

## Evidence for a trophic cascade on rocky reefs following sea star mass mortality in British Columbia

Jessica A Schultz, Ryan N Cloutier, Isabelle M Côté

Echinoderm population collapses, driven by disease outbreaks and climatic events, may be important drivers of population dynamics, ecological shifts and biodiversity. The northeast Pacific recently experienced a mass mortality of sea stars. In Howe Sound, British Columbia, the sunflower star *Pycnopodia helianthoides* — a previously abundant predator of bottom-dwelling invertebrates — began to show signs of a wasting syndrome in early September 2013, and dense aggregations disappeared from many sites in a matter of weeks. Here, we assess changes in subtidal community composition by comparing the abundance of fish, invertebrates and macroalgae at 20 sites in Howe Sound before and after the 2013 sea star mortality to evaluate evidence for a trophic cascade. We observed changes in the abundance of several species after the sea star mortality, most notably a four-fold increase in the number of green sea urchins, *Strongylocentrotus droebachiensis*, and a significant decline in kelp cover, which are together consistent with a trophic cascade. Qualitative data on the abundance of sunflower stars and green urchins from a citizen science database show that the patterns of echinoderm abundance detected at our study sites reflected wider local trends. The trophic cascade evident at the scale of Howe Sound was observed at half of the study sites. It remains unclear whether the urchin response was triggered directly, via a reduction in urchin mortality, or indirectly, via a shift in urchin distribution into areas previously occupied by the predatory sea stars. Understanding the ecological implications of sudden and extreme population declines may further elucidate the role of echinoderms in temperate seas, and provide insight into the resilience of marine ecosystems to biological disturbances.

16 **ABSTRACT**

17

18 Echinoderm population collapses, driven by disease outbreaks and climatic events, may be  
19 important drivers of population dynamics, ecological shifts and biodiversity. The northeast  
20 Pacific recently experienced a mass mortality of sea stars. In Howe Sound, British Columbia, the  
21 sunflower star *Pycnopodia helianthoides* — a previously abundant predator of bottom-dwelling  
22 invertebrates — began to show signs of a wasting syndrome in early September 2013, and dense  
23 aggregations disappeared from many sites in a matter of weeks. Here, we assess changes in  
24 subtidal community composition by comparing the abundance of fish, invertebrates and  
25 macroalgae at 20 sites in Howe Sound before and after the 2013 sea star mortality to evaluate  
26 evidence for trophic cascade. We observed changes in the abundance of several species after the  
27 sea star mortality, most notably a four-fold increase in the number of green sea urchins,  
28 *Strongylocentrotus droebachiensis*, and a significant decline in kelp cover, which are together  
29 consistent with a trophic cascade. Qualitative data on the abundance of sunflower stars and  
30 green urchins from a citizen science database show that the patterns of echinoderm abundance  
31 detected at our study sites reflected wider local trends. The trophic cascade evident at the scale  
32 of Howe Sound was observed at half of the study sites. It remains unclear whether the urchin  
33 response was triggered directly, via a reduction in urchin mortality, or indirectly, via a shift in  
34 urchin distribution into areas previously occupied by the predatory sea stars. Understanding the  
35 ecological implications of sudden and extreme population declines may further elucidate the role  
36 of echinoderms in temperate seas, and provide insight into the resilience of marine ecosystems to  
37 biological disturbances.

38

## 39 INTRODUCTION

40

41 Echinoderms can be subject to dramatic population fluctuations (Uthicke *et al.*, 2009). Rapid  
42 declines are often driven by disease or extreme climatic events. For example, the spread of mass  
43 mortality of the black sea urchin, *Diadema antillarum*, in the 1980s suggests that it was most  
44 likely caused by a pathogen (Lessios *et al.*, 1984). The event impacted an estimated 3.5 million  
45 km<sup>2</sup> of the Caribbean region, causing up to 99% urchin mortality at some sites (Lessios, 1988).  
46 While the precipitous decline of *Diadema* was a unique occurrence, other echinoderm mass  
47 mortality events occur repeatedly. On the Atlantic coast of North America, an amoeboid parasite  
48 causes episodic mortality events in green sea urchins, *Strongylocentrotus droebachiensis* (Jones  
49 & Scheibling, 1985), which are linked to hurricanes and are predicted to increase in frequency  
50 with climate change (Scheibling & Lauzon-Guay, 2010). Similarly, recurring events of wasting  
51 disease involving asteroids (sea stars), echinoids (sea urchins) and holothurians (sea cucumbers)  
52 in the Channel Islands, California, are associated with climate regime shifts and extreme weather  
53 events (Engle, 1994; Eckert *et al.*, 2000).

54       Because sea stars and sea urchins play key ecological roles in many marine ecosystems,  
55 echinoderm population collapses can be important drivers of biodiversity, population dynamics  
56 and ecological shifts. In fact, the term ‘keystone predator’ was originally coined for the purple  
57 star, *Pisaster ochraceus*, after experiments showed that its absence led to significant decreases in  
58 intertidal biodiversity (Paine, 1966). Many other echinoderm species have since been shown to  
59 influence community composition through predation or herbivory. These effects are apparent on  
60 coral reefs following echinoderm population booms (e.g., coral cover declines owing to eruptive  
61 crown-of-thorns star, *Acanthaster planci* (Sano *et al.*, 1984)), or busts (e.g., the transition from

62 coral- to algae-dominated reefs following the *D. antillarum* mortality event (Carpenter, 1990)).  
63 On temperate rocky reefs, fluctuations in the abundance of herbivorous urchins can also result in  
64 major community shifts, from kelp forests to urchin barrens and back again (Estes & Duggins,  
65 1995; Steneck *et al.*, 2003).

66 The northeast Pacific region has recently experienced a protracted mass mortality of sea  
67 stars that might rival the magnitude of the *Diadema* die-off of the 1980s (Johnson, 2016). The  
68 event was first noticed on the Olympic coast of Washington in June 2013 (Hewson *et al.*, 2014).  
69 In affected sea stars, the signs progress from a loss of turgor pressure, to lesions and ruptures of  
70 the body wall and autotomization of arms, and ultimately, disintegration and death (Fig. 1). The  
71 wasting syndrome has continued through 2014 and 2015, and has so far affected some 20 species  
72 from Alaska to Southern California (Stockstad, 2014). A virus may be involved (Hewson *et al.*,  
73 2014), but the precise causes and contributing factors remain poorly understood. Moreover, little  
74 is known so far of the extent and ecological consequences of this sea star mortality event at any  
75 location.

76 Many of the affected seastars were predatory species, raising the possibility of trophic  
77 cascades associated with their disappearance and marked community restructuring. In Howe  
78 Sound, southern Strait of Georgia, British Columbia, the sunflower star *Pycnopodia*  
79 *helianthoides* showed signs of advanced wasting in early September 2013. Dense aggregations  
80 disappeared from many sites in a matter of weeks (personal observations). This species is one of  
81 the world's largest predatory sea stars and it consumes a variety of prey, including echinoderms,  
82 gastropods and crustaceans (Herrlinger, 1983; Shivji *et al.*, 1983). In areas that lack other  
83 predators such as sea otters *Enhydra lutris*, such as in Howe Sound, sunflower stars can become  
84 the dominant predator of urchins (Duggins, 1983). By altering the abundance and/or distribution

85 of sea urchins, which in turn can have a conspicuous impact on the abundance of kelp, sunflower  
86 stars can influence the formation and persistence of urchin barrens, i.e. areas devoid of kelp  
87 because of the grazing activity of urchins (Duggins, 1981). Indeed, most well-substantiated  
88 examples of tri-trophic cascades in rocky subtidal ecosystems involve urchins as prey and major  
89 herbivore (Pinnegar *et al.*, 2000). We therefore expected that *Pycnopodia* prey, in particular  
90 urchins, would increase in abundance following the disappearance of their major predator,  
91 leading to reductions in kelp cover.

92 Here, we evaluate the extent of mortality of *P. helianthoides* in Howe Sound and test  
93 whether changes in the benthic community following the rapid decline of this predatory sea star  
94 are consistent with the hypothesis of a trophic cascade. We compare rocky reef community  
95 composition before and after the mass mortality using quantitative data derived from subtidal  
96 transects and qualitative information gathered by citizen scientists. In doing so, we provide  
97 empirical evidence that a trophic cascade quickly followed what might be one of the largest  
98 wildlife die-off events ever recorded (Johnson, 2016).

99

## 100 **MATERIALS AND METHODS**

### 101 **Subtidal surveys**

102 We compared sunflower star abundance and benthic community composition before (2009/2010)  
103 and after (2014) the 2013 wasting event using scuba-based surveys of 20 sites in Howe Sound,  
104 British Columbia (BC), Canada (Fig. 2). Surveys before the wasting event were conducted as  
105 part of a study of rockfish (*Sebastes* spp) habitat (Cloutier, 2011). We repeated these surveys  
106 after the wasting event using the same method, at the same GPS locations, depths (within 2 m)  
107 and time of year (within 14 days). Ten sites were surveyed in early summer (June – July) and 10

108 sites in late summer (August – October). In all surveys, we recorded the abundance of 18 taxa  
109 (species or species groups) of common benthic fishes and invertebrates (Table 1).

110 At each site we surveyed four transects (25 m long by 4 m wide) at depths between 8 and  
111 15 m (chart datum). We quantified fish and invertebrate abundance by counting all individuals of  
112 the target taxa occurring fully or partly within 0.25 m<sup>2</sup> quadrats placed at 15 random positions  
113 along each transect. We also estimated visually the percent cover of kelp (mainly the genera  
114 *Agarum*, *Costaria*, *Laminaria* and *Saccharina*) within the same quadrats.

115

### 116 **Citizen-contributed (REEF) surveys**

117 To verify that the patterns of echinoderm abundance detected at our 20 study sites reflected local  
118 trends accurately, we compiled qualitative data on the abundance of sunflower star and green  
119 urchin in Howe Sound and adjacent Indian Arm, east of Vancouver, from the Reef  
120 Environmental Education Foundation (REEF) citizen science database. Through REEF, scuba  
121 divers are trained in species identification and collect data on abundance of species sighted  
122 during recreational dives. Divers assign an abundance score from 1 – 4 to each species they can  
123 positively identify: score 1 = a single individual, 2 = 2-10 individuals, 3 = 11-100 individuals  
124 and 4 = > 100 individuals. Species with no abundance score were assumed to be absent, which  
125 we deemed to be a fair assumption given that our target taxa were easy to identify.

126 We extracted the abundance scores of sunflower stars and green sea urchins for all REEF  
127 surveys submitted between January 1, 2010 and November 1, 2014 in Washington and BC. To  
128 depict trends in abundance over time, we plotted 60-day running averages of the abundance  
129 scores for both species. Missing values were filled in using linear interpolation.

130

**131 Data analyses**

132 We used linear mixed-effects models in the R statistical platform (nlme package; Pinheiro *et al.*,  
133 2015) to compare sunflower star abundance, green urchin abundance and kelp cover before and  
134 after the sea star mortality. We obtained sunflower and green urchin abundance for each transect  
135 by summing the number of sunflower stars and, separately, green urchins across all quadrats and  
136 log-transforming the values prior to analysis. Kelp cover was averaged across all quadrats  
137 within each transect. In all cases, we included ‘site’ as a random effect, and verified the  
138 assumptions of normally distributed residuals, homoscedasticity and the absence of leverage by  
139 visually examining quantile, residual vs. fitted and Cook’s distance diagnostic plots,  
140 respectively.

141 To depict graphically site-level changes in the abundance of sunflower stars, green sea  
142 urchins and kelp, we plotted the relative difference in abundance for each group at each site.  
143 Relative abundance was calculated as the abundance after the mortality event minus the  
144 abundance prior to it divided by the mean abundance for both time periods. Abundance was  
145 calculated as the total count of each species at each site for sunflower stars and green urchins,  
146 and as the average percent cover at each site for algae.

147 To compare overall benthic community composition before and after the sea star  
148 mortality, we ran a permutation-based, non-parametric analysis of similarity (ANOSIM; Clarke,  
149 1993) using PRIMER (v. 1.0.3; Clarke & Gorley, 2006). Abundance matrices (species by site)  
150 were compiled for each period (i.e., pre- and post-mortality), in which abundance was estimated  
151 as the total count of each taxon across transects and/or quadrats at each site. The raw data were  
152 square-root-transformed to reduce the influence of very abundant or very rare species. Bray-  
153 Curtis similarity coefficients were computed between pairs of sites (Clarke & Warwick, 2001).

154 The ANOSIM procedure was carried out on the similarity matrix. ANOSIM generates an R  
155 statistic, which varies between 0 (samples are as similar across groups as they are within group)  
156 and 1 (all samples within groups are more similar to each other than to any sample across  
157 groups) and is tested for difference from zero with a permutation test (in this study, N = 999  
158 permutations). The differences in benthic assemblages were visualized in a non-metric,  
159 multidimensional scaling (MDS) plot in which samples that are more similar in community  
160 composition appear closer together than more dissimilar samples. Stress values of <0.1 suggest  
161 that distances among samples in an MDS plot accurately reflect the extent of community  
162 differences (Clarke & Warwick, 2001). Finally, we conducted an analysis of similarity  
163 percentages (SIMPER) to identify the main taxa responsible for any differences observed  
164 between pre- and post-mortality assemblages. We considered a taxon to be important to  
165 community differences if their individual contribution was 11% or more, which is twice the  
166 expected value if dissimilarity contributions were evenly distributed among all taxa in the  
167 analysis (i.e., 100 percent divided by 18 taxa, multiplied by 2). The SIMPER analysis also  
168 includes an indication of evenness, expressed as a consistency ratio (CR). CR is the average  
169 dissimilarity contribution of a taxon divided by the standard deviation in dissimilarity values of  
170 that taxon, for each time period. CR values greater than one suggest that the taxon contributed to  
171 dissimilarity between time periods equally across all sites (Terlizzi *et al.*, 2005).

172

173

174

175

176

## 177 RESULTS

178

### 179 **Sea star mortality**

180 At our monitored sites, the abundance of sunflower stars declined by  $89\% \pm 29\%$  (mean  $\pm$  SD),  
181 from an average of 0.42 ( $\pm$  0.76) sunflower stars per  $m^2$  before the mortality event to 0.06 ( $\pm$   
182 0.22) individuals per  $m^2$  after it (LME:  $t = 4.62$ ,  $df = 139$ ,  $p < 0.0001$ ; Fig. 3). Three sites had no  
183 sunflower stars in 2009/2010, and were not included in the percent decline calculation. All 17  
184 sites with sunflower stars in 2009/2010 had fewer sunflower stars in 2014.

185 The REEF data included 1568 surveys carried out at 28 sites broadly distributed across  
186 BC and Washington between 2010 and 2014. Although sunflower stars were sighted on 98% of  
187 surveys in the years before the mortality event and on 89% of surveys in the years afterward, a  
188 marked decline was evident in their abundance score trajectory (Fig. 5). At this larger geographic  
189 scale, sunflower stars started declining in approximately the third week of September, some 15  
190 weeks after the first report of seastar wasting in the region.

191 We were unable to detect a geographic pattern in the spread of the sea stars' mortality in  
192 our study area because of the speed at which the seastar wasting progressed. It was first  
193 observed in Howe Sound (at Whytecliff Park;  $49^{\circ}22'18.4''N$ ,  $123^{\circ}17'33.8''W$ ) on 2 September,  
194 2013, and we then noted it at all of our study sites the following month.

195

### 196 **Benthic community composition**

197 There was a significant shift in overall community composition following sea star mortality in  
198 Howe Sound (ANOSIM:  $R = 0.326$ ,  $p = 0.001$ ; Fig. 6), and many species changed in abundance  
199 from one period to the next (Table 1). The community shift was largely driven by an increase in

200 abundance of green urchins (Table 2). Green urchin abundance quadrupled after the near-  
201 disappearance of sunflower stars (LME:  $t = -3.10$ ,  $df = 139$ ,  $p = 0.0023$ ; Fig. 3). This trend is  
202 supported by the REEF surveys, although these qualitative data suggest that green urchin  
203 numbers began increasing in the first week of September, two to three weeks before the  
204 detectable onset of sea star decline (Fig. 5). There was also an increase in the abundance of cup  
205 corals, while the numbers of small shrimps and crabs decreased (Table 2). Cumulatively, these  
206 four taxa accounted for nearly two-thirds (62%) of the dissimilarity in benthic community  
207 composition before and after the sea star mortality, and their contributions were consistent across  
208 sites (CRs > 1; Table 2). Despite their marked decline, sunflower stars did not contribute  
209 disproportionately to the dissimilarity between time periods (SIMPER; individual contribution to  
210 dissimilarity = 7.15%). Overall, within-year similarity was higher after than before sea stars died  
211 (SIMPER; average inter-site similarity before = 46.28%, after = 58.11%; Fig. 6), suggesting that  
212 communities became more homogeneous following the seastar mortality.

213 In addition to shifts in benthic animal community composition, there was also a change in  
214 the abundance of kelp. Kelp cover decreased from 4% ( $\pm 10\%$ ) in 2009/2010 to <1% ( $\pm 2\%$ ) in  
215 2014 (LME:  $t = 2.669$ ,  $df = 139$ ,  $p = 0.0085$ ; Fig. 3). In all years, the kelp at our sites was almost  
216 exclusively the sea colander kelp, *Agarum fimbriatum*, but also included *Saccharina latissima*.

217 At the regional scale, the changes in abundance of sunflower stars (decline), green  
218 urchins (increase) and kelp (decline) were consistent with a trophic cascade (Fig. 3). At the site  
219 level, the patterns were more variable (Fig. 4). Eleven of the 17 sites that had some *P.*  
220 *helianthoides* before the sea star mortality showed increases in green urchin abundance  
221 concomitant with declines in sea star abundance (Fig. 4). Eight of these 17 sites showed declines  
222 in kelp cover concomitant with increases in green urchin abundance (Fig. 4). A clear alternation

223 of population trajectories from predators to herbivores to kelp was clear at eight of the 16 sites  
224 (Fig 4).

225

## 226 **DISCUSSION**

227

228 The wasting disease that affected echinoderms in the northeast Pacific in 2013/2014 heavily  
229 impacted populations of sunflower stars, the sea stars that formerly dominated subtidal  
230 communities. We found a noticeable shift in benthic community structure following the sea star  
231 decline. Community changes were largely driven by changes in the abundance of green sea  
232 urchins, cup corals, shrimps and crabs. The temporal coincidence of the alternating trajectories of  
233 abundance of sea stars, urchins and kelp, as well as the overlapping distributions and  
234 documented trophic linkages among these three taxa, meet the diagnostic criteria of a tri-trophic  
235 cascade (Grubbs *et al.* 2016), triggered by the mass mortality of predatory sunflower stars.

236 Sunflower star densities declined by almost 90%, on average, at our sites in Howe Sound,  
237 BC. Such a decline in sea stars rivals the largest magnitudes reported for disease-induced  
238 echinoderm mass mortalities (e.g., 70% of *Strongylocentrotus droebachiensis* in Nova Scotia  
239 (Scheibling & Stephenson, 1984); 95% of *S. franciscanus* in California (Pearse *et al.*, 1977);  
240 97% of *Diadema antillarum* across the Caribbean (Lessios, 1988)). The percent change in  
241 biomass of *P. helianthoides* must be even greater than the change in relative abundance because  
242 the sea stars we observed following the mortality event were almost exclusively juveniles (< 6  
243 cm diameter). The very large individuals (>50 cm diameter) present before the mortality event  
244 likely played a proportionately larger role in structuring benthic communities than the juveniles  
245 present after the event. The steep decline in sunflower star numbers, occurring some 15 weeks

246 after the first official sighting of sea star wasting, was clearly evident in the qualitative density  
247 scores generated by citizen science (REEF) surveys, which covered a broader geographic area.  
248 The time-series of REEF data suggests that sunflower star population levels were somewhat  
249 variable, perhaps reflecting variation in the sites surveyed by divers, but largely stable between  
250 the first snapshot in 2009/2010 and the onset of the wasting event in 2013. More generally, the  
251 benthic species composition of the Strait of Georgia region has remained remarkably stable in  
252 recent decades, even in the face of climate regime shifts (Marliave *et al.* 2011). It therefore  
253 seems unlikely that the sea star population declines, and concomitant changes in benthic  
254 community composition, could be ascribed to a different, unreported disturbance occurring prior  
255 to 2013.

256         The most striking change we observed in community composition was a marked increase  
257 in the abundance of green urchins. Overall, green urchins were nearly four times more numerous  
258 following the sea star mortality event than before. However, the mechanism of this population  
259 increase remains unclear. One possibility is that a recruitment pulse of green urchins coincided  
260 with sea star wasting disease, which would have generated a large urchin cohort even in the  
261 presence of sunflower stars. Another possibility is that urchin recruits – whether part of a normal  
262 or a large cohort – were able to survive better in the absence of abundant sea star predators  
263 (Duggins, 1981). The majority of urchins present a year following the seastar mortality were  
264 approximately 3 - 5 cm in diameter. Green urchins of this size on the east coast of North  
265 America are at least three years of age, and possibly more than a decade old (Russel, Ebert &  
266 Petraitis, 1998; Vadas *et al.*, 2000). If these growth rates are similar on the Pacific coast, then  
267 most of the urchins we saw could have settled several years before the sea star mortality event.  
268 However, urchin growth rates can be highly variable (Vadas *et al.*, 2000), depending on food

269 supply and temperature (Thompson, 1983; Meidel & Scheibling, 1999; Pearce *et al.*, 2005) ,  
270 Urchin growth rates have not yet been estimated in BC. A third possible explanation is that the  
271 observed increase in urchin abundance resulted from a shift in urchin behaviour following the  
272 sea star mortality event. The impact of ‘intimidation’ on predator–prey interactions can be as  
273 important as direct consumption (Lima & Dill, 1990; Preisser, Bolnick & Benard, 2005). Under  
274 risk of predation, prey individuals alter a suite of behaviours, including habitat choice, foraging  
275 range, and time under cover (Werner *et al.*, 1983; Peacor & Werner, 2001; Trussell, Ewanchuk  
276 & Bertness, 2003; Schmitz, Krivan & Ovadia, 2004). The effect of sunflower stars on urchin  
277 behaviour is well documented. In field experiments in Alaska, both green and purple (*S.*  
278 *purpuratus*) urchins moved away after *P. helianthoides* arms were placed in the centre of urchin  
279 aggregations (Duggins, 1981), and urchin distribution shifted rapidly when sea star abundance  
280 was experimentally increased (Duggins, 1983). Fear-released urchins could therefore respond by  
281 moving from refuges, perhaps in very shallow or deep habitats or in sheltered crevices  
282 inaccessible to sea stars (and divers), to more open substrates, making them easier to see and  
283 count.

284         The data from REEF surveys support a behavioural rather than a consumptive mechanism  
285 for the increase in urchin numbers. Whereas one would expect a delayed increase in urchin  
286 numbers following a release from predation (Wangersky & Cunningham, 1957), green urchin  
287 numbers began to increase at approximately the same time as the decline in sunflower stars was  
288 evident (Fig. 5). The observed change in green urchin abundance may therefore be due, at least  
289 in part, to green urchins modifying their distribution in response to the decline of sunflower stars.

290         Another conspicuous change we observed was a ~80% reduction in kelp cover (Fig. 3),  
291 pointing to a potential trophic cascade triggered by the sea star mortality event. There are many

292 documented examples of urchin abundance directly influencing the abundance of algae (e.g.  
293 Fletcher 1987; Carpenter, 1990; Estes & Duggins, 1995; McClanahan *et al.* 1996; Palacin *et al.*,  
294 1998; Scheibling, Hennigar & Balch, 1999; Villouta *et al.* 2001). As urchin numbers rise, either  
295 due to a large recruitment event (Hart & Scheibling, 1988) or the absence of a predator (Watson  
296 & Estes, 2011), kelp is rapidly depleted. The alternating directions of population trends of sea  
297 stars, urchins and kelp observed here are consistent with the hypothesis of a trophic cascade  
298 triggered by the sea star disease. The tri-trophic cascade was clearly evident at the larger scale of  
299 Howe Sound (Fig. 3), but detectable at only half of the sites, with a few additional sites showing  
300 only part of the cascade (Fig. 4). It is notable that the sites surveyed earliest (i.e., sites 1-5 on  
301 Figs 2 and 4) showed an increase in kelp cover, perhaps because not enough time had passed for  
302 changes to take place. At other sites where the trophic cascade was not detectable, it is possible  
303 that urchins moved elsewhere in search of better food sources (e.g., at sites 17 and 18 on Fig. 4),  
304 or that the presence of juvenile sea stars (i.e., site 20 on Fig. 4) resulted in different trophic  
305 interactions.

306         In contrast to green urchins, the abundance of many prey species did not increase in the  
307 near-absence of sunflower star predators. For example, there was no change in the abundance of  
308 red urchins (*S. franciscanus*) and white urchins (*S. pallidus*). Neither species is common in  
309 Howe Sound, and little is known about the ecology of *S. pallidus*. However, *S. franciscanus*  
310 may generally be less susceptible to sea star predation than other urchin species because they  
311 grow too large to be consumed (Duggins, 1981). Moreover, although crustaceans constitute a  
312 significant portion of the diet of sunflower stars (Shivji *et al.*, 1983; Estes & Duggins, 1995;  
313 Lambert, 2000), shrimps and crabs declined following the sea star mortality. Several of the  
314 crustaceans we monitored use kelp for both food and habitat. The spot prawn, *Pandalus*

315 *platyceros*, for instance, specifically uses the sea colander kelp as nursery habitat (Marliave &  
316 Roth, 1995). The decline of some crustacean taxa could result from the reduced kelp cover and  
317 therefore be a fourth step in the cascade documented here.

318 Another fourth link in the ecological cascade triggered by sea star mortality might  
319 involve cup corals. Their increase in abundance was surprising as cnidarians are not normally  
320 consumed by *P. helianthoides* (Shivji *et al.*, 1983; Herrlinger, 1983). However, cup corals are  
321 known to fare poorly in areas dominated by macroalgae (Fadlallah, 1983). Contact with algae  
322 causes coral polyp retraction, which in turn allows overgrowth by filamentous and coralline  
323 algae (Coyer *et al.*, 1993). Increases in density of cup corals can be swift (< 1 year), and of the  
324 magnitude observed here (3-4 times), after algae disappear (Coyer *et al.*, 1993). Of course, the  
325 reduced abundance of kelp and of sea stars may also have allowed for a less obstructed view of  
326 the substrate by the observers. As a number of taxa were not monitored in this study, there were  
327 likely other changes following the sea star mortality event that we did not detect.

328 In conclusion, our study contributes to understanding the ecological consequences of the  
329 northeast Pacific sea star mass mortality. The most notable change was a marked increase in the  
330 number of green sea urchins, which might have already had trickle-down effects on other levels  
331 of the ecosystem by the time we detected it. It is unclear whether the changes observed will  
332 persist as long-term consequences of the near-disappearance of sea stars. Nonetheless, further  
333 monitoring will help elucidate the resilience of this ecosystem in the face of acute biological  
334 disturbances. Although such a sudden and drastic decline in sea star populations is alarming, it  
335 provides a large-scale natural experiment that may advance our understanding of subtidal trophic  
336 cascades and invertebrate population dynamics.

337

338

339 **ACKNOWLEDGEMENTS**

340

341 We thank the Vancouver Aquarium Marine Science Centre for all aspects of this study, and in  
342 particular the Howe Sound Research team: Jeff Marliave, Donna Gibbs, Laura Borden, and Boaz  
343 Hung for support with all aspects of this study. Thank you to volunteer divers Roya Esragh, Marielle  
344 Wilson, Brian Caron, Justin Lisaingo, Crystal Kulstar, and Alex Clegg. Comments by Jeff Marliave,  
345 Alejandro Frid, Jane Williamson and one anonymous reviewer greatly improved the manuscript.

**Figure 2. Rocky reef survey sites in Howe Sound, British Columbia.** Benthic community composition was assessed at each of the 20 sites once in 2009 or 2010 and again in 2014. A mass mortality of sea stars occurred in the summer and fall of 2013 in this area. A site-level trophic cascade following the mortality was detectable at some sites (solid circles) but not others (open circles). (Map data © 2015 WorldMap).

467 **Table 1. Taxa recorded during subtidal surveys in Howe Sound, British Columbia.** Mean  
 468 density and standard deviation per 15 m<sup>2</sup> are given for each taxon as recorded before and after  
 469 the sea star mortality event.

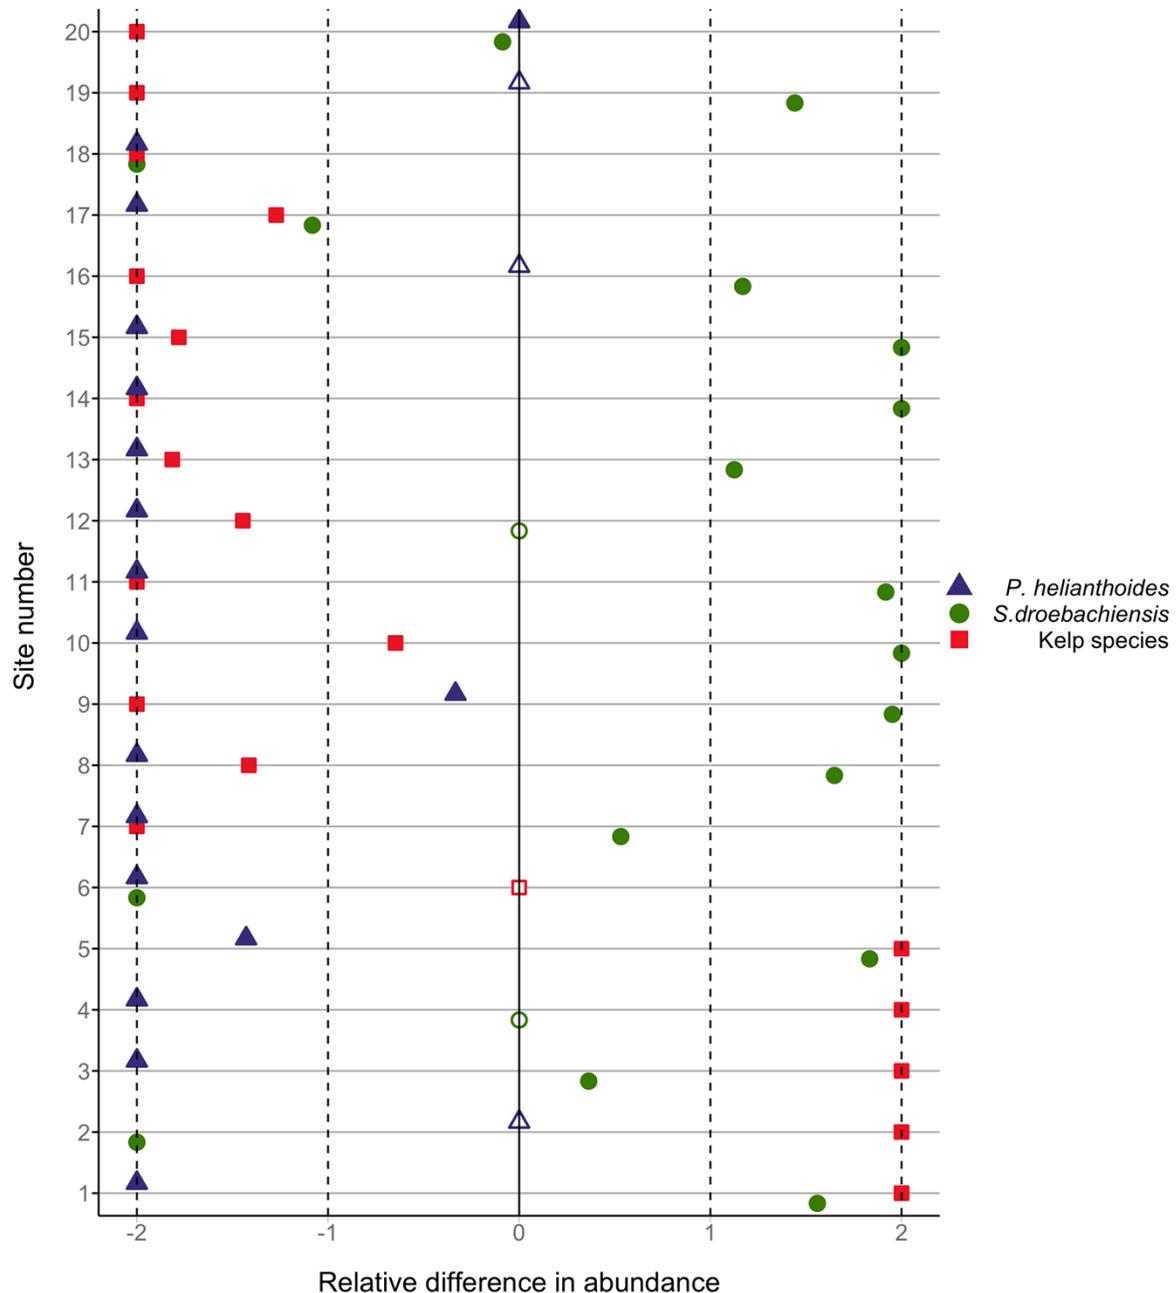

Taxon	Species or genera included in taxon	Mean density (SD)	
		Before	After
Invertebrates			
Sunflower star	<i>Pycnopodia helianthoides</i> Brandt, 1835	6.4 (11.4)	0.9 (3.3)
Green urchin	<i>Strongylocentrotus droebachiensis</i> O. F. Müller, 1776	18.3 (41.0)	77.2 (157.4)
Red urchin	<i>Strongylocentrotus franciscanus</i> Aggasiz, 1863	0.4 (0.9)	0.3 (0.6)
White urchin	<i>Strongylocentrotus pallidus</i> G. O. Sars, 1871	1.1 (2.0)	0.3 (0.4)
California cucumber	<i>Parastichopus californicus</i> Linnaeus, 1758	6.1 (9.0)	13.1 (8.9)
Dungeness crab	<i>Metacarcinus magister</i> Dana, 1852	0.1 (0.2)	0.0
Red rock crab	<i>Cancer productus</i> Randall, 1839	0.1 (0.3)	0.4 (0.7)
Spot prawn	<i>Pandalus platyceros</i> Brandt, 1851	22.1 (89.1)	0.3 (0.8)
Squat lobster	<i>Munida quadrispina</i> Benedict, 1902	4.0 (9.0)	0.3 (0.6)
Miscellaneous crabs	Primarily anomurans, including lithode and hermit crabs; several brachyuran genera including <i>Cancer</i> , <i>Pugettia</i> , <i>Scyra</i> , and <i>Oregonia</i>	21.7 (35.0)	16.3 (23.5)
Miscellaneous shrimps	Primarily <i>Pandalus danae</i> Stimpson, 1857, but also other members of the genus <i>Pandalus</i> , as well as the genera <i>Lebbeus</i> , <i>Eualus</i> , <i>Heptocarpus</i> and possibly others	37.0 (38.6)	15.8 (11.2)
Giant Pacific octopus	<i>Enteroctopus dofleini</i> Wülker, 1910	0.1 (0.2)	0.0
Cup corals	<i>Balanophyllia elegans</i> Verrill, 1864, <i>Caryophyllia alaskensis</i> Vaughan, 1941	6.7 (15.8)	22.1 (19.0)
Benthic fishes			
Grunt sculpin	<i>Rhamphocottus richardsonii</i> Günther, 1974	0.1 (0.2)	0.1 (0.2)
Longfin sculpin	<i>Jordania zonope</i> Starks, 1895	0.2 (0.4)	2.7 (4.1)
Sailfin sculpin	<i>Nautichthys oculo fasciatus</i> Girard, 1858	0.1 (0.2)	0.0
Scalyhead sculpin	<i>Artedius harringtoni</i> Starks, 1896	0.8 (1.6)	1.8 (2.3)
Miscellaneous sculpins	Cottid genera including <i>Artedius</i> , <i>Orthanopias</i> , <i>Oligocottus</i> , <i>Radulinus</i> , <i>Chitonotus</i> and possibly others.	5.5 (4.6)	0.7 (1.2)

**Figure 4. Relative difference in abundance of seastars, urchins and kelp by site.** The relative difference in total count of sunflower stars (blue triangles) and green urchins (green circles), and the relative difference in the mean percent cover of algae (red squares) before and after the sea star mass mortality. Open symbols indicate sites where population density was zero both before and after the mass mortality. Relative difference was calculated as the change in abundance divided by the mean abundance of both time periods. A relative difference of -2 indicates the population declined to zero. Sites are numbered chronologically according to the order in which they were surveyed, from June to August, 2014.

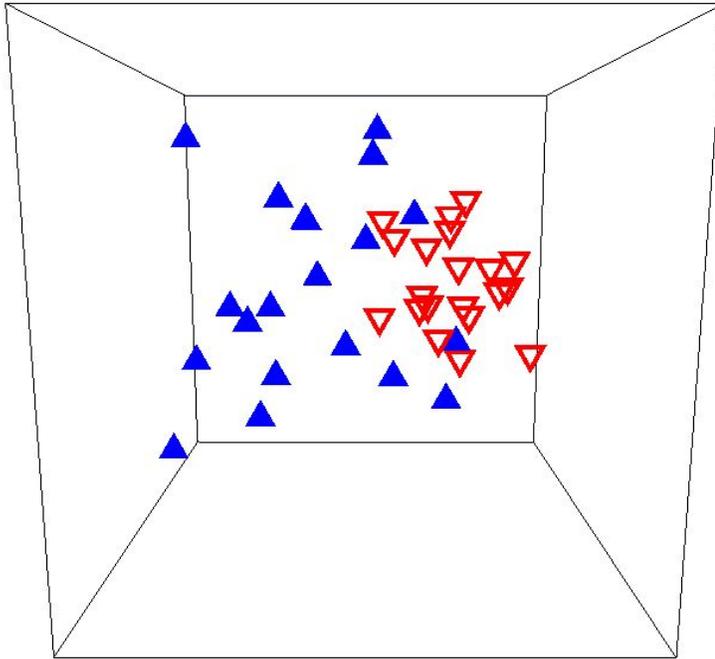

488

489

490 **Figure 5. Sunflower star and green sea urchin abundance trajectories.** Sixty-day running  
491 average abundance scores for green sea urchins (*Strongylocentrotus droebachiensis*; green solid  
492 line) and sunflower stars (*Pycnopodia helianthoides*; purple dashed line) recorded in REEF  
493 surveys from January 2010 to November 2014 in Washington and British Columbia ( $n = 1568$   
494 surveys). Grey bands indicate 95% confidence intervals of the running average. The vertical red  
495 dotted line indicates the date of the first recorded observation of sea star wasting syndrome (7  
496 June 2013), which was on the Olympic coast of WA.

497

498

499 **Figure 6. Rocky reef species assemblages before and after sea star mortality.**

500 Multidimensional scaling plot of benthic community composition on rocky reefs before (blue  
501 triangles) and after (inverted red triangles) the 2013 sea star mass mortality event in Howe  
502 Sound, British Columbia. The analysis included 18 fish and invertebrate taxa at 20 sites,  
503 surveyed both in 2009/2010 and 2014. The associated stress value (0.13) suggests some  
504 distortion in the multivariate representation of the data.

505 **Table 2. Differences in pre- and post-mortality benthic assemblages.** The four taxa that  
 506 contributed disproportionately to dissimilarity in benthic community composition on rocky reefs  
 507 before and after the 2013 sea star mass mortality. Mean densities (# per 30 m<sup>2</sup> ± 1 SD),  
 508 consistency ratios, and individual and cumulative contributions (in %) to differences between  
 509 years are shown. The consistency ratio is calculated as a species' average dissimilarity  
 510 contribution divided by the standard deviation of dissimilarity values. A consistency ratio > 1  
 511 indicates an even contribution to community dissimilarity across sites. The analysis was  
 512 conducted on square-root-transformed data (see Methods) but untransformed densities are  
 513 presented here.

Taxon	Mean density (SD)		Consistency ratio	Individual contribution (%)	Cumulative contribution (%)
	Before	After			
<i>Strongylocentrotus droebachiensis</i>	18.3 (41.0)	77.2 (157.5)	1.09	18.91	18.91
Cup corals	6.7 (15.8)	22.2 (19.1)	1.41	13.04	31.95
Misc. shrimps	37.0 (38.7)	15.9 (11.2)	1.3	11.29	43.23
Misc. crabs	21.7 (35.0)	16.3 (23.5)	1.05	11.15	54.38
<i>Pycnopodia helianthoides</i>	6.4 (11.4)	0.9 (3.3)	1.18	7.15	69.05
