

## **Forest birds respond to the spatial pattern of exurban development in the Mid-Atlantic region, USA**

Marcela Suarez-Rubio, Todd R Lookingbill

Housing development beyond the urban fringe (i.e. exurban development) is one of the fastest growing forms of land-use change in the United States. Exurban development's attraction to natural and recreational amenities has raised concerns for conservation and represents a potential threat to wildlife. Although forest-dependent species have been found particularly sensitive to low housing densities, it is unclear how the spatial distribution of houses affects forest birds. The aim of this study was to assess forest bird response to changes in the spatial pattern of exurban development. We evaluated landscape composition around North American Breeding Bird Survey stops between 1986 and 2009 by developing a compactness index to assess changes in the spatial pattern of exurban development over time. We used Threshold Indicator Taxa Analysis to detect the response of forest and forest-edge species in terms of occurrence and relative abundance along the compactness gradient at two spatial extents (400-m and 1-km radius buffer). Our results show that most forest birds and some forest-edge species were positively associated with high levels of compactness at the landscape extent. In contrast, the spatial configuration of exurban development was an important predictor of occurrence and abundance for only a few species at the local extent. The positive response of forest birds to compactness at the landscape extent could represent a systematic trajectory of decline and could be highly detrimental to bird diversity if exurban growth continues and becomes more compacted development.

15 **ABSTRACT**

16 Housing development beyond the urban fringe (i.e. exurban development) is one of the fastest  
17 growing forms of land-use change in the United States. Exurban development's attraction to  
18 natural and recreational amenities has raised concerns for conservation and represents a potential  
19 threat to wildlife. Although forest-dependent species have been found particularly sensitive to  
20 low housing densities, it is unclear how the spatial distribution of houses affects forest birds. The  
21 aim of this study was to assess forest bird response to changes in the spatial pattern of exurban  
22 development. We evaluated landscape composition around North American Breeding Bird  
23 Survey stops between 1986 and 2009 by developing a compactness index to assess changes in  
24 the spatial pattern of exurban development over time. We used Threshold Indicator Taxa  
25 Analysis to detect the response of forest and forest-edge species in terms of occurrence and  
26 relative abundance along the compactness gradient at two spatial extents (400-m and 1-km radius  
27 buffer). Our results show that most forest birds and some forest-edge species were positively  
28 associated with high levels of compactness at the landscape extent. In contrast, the spatial  
29 configuration of exurban development was an important predictor of occurrence and abundance  
30 for only a few species at the local extent. The positive response of forest birds to compactness at  
31 the landscape extent could represent a systematic trajectory of decline and could be highly  
32 detrimental to bird diversity if exurban growth continues and becomes more compacted  
33 development.

## 37 INTRODUCTION

38 As the world's human population has grown over the last century and residential housing has  
39 continued to sprawl even in areas where human population is declining (Pendall 2003; Seto et al.  
40 2012), the rapid increase of housing development has expanded not only at the edge of cities but  
41 also beyond the urban fringe to increasingly more rural areas (e.g., Davis & Hansen 2011;  
42 Hansen et al. 2005; McKenzie et al. 2011; Suarez-Rubio et al. 2012a). Housing development  
43 beyond the urban fringe (i.e. exurban development) is characterized by low-density, scattered  
44 housing units further away than the suburbs but within commuting distance to an urban center  
45 (Berube et al. 2006; Daniels 1999; Lamb 1983; Nelson 1992; Theobald 2001). In the  
46 conterminous United States, low-density development has been prominent since the 1950s  
47 (Brown et al. 2005) and growing at a rate of about 10% to 15% per year (Theobald 2001). By  
48 2000, 25% of the nation was already considered exurbia (Brown et al. 2005) and forecasts have  
49 indicated that this pattern of land use will continue into the future (Brown et al. 2014; Kirk et al.  
50 2012).

51 The attraction of exurban development to areas with high quality natural and recreational  
52 amenities (Gonzalez-Abraham et al. 2007; Hammer et al. 2004) has raised environmental and  
53 ecological concerns (Gude et al. 2006; Hansen et al. 2005; Leu et al. 2008; Sampson & DeCoster  
54 2000). Exurban development can alter disturbance regimes such as wildfires (NIFC 2013;  
55 Radeloff et al. 2005) and biogeochemical cycles by changing greenhouse gas fluxes (Dale et al.  
56 2005; Huang et al. 2014). In addition, the loss of vegetation cover and structural complexity  
57 around houses in exurban areas may have negative impacts on wildlife communities (Casey et al.  
58 2009; Odell & Knight 2001) by fragmenting and degrading habitats and natural resources  
59 (Friesen et al. 1995; Suarez-Rubio et al. 2013; Theobald et al. 1997). As a consequence, exurban

60 development has been linked to reduced survival and reproduction of some wildlife species  
61 (Riley et al. 2003; Tewksbury et al. 1998) and changes in the behavior and habitat use of other  
62 species, for example by interrupting bird migration and movement (Lepczyk et al. 2004; Miller  
63 et al. 1998).

64 Forest birds have been found particularly sensitive to new housing (Pidgeon et al. 2007)  
65 even at densities as low as 0.095 house/ha (Friesen et al. 1995; Merenlender et al. 2009; Suarez-  
66 Rubio et al. 2011). Area-sensitive, some cavity-nesting, and bark-foraging birds are relatively  
67 more susceptible to the effects of exurban development than granivores, omnivores, and ground  
68 foragers (Fraterrigo & Wiens 2005; Glennon & Kretser 2013; Kluza et al. 2000; Merenlender et  
69 al. 2009). Although the mechanisms are not well understood, changes in bird communities have  
70 been associated with increased predation (Engels & Sexton 1994; Lumpkin et al. 2012), brood  
71 parasitism (Chace et al. 2003), free-roaming pets (Dauphiné & Cooper 2009), and activities of  
72 landowners (Lepczyk et al. 2004).

73 The effects of exurban development extend beyond immediate house surroundings. In the  
74 Rocky Mountain region of the western U.S., an impact zone of up to 180 m from houses has  
75 been observed for bird and small-mammal communities (Odell & Knight 2001). Similarly, in the  
76 northeastern U.S., an ecological effect zone of up to 200 m has been documented for breeding  
77 birds (Glennon & Kretser 2013). It is likely that the size of the zone of influence of exurban  
78 development is dependent upon the spatial distribution of houses (Hansen et al. 2005). If houses  
79 are clustered, the ecological effects of each house overlap, reducing the overall negative impacts.  
80 Thus, clustered development is thought to minimize impacts on wildlife habitat relative to highly  
81 dispersed low-density housing (Gagné & Fahrig 2010; Glennon & Kretser 2013; Odell et al.  
82 2003; Theobald et al. 1997). However, little is known about how the spatial pattern of exurban

83 areas changes as this form of development progresses and whether forest birds respond to  
84 changes in exurban spatial pattern.

85         The aim of this study was to assess forest bird response to changes in the spatial pattern of  
86 exurban development. We developed a compactness index to quantify the spatial configuration  
87 of exurban development around North American Breeding Bird Survey stops in the Mid-Atlantic  
88 region of the U.S. between 1986 and 2009 and assessed the response of selected bird species  
89 (i.e., forest and forest-edge species) along this compactness gradient. In addition, we determined  
90 whether species responded differently to exurban pattern at the local (400-m radius buffer) and  
91 landscape scale (1-km radius buffer). We hypothesized that exurban development would be more  
92 compact overtime and thus forest birds would exhibit a decrease in occurrence and relative  
93 abundance, whereas forest-edge species would respond positively to compactness of exurban  
94 development. To our knowledge, this is the first time that a continuous gradient approach has  
95 been used to quantify compactness as exurban development progresses and to identify threshold  
96 responses along this gradient.

## 97 **MATERIALS AND METHODS**

### 98 **Study area**

99 Our study area encompassed approximately 4300 km<sup>2</sup> and included nine counties in north-central  
100 Virginia (Clarke, Culpeper, Fauquier, Frederick, Madison, Page, Rappahannock, Shenandoah,  
101 and Warren) and two in western Maryland (Washington and most of Frederick; Fig. 1). The  
102 region has experienced high population growth rates, ranging from 4% (Page County) to 36%  
103 (Culpeper County) in the past decade (U.S. Census Bureau 2013). The region has also  
104 experienced an increase in exurban settlements over the same time period (Suarez-Rubio et al.

105 2012a), stimulated at least in part by the close proximity of natural amenities (Suarez-Rubio et  
106 al. 2012b).

### 107 **Breeding bird survey**

108 Using the North America Breeding Bird Survey (BBS) (Peterjohn & Sauer 1994; Sauer et al.  
109 2003), a large-scale annual roadside survey to monitor the status and trend of breeding bird  
110 populations in the United States and southern Canada, we selected two groups of species that  
111 represent contrasting habitat preferences (forest vs. edge). Forest species —Ovenbird (*Seiurus*  
112 *aurocapilla*), Red-eyed Vireo (*Vireo olivaceus*), American Redstart (*Setophaga ruticilla*), Wood  
113 Thrush (*Hylocichla mustelina*), Scarlet Tanager (*Piranga olivacea*), and Eastern Wood-Pewee  
114 (*Contopus virens*) (Poole 2005)— were defined as birds that utilize a wide variety of deciduous  
115 and mixed deciduous-coniferous forests and that might favor interior forested habitats  
116 (Mikusiński et al. 2001). Forest-edge species —Eastern Towhee (*Pipilo erythrophthalmus*),  
117 Eastern Phoebe (*Sayornis phoebe*), Gray Catbird (*Dumetella carolinensis*), Northern Cardinal  
118 (*Cardinalis cardinalis*), and Indigo Bunting (*Passerina cyanea*) (Poole 2005)— are those species  
119 that are strongly associated with forest edges and open habitats (Mikusiński et al. 2001). These  
120 11 species were also selected because they were detected on at least 5% of surveys during the  
121 1986-2009 interval. In addition, many of the species are reported to have experienced population  
122 declines or reduced fecundity in their distribution range due to habitat loss or fragmentation  
123 (Donovan & Flather 2002; Hagan 1993; Sherry & Holmes 1997; U.S. NABCI Committee 2009).

124 From each BBS route located in the study area, we uniformly selected a maximum of 10  
125 survey stops (every fifth stop along the route) to reduce overlap between adjacent areas around  
126 survey stops and decrease the likelihood of spatial autocorrelation. We only considered survey  
127 stops that had detailed direction descriptions (i.e., geocoding information and characterization of

128 site-specific features) and fell within the study region (125 survey points in total) (Fig. 1). We  
129 focused our analysis on survey stops instead of the entire route because of our interest in local  
130 variability of breeding habitats.

131 To characterize local characteristics of breeding habitats, we established potential zones of  
132 influence (Glennon & Kretser 2013) of 400-m and 1-km radius around the selected BBS stops.  
133 These areas represented both breeding bird territories (Bowman 2003; Mazerolle & Hobson  
134 2004), which were assumed to be in the immediate surroundings of survey stops, and areas  
135 feasibly visited during bird daily movements (Krementz & Powell 2000; Lang et al. 2002).  
136 Within these areas, we quantified the proportion of forest and exurban development and the  
137 spatial pattern of exurban development from 1986 to 2009.

138 We used a hierarchical Bayesian model to adjust BBS counts (Suarez-Rubio et al. 2013)  
139 and account for BBS sources of variability such as observer differences (Sauer et al., 1994), first-  
140 year observers' skills (Erskine 1978; Kendall et al. 1996), environmental conditions (Robbins et  
141 al. 1986), and habitat features (Sauer et al. 1995). We modeled count data as hierarchical over-  
142 dispersed Poisson and fit models using Markov Chain Monte Carlo (MCMC) methods in  
143 WinBUGS 1.4.3 (Lunn et al. 2000). We specified  $C_{it}$  as the count for each species on stop  $i$  and  
144 time  $t$  where  $i=1, \dots, N$ ;  $t=1, \dots, T$ ; and  $N$  and  $T$  were the number of stops and the number of  
145 years species were observed, respectively. The full model was then:

$$146 \quad \log(\mu_{it}) = \beta_{0stop} + \beta_{1stop} \times Year_t + \beta_2 \times FirstYear_{it} + Route_{it} + Observer_{it} + Noise_{it}$$

147 where each stop was assumed to have a separate intercept ( $\beta_0$ ) and time trend ( $\beta_1$ ). We used two  
148 Markov chains for each model and examined model convergence and performance through  
149 Gelman-Rubin diagnostics (Gelman et al. 2004; Link & Barker 2010). Once the model reached

150 convergence, we derived estimates of the count at each stop and in each year which were then  
151 used for the threshold analysis.

## 152 **Defining exurban development**

153 To characterize the land cover in the areas around survey stops, we classified Landsat 5 TM  
154 images for 1986, 1993, 2000, and 2009. We performed standard pre-processing procedures  
155 (atmospheric and topographic correction) prior to image classification and conducted a  
156 supervised classification of areas of exurban development using a training dataset generated from  
157 aerial photos. Exurban development was defined as areas with housing densities between 1 unit  
158 per 0.4 ha and 1 unit per 16.3 ha (e.g., 6 - 250 houses per km<sup>2</sup>) (Brown et al. 2005). We  
159 identified exurban development using both spectral and structural characteristics following the  
160 methodology outlined in (Suarez-Rubio et al. 2012a). We derived spectral characteristics from  
161 spectral mixture analysis (Adams et al. 1986) of the corrected Landsat images to estimate the  
162 fractional cover of vegetation, substrate, non-photosynthetic vegetation, and shade within each  
163 image. Based on spectral mixture analysis outputs, we built decision trees to classify exurban  
164 development for each of the four image dates.

165 For pixels belonging to branches of the decision trees that could not discriminate between  
166 exurban and urban areas based on spectral characteristics alone, we used morphological spatial  
167 pattern analysis (MSPA) to classify the imagery (Soille 2003; Vogt et al. 2007). The analysis  
168 evaluates map geometry by applying mathematical morphological operators to allocate each  
169 pixel to one of a mutually exclusive set of classes. We used an 8-neighbor rule as our structural  
170 element (i.e., both cardinal directions and diagonal neighbors are considered) and edge width of  
171 one. Pixels that fell into the MSPA-Islet (representative of isolated housing units), Bridge,  
172 Branch, and Loop classes (representative of associated roads) were considered exurban

173 development. All other MSPA classes were considered urban development. Lastly, all cells  
174 originally designated as exurban development in the decision tree were then added back to attain  
175 the final exurban development maps.

### 176 **Analyzing the spatial pattern of exurban development**

177 To examine the spatial pattern of exurban development, we used the final exurban development  
178 maps as foreground and analyzed them using MSPA. Here, we focused specifically on the Islet  
179 class which represented scattered, isolated housing units. Using the MSPA classification output,  
180 we developed a compactness index to describe the degree of compactness of exurban  
181 development surrounding each survey stop at each time period considered. The index is a  
182 measure of the proportion of exurban development within the Islet class (i.e. isolated pixels) and  
183 ranged from 0% (all Islets) to 100% (no Islets). Survey stops lacking exurban development  
184 within the potential zone of influence were excluded from the analysis (28 and 20 survey stops  
185 for the 400-m and 1-km radius buffers, respectively were excluded). Hence, dispersed exurban  
186 development was represented by 0% and clumped exurban development by 100% compactness  
187 (see example in Fig. 2).

### 188 **Identifying species response to compactness of exurban development**

189 To examine the relationship between compactness of exurban development and species adjusted  
190 counts at the survey stops, we fitted a non-parametric locally weighted polynomial regression  
191 (loess) (Cleveland & Devlin 1988). When the loess regression highlighted nonlinearity in the  
192 relationship, then a change-point analysis to test for nonlinear threshold response was used.

193 We estimated potential species thresholds to compactness of exurban development using  
194 Threshold Indicator Taxa ANalysis (TITAN) (Baker & King 2010). TITAN allows the

195 identification of change points in both occurrence frequency and relative abundance of individual  
196 taxa along an environmental gradient. It distinguishes responses of individual taxa with low  
197 occurrence frequencies or highly variable abundances and does not assume linear response along  
198 all or part of an environmental gradient. TITAN uses normalized indicator species taxa scores ( $z$ )  
199 to establish a change-point location that separates the data into two groups and maximizes  
200 association of each taxon with one side of the partition. Z scores measure the association of  
201 taxon abundance weighted by their occurrence and is normalized to facilitate cross-taxa  
202 comparison. Thus, TITAN distinguishes negative ( $z^-$ ) and positive ( $z^+$ ) indicator response taxa.

203 To measure quality of the indicator response and assess uncertainty around change-point  
204 locations, TITAN bootstraps the original dataset and recalculates change points with each  
205 simulation. Uncertainty is expressed as quantiles of the change-point distribution. Narrow  
206 intervals between upper and lower change-point quantiles (i.e., 5 and 95%) indicate nonlinear  
207 response in taxon abundance whereas broad quantile intervals are characteristic of taxa with  
208 linear or more gradual response. Diagnostic indices of the quality of the indicator response are  
209 purity and reliability. Purity is the proportion of bootstrap replicates that agree with the direction  
210 of the change-point for the observed response. Pure indicators (purity  $\geq 0.95$ ) are those that  
211 consistently assign the same response direction during the resampling procedure. Reliability is  
212 the proportion of change-point individual value scores (IndVal) among the bootstrap replicates  
213 that consistently have p-values below defined probability levels (0.05). Reliable indicators  
214 (reliability  $\geq 0.95$ ) are those with consistently large IndVal.

215 We ran TITAN for the 11 selected bird species and compactness index in R 3.0.1 (R  
216 Development Core Team 2013). We used the minimum number of observations on each side of

217 the threshold split that is required by TITAN ( $n = 5$ ) and specified 250 permutations to compute  
218 z scores and diagnostic indices as suggested by Baker and King (2010).

## 219 RESULTS

### 220 Landscape composition and compactness of exurban development around survey stops

221 Landscape composition around survey stops changed through time during the time period  
222 studied, except for the 21% of stops that were inside protected areas (Table 1). The inclusion  
223 here of MSPA classes that represented associated roads (i.e., Bridge, Branch, and Loop) in  
224 addition to scatter isolated pixels (i.e., Islets) in the definition of exurban development differed  
225 from other operational definitions of exurban development used in previous work; as a result, the  
226 total amount of development that was classified as exurban was higher for our study than was  
227 reported for more restrictive definitions (e.g., Suarez-Rubio et al. 2012a). For both the 400-m  
228 and 1-km radius buffers, there was a 6% increase in exurban development from 1986 to 2009  
229 (Table 1).

230 Compactness of exurban development also increased over time (Table 1). For the 400-m  
231 radius buffer, compactness increased from 18% in 1986 to 39% in 2009. For the 1-km radius  
232 buffer, compactness increased even more, from 11% in 1986 to 44% in 2009. For both extents,  
233 the increase was higher between 2000 and 2009 than for any other time period. Compactness was  
234 slightly correlated with exurban development (Pearson's correlation coefficient for 400-m buffer:  
235 0.38, and 1-km buffer: 0.46) and not correlated with forest at neither extent (Pearson's  
236 correlation coefficient for 400-m buffer: -0.15, 1-km buffer: 0.04).

## 237 **Response of bird species to compactness of exurban development**

238 Non-parametric locally weighted polynomial regression (loess) models indicated a non-linear  
239 relationship between the compactness index and adjusted counts of selected bird species (see  
240 examples in Fig. 3). Forest species differed in their threshold response to compactness of  
241 exurban development (Fig. 4). For the 400-m radius buffer, only one of the six forest species was  
242 significant and reliable indicator taxa. Scarlet Tanager responded negatively to the compactness  
243 of exurban development. Although Wood Thrush also responded negatively, the quality of the  
244 indicator was less reliable (0.80) (Table 2). In contrast, for the 1-km radius buffer, almost all  
245 forest species responded positively and reliably to the compactness of exurban development  
246 (Table 2).

247 Forest-edge species also had significant though less consistent threshold responses to  
248 compactness of exurban development at both extents (Fig. 4). For the 400-m radius buffer,  
249 Eastern Phoebe and Gray Catbird had a significant positive response to the compactness metric,  
250 while Eastern Towhee responded negatively to compactness. For the 1-km radius buffer, Eastern  
251 Phoebe, Gray Catbird, and Indigo Bunting were positive indicator taxa of compactness, with  
252 reliability values and change points similar to those exhibited by forest species.

253 In general, reliability information was redundant with purity (i.e., taxa with  $\geq 0.95$  purity  
254 were usually also reliable) (Table 2). Rarely did the direction of the response change with extent  
255 of analysis. For example, Ovenbird responded positively to compactness of exurban  
256 development for the 1-km radius buffer. Although the direction of the response changed for the  
257 400-m radius buffer, the indicator was marginally significant ( $p = 0.052$ ) and poorly reliable at  
258 this extent (reliability = 0.38). In general, where there were differences in the reliability and  
259 direction of response at different extents, the 1-km relationships were more reliable.

260 Most species (both forest and forest-edge) had relatively broad bootstrapped change-point  
261 distributions indicating a more gradual response to the level of compactness of exurban  
262 development (Fig. 4). In addition, the width of the bootstrapped change-point distributions varied  
263 between the two buffer distances for only a few species. For example, Eastern Phoebe was one of  
264 the few species with a sharp response to compactness, which occurred only at the 400-m radius  
265 buffer.

## 266 **DISCUSSION**

267 Our results suggest that both forest birds and some forest-edge species responded to spatial  
268 patterns of exurban development at the landscape extent (1-km radius buffer) (Fig. 4B). Contrary  
269 to our prediction, forest birds exhibited a positive response to compactness of exurban  
270 development with change points between 21% and 78% (Table 2). These results indicate that  
271 frequency and abundance of forest birds increase as compactness increases. There are few  
272 reasons that could explain this pattern. First, although compactness of exurban development  
273 increased over time, these bird species were also increasing in abundance generally in the region  
274 (Suarez-Rubio et al. 2013) partly due to the relatively intact forests adjacent to the study area  
275 (e.g., protected areas). Second, forest disturbance associated with exurban development may  
276 benefit forest birds, especially forest birds such as American Redstart and Red-eyed Vireo that  
277 seem to occur more frequently in early and mid-successional forests and even start to decline as  
278 forests mature (Holmes & Sherry 2001; Hunt 1998). Lastly, response of forest birds may follow  
279 a systematic temporal trajectory (Pidgeon et al. 2014). In a first stage of development, bird  
280 species richness has either a stable or positive association with residential development because  
281 of resources introduced by people (e.g., feeders) and subsequently, as the number of houses  
282 increases over time, the association becomes negative (Pidgeon et al. 2014). Therefore, the

283 positive response of forest birds to compactness may suggest that the study area is in a first stage  
284 of development when the housing density is still low, but if compactness or exurban growth  
285 continues, it would inevitably lead to the second phase which could represent species losses.

286 Surprisingly, Indigo Bunting and Gray Catbird (i.e., forest-edge species) also responded  
287 positively to compactness of exurban development at the landscape extent with change points  
288 similar to those exhibited by forest birds (Table 2, Fig. 4B). Although Indigo Bunting is known  
289 for its strong preference for edges, and surely human habitat modification (e.g., clearing of  
290 woods) increases suitable habitat for buntings (Payne 2006), bunting numbers have declined in  
291 eastern North America since the last quarter of the twentieth century (Sauer et al. 2014). These  
292 declines have been associated with increasing levels of brood parasitism and predation that occur  
293 in fragmented habitats (Donovan & Flather 2002; Robinson et al. 1995). Gray Catbird also  
294 prefers early successional habitats, and shrubs around houses have probably increased the  
295 availability of breeding habitat for this species (Smith et al. 2011b). Compact exurban  
296 development perhaps minimize the disturbance associated with domestic predators introduced in  
297 exurban areas that usually prey directly on nests (Balogh et al. 2011; Lepczyk et al. 2003;  
298 Lumpkin et al. 2012).

299 At the local extent (i.e., 400-m radius buffer), Scarlet Tanager responded negatively,  
300 whereas Gray Catbird responded positively to compactness of exurban development, with both  
301 exhibiting gradual responses (Fig. 4A). Scarlet Tanager is an interior forest species that is very  
302 sensitive to forest fragmentation (Rosenberg et al. 1999). In a previous study, this species was  
303 found to have a negative response to the amount of exurban development at very low levels  
304 (Suarez-Rubio et al. 2013). Thus, Scarlet Tanager appears to be negatively affected by exurban  
305 development regardless of its spatial configuration. The positive response of Gray Catbird to

306 compactness of exurban development perhaps indicate that predation pressure by introduced  
307 domestic predators in exurban areas (Lepczyk et al. 2003; Lumpkin et al. 2012) affects catbirds  
308 at the local extent. Exurban areas have large numbers of non-native plant species (Gavier-Pizarro  
309 et al. 2010; Lenth et al. 2006; Maestas et al. 2003), and there is some evidence that nests in  
310 exotic shrubs are twice as likely to be depredated and suffer higher rates of nest failure than nests  
311 in native shrubs (Borgmann & Rodewald 2004), although this is not always the case (Meyer et  
312 al. 2015).

313         Interestingly, most forest birds did not exhibit threshold responses to compactness of  
314 exurban development at the local extent. This difference in response at the local and landscape  
315 extent suggests that the effects of compactness of exurban development are scale dependent.  
316 Smith et al. (2011a) demonstrated that effects of fragmentation change with the extent of  
317 analysis because ecological processes (e.g. predation) act at different spatial scales. Thus, the  
318 effects of compactness of exurban development might be associated with the size of the  
319 disturbance zone. Other studies have found an ecological effect zone of up to 200 m from  
320 exurban homes in which avian densities were altered (Glennon & Kretser 2013; Odell & Knight  
321 2001).

322         Our results reveal that the responses of forest birds varied, but extended well beyond a  
323 200-m radius. When considering a 400-m zone of influence, most forest birds did not respond  
324 significantly to the spatial pattern of exurban development. However, the spatial compactness of  
325 development was associated with a positive response at the 1-km zone for nearly all forest bird  
326 species. Previous studies have shown that forest birds are very sensitive to the amount of exurban  
327 development (e.g., Pidgeon et al. 2007; Suarez-Rubio et al. 2013). Our results show that forest  
328 birds are also sensitive to its spatial configuration at large extents. In general, if exurban

329 development occurs in the landscape, it affects the entire 400-m radius buffer regardless of its  
330 arrangement, but by aggregating exurban development within the 1-km radius buffer, safe zones  
331 were retained that could support forest birds.

332 By assessing the spatial pattern of exurban development for the multiple images, we were  
333 able to capture the dynamics of landscape change over time (Table 1) as was also done  
334 previously for the conterminous United States (e.g., Mockrin et al. 2012; Pidgeon et al. 2014).  
335 As exurban areas grew, scattered, isolated exurban development became more contiguous and  
336 clumped. Thus, our results demonstrate the effects of the spatial pattern of exurban development  
337 within the larger context of forest habitat loss. At the level of individual survey stops, the  
338 positive but weak correlation between exurban development and compactness indicates that there  
339 is variance in spatial configuration that is independent from the overall amount of exurban  
340 development.

341 A critical unknown of exurban growth is the possible cumulative impacts on wildlife.  
342 Evaluating potential cumulative impacts requires an enhanced understanding of both the density  
343 and patterns of residential development and of the distinct effects of these two components of  
344 landscape change (Pidgeon et al. 2014; Theobald et al. 1997). We have taken a first step by  
345 identifying the extent at which forest and forest-edge species respond to the spatial patterning of  
346 exurban development and highlight that the positive response of forest birds to compactness at  
347 the larger extent should be taken cautiously because this could represent a systematic trajectory  
348 of decline (Pidgeon et al. 2014) and if exurban growth continues to increase, as trends suggest,  
349 this will lead towards more contagious development which could be highly detrimental to bird  
350 diversity.

351 **ACKNOWLEDGEMENTS**

352 The authors thank thousands of volunteers who have collected Breeding Bird Survey Data and  
353 D. Ziolkowski and K. Pardieck (USFWS) for providing the bird data, the topographic maps, and  
354 the description of the BBS stops. S. Wilson and R. Hildebrand provided helpful analytic advice.

**Figure 1** (on next page)

Study area (shaded region).

Circles represent 125 North American Breeding Bird Survey (BBS) routes that were uniformly selected from routes.

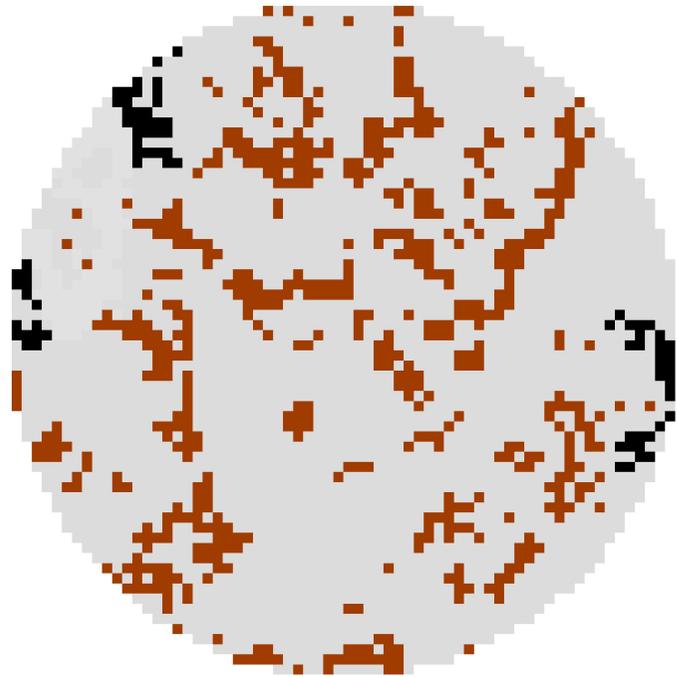

**Figure 2** (on next page)

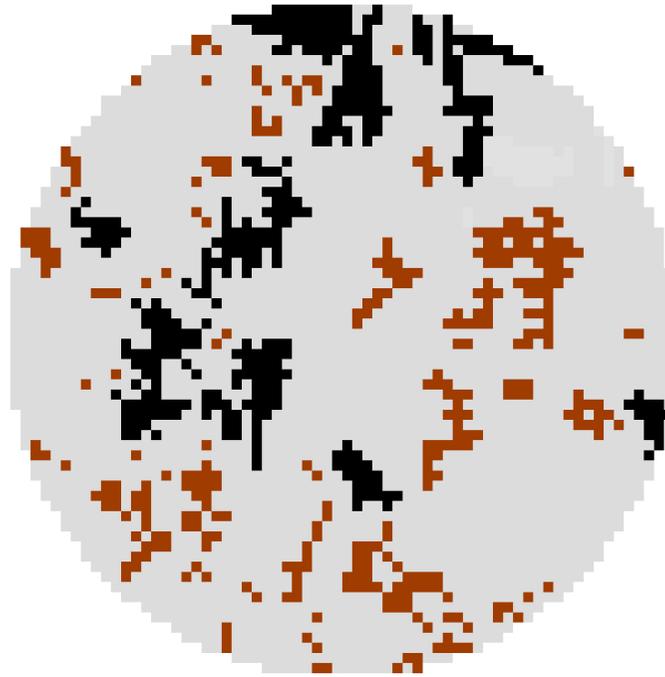

Example of morphological spatial pattern analysis (MSPA) output used to derive level of compactness of exurban development around surrounding areas of selected BBS stops.

The illustration shows compactness around 1-km radius buffer of three different BBS stops in 2009 with similar amount of exurban development ( $20.0 \pm 1.3\%$ ) among the three landscapes.

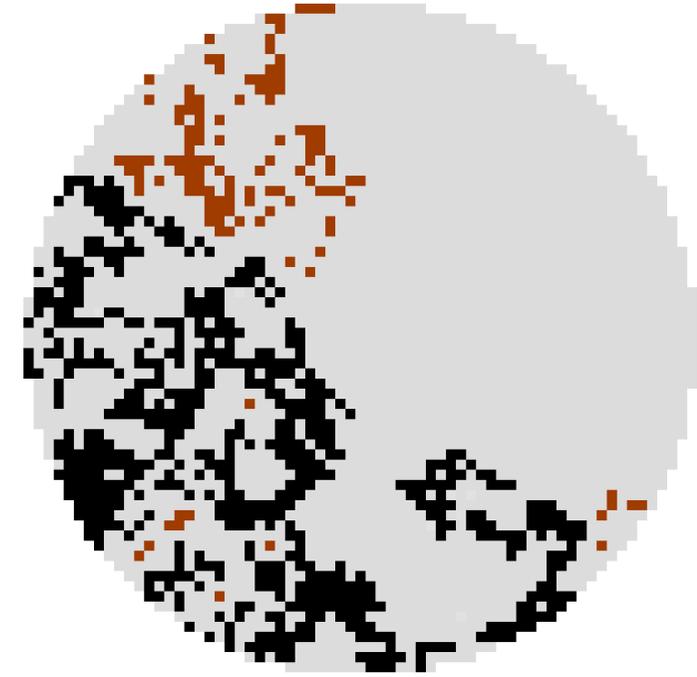

Compactness: 12 %

52 %

83 %

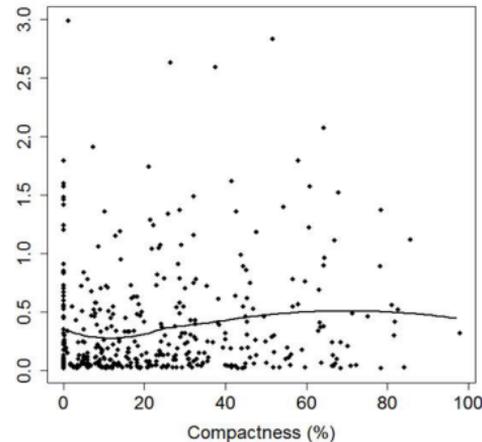

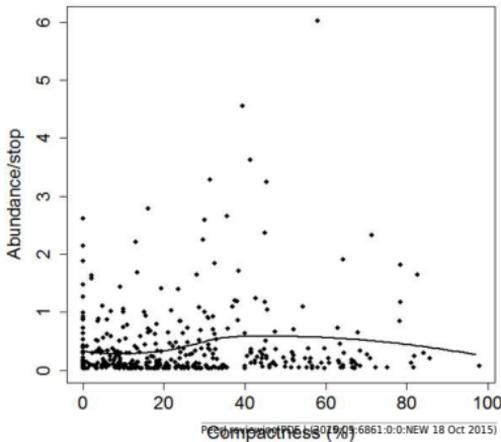

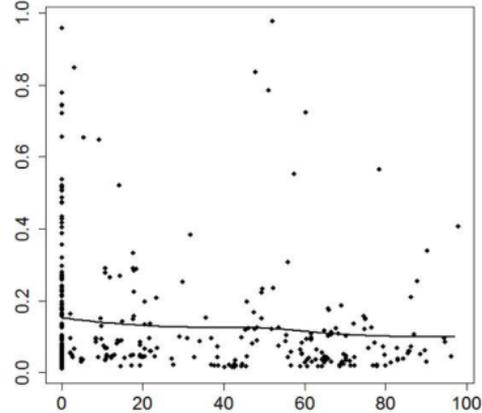

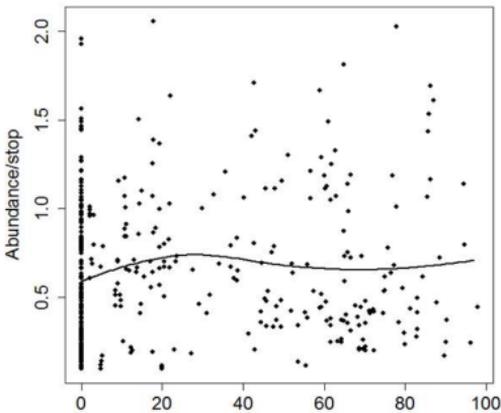

Legend

-  MSPA - Islet
-  MSPA - All other classes

**Figure 3**(on next page)

Example relationships between compactness of exurban development and adjusted counts of selected bird species around BBS stops.

A, C represent forest-edge and B, D forest birds for 400-m (upper panels) and 1-km radius buffer (bottom panels).

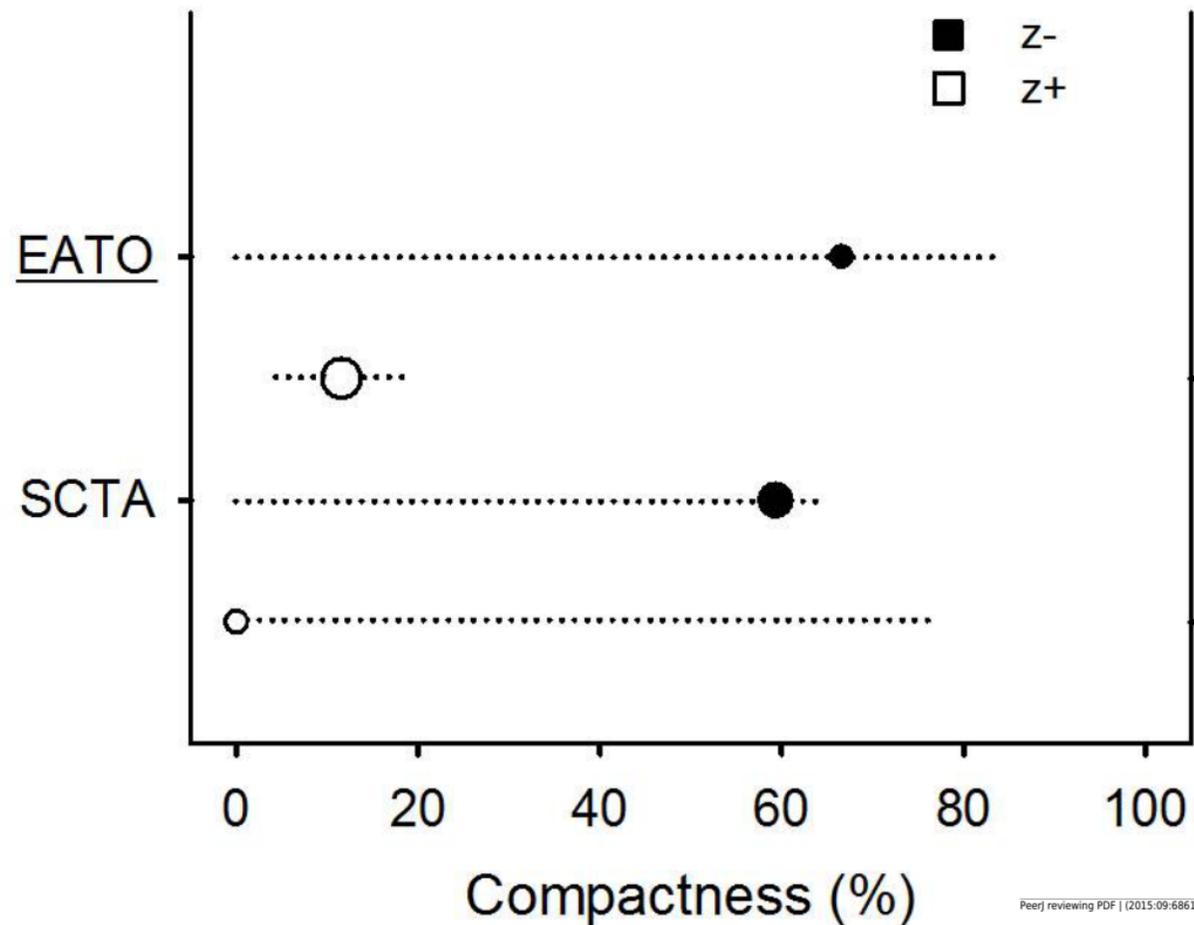

**Figure 4**(on next page)

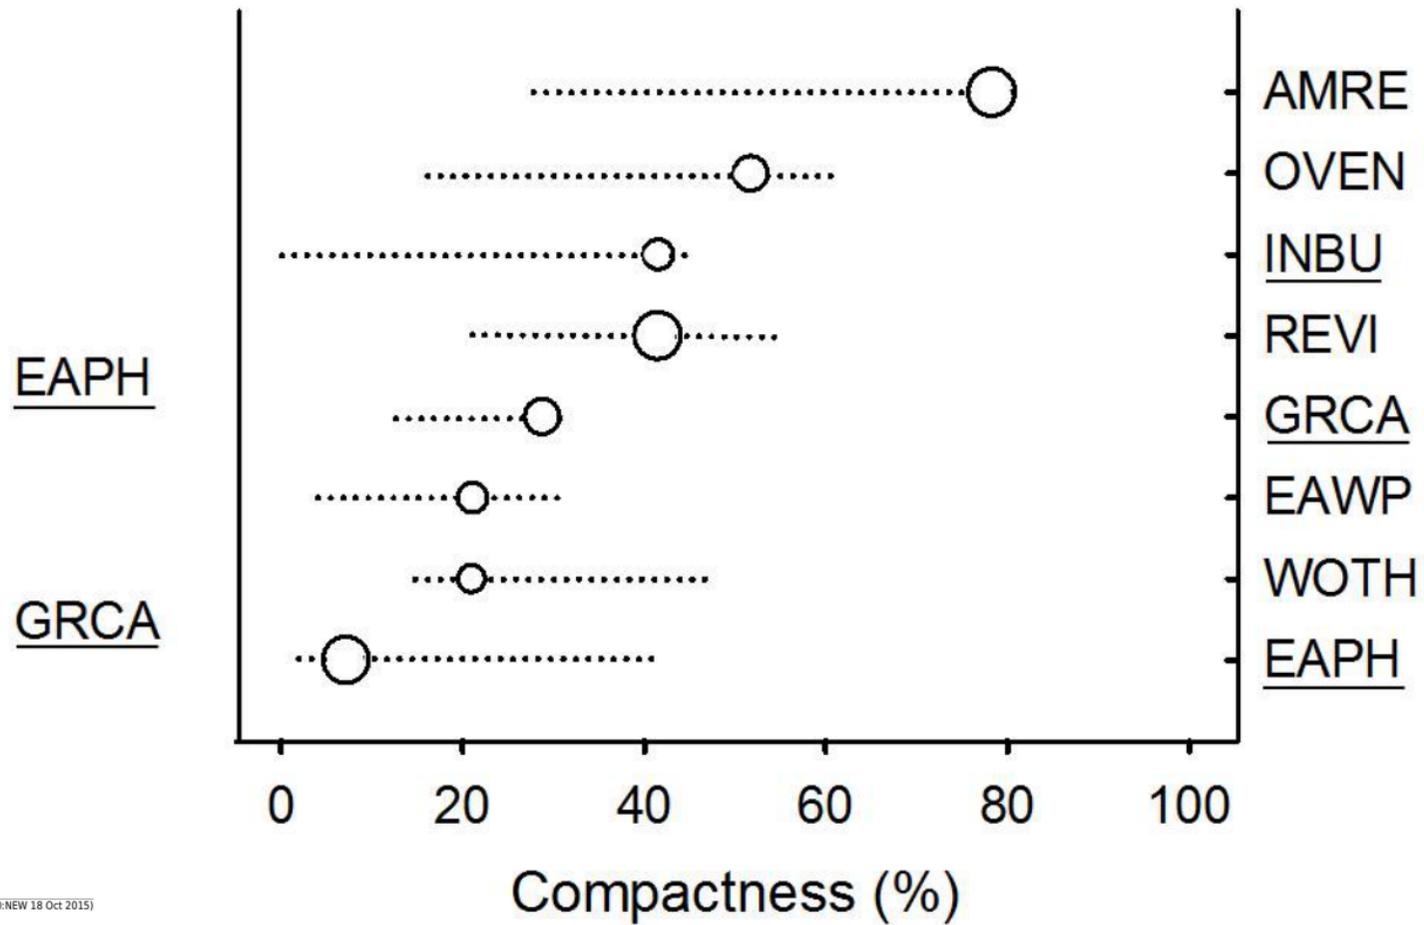

Change points of significant ( $p < 0.05$ ) and reliable (purity  $\geq 0.90$  and reliability  $\geq 0.90$ ) indicator bird species of compactness of exurban development for (A) 400-m and (B) 1-km radius buffer around selected BBS stops.

Indicator taxa are plotted in increasing order with respect to their observed change point. Solid circles represent negative (z-) indicator taxa (with corresponding species on the left axes) and open circle correspond to positive (z+) indicator taxa (with corresponding species on the right axes). Circles are sized based on z scores, and lines represent the 5 and 95% percentiles among 250 bootstrap replicates. Short lines indicate nonlinear response in taxon abundance, whereas long lines represent linear or more gradual response. Taxa IDs correspond to the American Ornithologist Union alpha codes for English common names. Underlined codes denote forest-edge species. Change points of significant ( $p < 0.05$ ) and reliable (purity  $\geq 0.90$  and reliability  $\geq 0.90$ ) indicator bird species of compactness of exurban development for (A) 400-m and (B) 1-km radius buffer around selected BBS stops. Indicator taxa are plotted in increasing order with respect to their observed change point. Solid circles represent negative (z-) indicator taxa (with corresponding species on the left axes) and open circle correspond to positive (z+) indicator taxa (with corresponding species on the right axes). Circles are sized based on z scores, and lines represent the 5 and 95% percentiles among 250 bootstrap replicates.
