation abilities (Biegel & Müller, 2010), it was imperative to determine which ion Rnf translocates in strain G20. Growth experiments showed that lactate-sulfate grown cells were insensitive to the  $Na^+$  ionophore, ETH2120, (Figs. S5, S6) but were highly sensitive to the protonophore, TCS (Fig. 2). Resting cells were also shown to be highly sensitive to TCS suggesting that the proton gradient is needed for sulfate reduction. A similar growth profile was observed in *C. ljungdahlii*, for which this result was interpreted to infer that a proton gradient was needed for growth (Tremblay et al., 2013).

When grown on lactate-sulfate or lactate-sulfite, TCS partially inhibited the growth of the parent strain and completely inhibited the growth of *rnfA* and *rnfD* mutants (Fig. 2). The stronger effect on the mutants suggested that TCS at 5  $\mu\text{M}$  was partially dissolving the proton gradient in the parent strain and this was confirmed when cells

315 were shown to be completely inhibited at 20 $\mu$ M TCS. We would therefore expect that  
 316 at 5  $\mu$ M TCS, growth processes requiring additional proton motive force (or ATP  
 317 synthesis) would be more highly inhibited than those requiring less ATP. The use of  
 318 sulfate as an electron acceptor initially requires energy to activate sulfate to  
 319 adenosine-5'-phosphosulfate (Gavel et al., 1998). The requirement for energy to  
 320 activate sulfate may explain why lactate-sulfate grown cells are more susceptible to the  
 321 action of TCS than are lactate-sulfite-grown cells as the proton gradient generated  
 322 during sulfate respiration would be needed to make ATP for sulfate activation. The  
 323 inability of *rnf* mutants to grow in the presence of 5  $\mu$ M TCS is consistent with its role  
 324 in the generation of a proton motive force. In fact, the magnitude of the proton motive  
 325 force in *rnf* mutants is much less than that in the parent strain of G20 (Table 5).

326 Ideally, we would have generated complemented *rnf* mutants to prove that the  
 327 observed insertions were not having polar effects on other genes. We have attempted  
 328 to clone the *rnfA* and *rnfD* genes into *Escherichia coli* as the first step in  
 329 complementing the mutants. Unfortunately we have not been successful. Another  
 330 group has experienced similar problems with *rnfAB* of *Clostridium ljungdahlii* and  
 331 suggested that *rnf* genes may be toxic to *E. coli* in some cases (Tremblay et al., 2013).  
 332 Gap analysis was used to show that the insertions did not block transcription of  
 333 downstream genes providing some evidence that polar effects are not important. As  
 334 well, we carried out RT-PCR analysis of downstream genes. There was a decreased  
 335 level of expression of the terminal gene in the Rnf operon (*rnfF*) by the *rnfA* mutant,  
 336 however, there was little effect of the insertions (mutations) on expression of genes  
 337 downstream of the operon.

338 Experiments reported here and elsewhere (Price et al., 2014) show that the *rnf*  
339 mutants are unable to grow on H<sub>2</sub>, formate and ethanol. These results point to a critical  
340 role for Rnf during growth on the above substrates and are consistent with a higher  
341 expression level of *rnf* genes when growing with H<sub>2</sub> and sulfate relative to lactate and  
342 sulfate (Table 3).

343 A proton gradient is thought to be generated during H<sub>2</sub> metabolism in *Desulfovibrio*  
344 (Badziong & Thauer, 1980) and used for the synthesis of ATP. Membrane vesicle  
345 experiments carried out in our lab in an attempt to demonstrate the generation of an ion  
346 gradient coupled to the oxidation of reduced ferredoxin and reduction of NAD<sup>+</sup> have  
347 been unsuccessful. The protein product of the decaheme cytochrome that precedes the  
348 *rnf* operon has been proposed to accept electrons from hydrogenases and shuttle them to  
349 Rnf (Matias et al., 2005; Pereira et al., 2011). However, mutants in this gene had no  
350 effect on fitness during growth experiments on ethanol, formate or H<sub>2</sub> (Price et al.,  
351 2014). This suggests that Rnf is not likely receiving electrons directly from H<sub>2</sub>. It is  
352 more likely that *D. alaskensis* relies extensively on ferredoxin oxidation by Rnf to  
353 produce a proton gradient during growth on substrates that do not yield net ATP by  
354 substrate-level phosphorylation. For those substrates that do yield ATP by substrate  
355 level phosphorylation such as malate, fumarate, pyruvate and lactate, a decreased  
356 growth rate and or yield was observed in most cases for *rnf* mutants (Fig. 1)(Price et al.,  
357 2014) suggesting that both Rnf and the F<sub>1</sub>F<sub>o</sub> ATPase are involved in generating a PMF  
358 under those conditions.

359 We are not familiar with any studies describing mechanisms of ferredoxin  
360 reduction in *Desulfovibrio*, however, several possible mechanisms have been suggested

(Pereira et al., 2011; Price et al., 2014). During H<sub>2</sub> oxidation, these include a possible cytoplasmic electron-bifurcating hydrogenases-linked to a heterodisulfide reductase for which mutants grow poorly on H<sub>2</sub> and formate (Hdr/flox-1). For ethanol oxidation, the acetaldehyde:ferredoxin oxidoreductase could be used, and with pyruvate and lactate oxidation, would involve pyruvate:ferredoxin oxidoreductase.

Results from this study are consistent with the fact that *D. alaskensis* Rnf complex functions as a proton rather than a sodium pump and is essential for growth on substrates that do not involve ATP synthesis by substrate-level phosphorylation. Mutation of Rnf limits the development of the PMF and, thus, affects ATP synthesis during growth.

Standard deviation in parentheses. Value for the *rnfA* mutant were statistically different from the parent strain at  $p < 0.05$ .

Table 5. Magnitude of the  $\Delta\text{pH}$ ,  $\Delta\Psi$  and total proton motive force of the *D. alaskensis* G20 parent strain and the *rnfA* mutant growing on lactate and sulfate. Standard deviation in parentheses. Value for the *rnfA* mutant were statistically different from the parent strain at  $p < 0.05$ .

Measurement	Parent Strain	<i>rnfA</i> mutant
$\Delta\Psi$	-158 mV (2.1)	-117 mV (3.2)
$\Delta\text{pH}$	0.43 (0.057)	0.29 (0.015)
PMF	-185 mV (3.1)	-135 mV (4.1)

# Figure 1(on next page)

Figure 1-Growth curves of parent strain and mutants.

Figure 1. Growth curves on (A) lactate-sulfate (B) lactate-sulfite (C) pyruvate-sulfate and (D) formate-sulfate. Curves are for *D. alaskensis* parent strain (£) *rnfA* (□) and *rnfD* (r) mutants. Error bars show standard deviation.

Fig. 1

## Figure 2 (on next page)

Figure 2. Effect of TCS on parent strain and mutants.

Figure 2. Growth curves with (A) lactate-sulfate and (B) lactate sulfite for *D. alaskensis* parent strain no addition (£) and with 5µM (r) or 20 µM (ˆ) TCS. Growth curve of the *rnfA* mutant with 5µM TCS (□) is also shown. Error bars show standard deviation.
