

# Foraging efficiency of red wood ants, *Formica aquilonia* (Hymenoptera: Formicidae) in relation to tree characteristics and stand age

Heloise Gibb, Jon Andersson, Therese Johansson

**Background.** Optimal foraging theory states that organisms forage to maximise their energy intake per unit time. Ants are central-place foragers, so are expected to harvest greater loads from more distant and higher quality resources. We first tested this prediction at a small scale and second, at larger scales, we asked if forest successional stage affected the optimisation of worker foraging loads. **Methods.** First, we performed a fine-scale study examining the effect of distance and resource quality (tree diameter and species) on harvesting of honeydew by red wood ants, *Formica aquilonia*, in terms of crop load per worker ant and numbers of workers walking up and down each tree (ant activity) (experiment 1). Second, we calculated what the combination of load and worker number responses meant for colony-level optimisation of foraging efforts. Third, at a larger scale, we tested whether the relationship between worker load and resource quality and distance depends on stand age (experiment 2). **Results.** The first study revealed that seventy percent of ants descending trees carried honeydew, and the percentage of workers that were honeydew harvesters did not depend on tree species or diameter, but was weakly related to distance. Consistent with predictions from optimal foraging theory, distance positively affected load in both large- and small-scale experiments. Diameter had weak negative effects on load, which experiment 2 showed were dependent on stand age. **Discussion.** Stand age thus did not affect the optimal foraging relationship, beyond effects due to tree diameter and distance. Because ant activity declines with increasing distance to resources the net result at fine scales was that very little honeydew was harvested from more distant trees if they were small, but that harvesting from larger trees was relatively constant within the range of distances sampled. Although forestry alters the activity and foraging success of red wood ants, it thus does not alter the fundamental rules determining allocation of foraging effort.

## 19 Foraging efficiency of red wood ants

20 Heloise Gibb, Jon Andersson & Therese Johansson

### 21 Abstract

22 **Background.** Optimal foraging theory states that organisms forage to maximise their energy  
23 intake per unit time. Ants are central-place foragers, so are expected to harvest greater loads  
24 from more distant and higher quality resources. We first tested this prediction at a small scale  
25 and second, at larger scales, we asked if forest successional stage affected the optimisation of  
26 worker foraging loads.

27 **Methods.** First, we performed a fine-scale study examining the effect of distance and resource  
28 quality (tree diameter and species) on harvesting of honeydew by red wood ants, *Formica*  
29 *aquilonia*, in terms of crop load per worker ant and numbers of workers walking up and down  
30 each tree (ant activity) (experiment 1). Second, we calculated what the combination of load and  
31 worker number responses meant for colony-level optimisation of foraging efforts. Third, at a  
32 larger scale, we tested whether the relationship between worker load and resource quality and  
33 distance depends on stand age (experiment 2).

34 **Results.** The first study revealed that seventy percent of ants descending trees carried  
35 honeydew, and the percentage of workers that were honeydew harvesters did not depend on tree  
36 species or diameter, but was weakly related to distance. Consistent with predictions from  
37 optimal foraging theory, distance positively affected load in both large- and small-scale  
38 experiments. Diameter had weak negative effects on load, which experiment 2 showed were  
39 dependent on stand age.

40 **Discussion.** Stand age thus did not affect the optimal foraging relationship, beyond effects due  
41 to tree diameter and distance. Because ant activity declines with increasing distance to resources  
42 the net result at fine scales was that very little honeydew was harvested from more distant trees if  
43 they were small, but that harvesting from larger trees was relatively constant within the range of  
44 distances sampled. Although forestry alters the activity and foraging success of red wood ants, it  
45 thus does not alter the fundamental rules determining allocation of foraging effort.

## 47 **Introduction**

48 Optimal foraging theory states that organisms forage to maximise their energy intake per unit  
49 time (MacArthur & Pianka 1966). More specifically, central place foraging theory (Orians &  
50 Pearson 1979) considers the case where animals return to a central place (e.g., a nest). It predicts  
51 that more valuable resources or larger loads will be harvested at greater distances from the  
52 central place. This is because the energy expenditure of foragers is proportional to the distance  
53 travelled. Load-distance relationships have previously been observed in a range of taxa that act  
54 as central place foragers (Giraldeau & Kramer 1982; Kacelnik et al. 1986; Kaspari 1991;  
55 Mellgren et al. 1984).

56 As central place foragers, ants commonly show load-distance relationships (Bonser et al. 1998;  
57 but see Holder & Polis 1987; Wright et al. 2000). Even in only moderately polymorphic or  
58 monomorphic species, larger ants travel greater distances to forage and they are more efficient,  
59 i.e., they are able to carry a greater load relative to their body weight (Herbers & Cunningham  
60 1983; McIver 1991; McIver & Loomis 1993; Rosengren & Sundström 1987; Wright et al. 2000),  
61 but see Rissing & Pollock (1984). In addition to distance, the harvesting efficiency of ants is  
62 affected by a range of other factors, including resource quality, such as sucrose concentration,  
63 carbohydrate:protein ratio, resource quantity, temperature or crowding (Bonser et al. 1998; Cerda  
64 et al. 1998; Detrain et al. 2000; Dreisig 1988; Kay 2002; Segev et al. 2014).

65 Habitat structure plays a key role in determining the success of species (e.g., Cushman 2006;  
66 Petren & Case 1998; Stephens et al. 2004), particularly ants (Gibb & Parr 2010; Lassau &  
67 Hochuli 2004; Sarty et al. 2006; Sorvari & Hakkarainen 2004). For example, larger ants are more  
68 successful competitors in structurally simple habitats, probably because they are faster to

69 discover and exploit resources (Gibb & Parr 2010). Anthropogenic disturbances, including  
70 urbanisation, agriculture and forestry, transform landscapes, significantly altering habitat  
71 structure (Gibb & Hochuli 2002; Harrison & Bruna 1999). For example, forestry practices in  
72 mid-boreal Sweden have resulted in a disproportionately large area of relatively young and dense  
73 stands, with structure differing substantially from old growth stands (Linder & Östlund 1998).  
74 Previous studies suggest that stand age (a measure of time since disturbance or successional  
75 stage) and the associated structural differences have significant effects on the abundance and  
76 behaviour of ants (Gibb & Johansson 2010; Punttila 1996; Sorvari & Hakkarainen 2004) and on  
77 resource quality (Johansson & Gibb 2012). However, no previous study has tested whether  
78 successional stage affects the optimal foraging relationship for ants. We might expect effects  
79 because successional stage alters not only resource quality (Guariguata & Ostertag 2001;  
80 Johansson & Gibb 2012), but also affects the biotic environment of boreal forest ants, increasing  
81 competition (Gibb 2011) and altering predation risk (Niemelä et al. 1996).

82 Although most studies of central place foraging in ants focus on individual workers (e.g., Bonser  
83 et al. 1998; Holder & Polis 1987; Wright et al. 2000), the aim of workers should be to optimise  
84 the foraging of the colony as a whole by altering both individual loads and number of foragers  
85 active. This is because the evolution of eusocial organisms is expected to operate at the level of  
86 the colony as workers of most species are sterile. Here, we use northern red wood ants, *Formica*  
87 *aquilonia* (Yarrow, 1955), in boreal forests to test, first whether individual workers adjust their  
88 crop loads (mass gain) with respect to resource distance and quality (experiment 1). Second, we  
89 use activity data from a previous study to model how colony-level mass gain is affected by  
90 resource distance and quality. Third, we test whether the relationship between worker load and  
91 resource quality and distance depends on forest succession (experiment 2).

## 92 **Materials and Methods**

### 93 *Ethics statement*

94 This study complies with the current laws of Sweden. Permissions for use of the insecticide were  
95 obtained from the relevant local authority, Länsstyrelsen Västerbotten. The forestry companies  
96 Holmen Skog AB, Sveaskog AB, SCA and Scaninge gave permission to use their land.

### 97 *Study sites and species*

98 This study was conducted in boreal forests in northern Sweden between the latitudes of 63.6°N  
99 and 64.5°N and longitudes of 19.7°E and 20.7°E. The forest was dominated by Norway spruce,  
100 *Picea abies* (70-100%), while birches, *Betula pubescens* and *Betula pendula*, and Scots pine,  
101 *Pinus silvestris*, also occurred in significant numbers. The field layer consisted mainly of dwarf  
102 shrubs (*Vaccinium spp.*) and soils were moist and of the sandy moraine type. A detailed study of  
103 optimal foraging theory was first conducted in a single mature production forest (experiment 1).  
104 The effect of stand age on optimal foraging was then examined using a further twelve stands  
105 (experiment 2): mature stands (n=4, tree age 80–100 years, non-sapling mean basal diameter  
106 (BD) =  $30.3 \pm 1.6$  cm, mean height (H) =  $17.9 \pm 0.6$  m), middle aged stands (n=4, 30–40 years,  
107 BD =  $13.8 \pm 0.9$  cm, H =  $8.1 \pm 0.3$  m) and clear cuts with 5–10 retention trees per ha (n=4, 1–4  
108 years, BD =  $4.8 \pm 0.7$  cm, H =  $2.1 \pm 0.3$  m). Further details on site characteristics are provided in  
109 Table S1. Measures of basal diameter included all trees > 1 cm BD. Basal diameter was used in  
110 preference to diameter at breast height so that seedlings, which may be shorter than 1.3 m in  
111 height, but also provide a food source to ants, could be included. Stands of different ages were  
112 geographically interspersed and each study plot supported several nests of the northern red wood  
113 ant, *Formica aquilonia*. Mean  $\pm$  SE stand separation was  $17.5 \pm 1.0$  km.

114 *F. aquilonia* belongs to the *F. rufa* group, which consists of territorially dominant ant species  
115 that have been reported to structure ant communities (Gibb 2011; Gibb & Johansson 2011;  
116 Savolainen & Vepsalainen 1989). It has polygynous and polydomous colonies throughout its  
117 range (Pamilo 1982) and is the most common *F. rufa* group species in the central boreal region  
118 of Fennoscandia (Collingwood 1979). In the study area, *F. aquilonia* is commonly observed  
119 climbing trees, where it tends the aphids *Cinara pruinosa* and *C. piceicola* (Johansson & Gibb  
120 2012) (aphids identified by R. Danielsson, University of Lund and Nils Ericson, Umeå). A  
121 previous study showed that honeydew makes up approximately 80% of the diet of *F. aquilonia*  
122 in Finland, with the remainder consisting of invertebrate prey (Domisch et al. 2009).

123 *Experiment 1: Do ants adjust their foraging based on resource quality and distance?*

124 Our aim here was to determine if the quantity of honeydew harvested from a mature tree per  
125 forager was affected by resource quality (tree species and basal diameter) or distance from the  
126 nest. For this reason, we selected a mature forest, where variation in stem basal diameter was  
127 greater than younger stands. Tree species affects the quality of aphid honeydew (Douglas 1993)  
128 and, within tree species, honeydew quality is affected by diameter through changes in the  
129 concentrations of some sugars (Johansson & Gibb 2012) and secondary metabolites (Price 1991;  
130 Whitham 1978). Unpublished data from our study sites suggests that the composition of sugars  
131 and amino acids differs among honeydew samples collected from *P. abies*, *P. sylvestris* and  
132 *Betula spp.* Sampling was performed once at each site on fine days in July 2007. We selected  
133 10 nests of *F. aquilonia* in mature forest and located two spruce, one birch and one pine tree with  
134 high levels of ant activity within 20 m of each nest (thousands of workers active on and around  
135 the nest), with clear trails originating from the target nest. The distance from the nest and the  
136 basal diameter of each tree was measured and ambient temperatures were recorded for each tree

137 at the time sampling commenced. Nests contained multiple entrance holes, so distances were  
138 measured from the centre of the nest.

139 We used modified battery-driven vacuum cleaners with aspirators attached to collect 20 ants  
140 walking up and 20 ants walking down each of the trees (a total of 40 ants x 10 nests x 4 trees =  
141 1600 ants). This method was selected as ants proved less likely to squirt formic acid (and  
142 therefore lose weight) when removed using an aspirator than by forceps. The forty ants were  
143 collected from each tree in quick succession, irrespective of the tasks they were performing. For  
144 collected individuals, we recorded whether the ant was carrying anything (needles or leaves or  
145 arthropod prey) and its liquid feeding status. Liquid feeding status was assessed by examining  
146 the gaster of individuals and allocating them to the following classes: 1) full: arthrodiol  
147 membrane stretched, such that the length of arthrodiol membrane visible along the mid-line of  
148 the gaster was at least half of that of the sclerites; 2) half full: some stretching of the arthrodiol  
149 membrane, but with the visible length less than half that of the sclerites; 3) empty: no visible  
150 stretching of the arthrodiol membrane.

151 Ants were killed or subdued using ether in the field and were later frozen for 3 days at -20°C.  
152 They were weighed in groups of twenty ants travelling in the same direction on the same tree.  
153 Any needles or prey items were removed before weighing. The total mass of ants was divided  
154 by twenty to obtain a mean mass per ant and the mean mass of the “Up” ants was subtracted  
155 from that of the “Down” ants to determine the average mass gain of ants on each tree.

156 *Experiment 2: Is optimal foraging of individuals affected by stand age?*

157 To compare the mass of honeydew collected by individual ants in different stand ages, we  
158 collected ants moving up and down trees on fine days in July 2008 using the methods described  
159 above. Ten spruce trees were selected at each site between 0.5 and 35 m from a central nest (this

160 distance range was necessary to include sufficient trees on clear-cuts). Trees with high  $F$ .  
161 *aquilonia* activity were preferred in order to reduce collection times. We collected five ants  
162 moving up and five ants moving down each of the ten trees at four sites belonging to each of the  
163 three stand ages for a total of 1200 ants. We did not specifically select ants with laden and non-  
164 laden gasters because we aimed to compare harvesting efficiency per ant. Ants were placed in a  
165 cold box (approximately 5°C) in the field and were later frozen for 3 days at -20°C to ensure that  
166 they were killed. Ants were weighed individually in the lab using a Mettler AE166 balance  
167 (sensitive to  $\pm 0.1$  mg) and maximum head width was measured using an eyepiece micrometer  
168 on a Leica MS5 microscope. Any needles or prey items were removed before weighing.

#### 169 *Statistical analyses*

170 For experiment 1, a paired t-test on JMP (SAS-Institute 2007) was used to compare the mean  
171 mass of ants walking up and down per tree. We used a general linear mixed model to test the  
172 effects of the fixed predictors temperature, tree species, diameter,  $\log_{10}$ distance and their  
173 interactions and the random predictor nest, on: 1) the mean mass gain per ant; and 2) the  
174 exponential-transformed percentage of individuals carrying discernible liquid loads. Distance  
175 was  $\log_{10}$ -transformed to improve model fit. We tested all possible models on MuMin(Barton  
176 2011) in R (R Development Core Team 2013) and, because there was no clear best model, we  
177 performed model averaging of models within 2 AICc of the best model to determine the relative  
178 importance of variables in the set of best models (Burnham & Anderson 2002). We present the  
179 coefficients from the model-averaged model with shrinkage, the importance of each variable  
180 among the set of best models and p-values. A z-test was used to compare the slopes of the ant  
181 mass (mean per tree) - distance from nest relationship for: 1) ants walking up and; 2) ants  
182 walking down a tree.

183 We modelled the effect of distance from a nest and tree diameter on harvesting rates at the  
184 colony level using the parameters from the model-averaged model predicting mean mass gain  
185 per ant from experiment 1 (described above) and the best model predicting ant activity per  
186 minute from a previous study (Gibb & Johansson 2010). To illustrate responses across a  
187 distribution of diameters typical of mature stands, we present results for trees of basal diameter  
188 10 cm, 25 cm and 40 cm. We used set values of 18.9°C for temperature (the mean value during  
189 surveys) and spruce for tree species (the most commonly occurring tree species) for the modelled  
190 data.

191 Finally, for data from experiment 2, a general linear mixed model with head width as a covariate  
192 and site as a (random) blocking factor, was used to test the effect of temperature, stand age,  
193 distance ( $\log_{10}$ -transformed), diameter and their interactions on the mass of ants walking down  
194 trees. We again tested all possible models on MuMin and performed model averaging of models  
195 within 2 AICc of the best model to determine the relative importance of variables in the set of  
196 best models. We present the coefficients from the model-averaged model with shrinkage. We  
197 report both marginal (fixed effects;  $R_{GLMM(m)}^2$ ) and conditional (fixed + random effects;  
198  $R_{GLMM(c)}^2$ )  $R^2$  values (Nakagawa 2013), calculated using the package MuMIn. We also used  
199 ANOVA on JMP to test the effect of stand age on microsite temperature.

## 200 **Results**

### 201 *Overview of ant loads*

202 On average, ants walking up a tree weighed significantly less than those walking down ( $t_{(1, 39)} = -$   
203  $9.766, p < 0.0001$ ), gaining  $2.11 \pm 0.19$  mg (Mean  $\pm$  SE) in mass, or approximately 33% of the  
204 average mass of an ant walking up the tree (up ants:  $6.42 \pm 0.17$  mg; down ants:  $8.53 \pm 0.27$

205 mg). Observations of the loads carried by ants suggested that most ants walking down a tree  
206 were carrying a discernible honeydew load (full or half full) ( $70.4 \pm 4.9$  %). Although the mean  
207 weight gain for ants was 33%, not all ants carried honeydew loads, indicating that ants with loads  
208 carried around 47% of their body weight.  $8.0 \pm 4.0$  % of ants carried nest material from trees,  
209 i.e. needles (birch leaves were never taken) and  $3.5 \pm 1.7$  % carried arthropod prey (mainly  
210 aphids and spiders) (Figure 1).

211

212 *Do ants adjust their foraging based on resource quality and distance?*

213 Analysis of the effects of quality (tree species and basal diameter) and distance of the tree from a  
214 nest on mass gain revealed a reasonable fit with little contribution of random effects ( $R^2_{\text{GLMM}(m)} = 0.41$ ,  $R^2_{\text{GLMM}(c)} = 0.41$ ) (Table 1). Mass gain was negatively related to tree diameter,  
215 suggesting individual ants gained less on larger trees (Figure 2). Consistent with predictions,  
216 mass gain was positively related to distance to nest, with ants travelling further carrying heavier  
217 loads (Figure 2). The model showed weaker predictive power for the percentage of workers  
218 carrying observable honeydew loads, with the random factor ‘nest’ contributing most to model  
219 fit ( $R^2_{\text{GLMM}(m)} = 0.11$ ,  $R^2_{\text{GLMM}(c)} = 0.49$ ). The percentage of liquid bearers responded only weakly  
220 to distance, while tree species and diameter did not appear in any of the best models.

222 The relationship between distance and mean mass of ants was significant only for ants walking  
223 down trees. Slopes for the relationship between distance and mass were significantly different  
224 ( $Z = 3.37$ ,  $p < 0.0005$ ) (Figure 3). This suggests that the distance a worker travels was not  
225 determined by its size, but that ants walking further acquired a larger load.

226 The model incorporating the mass of honeydew harvested per ant and ant activity per tree  
227 suggests that the effect of distance from the colony on the mass gained by the colony at each tree  
228 depends on tree basal diameter (Figure 4). Trees with larger diameters (40 cm) made relatively  
229 consistent contributions to mass gain, independent of distance (within 20 m from a colony),  
230 while the contribution of honeydew from smaller trees (diameter = 10 cm) decreased with  
231 increasing distance from a colony. This is because mass gain increased, while activity decreased  
232 with distance and activity increased, while mass gain decreased with diameter.

233 *Is optimal foraging by individuals affected by stand age?*

234 The best model testing the effects of head width, temperature, stand age, tree diameter, distance  
235 and their interactions on mass gain of ants was a good fit to the data ( $R^2_{\text{GLMM(m)}} = 0.62$ ,  $R^2_{\text{GLMM(c)}} = 0.66$ ).  
236 There were no significant interactions between stand age and distance, although  
237 interactions with diameter were included in the best models, indicating that stand age had a  
238 minimal influence on the optimal foraging relationship (Table 2). The covariate ‘head width’  
239 was an important predictor of worker mass, as expected. Consistent with detailed surveys in the  
240 mature stand, distance was positively related to load. Microsite temperatures measured during  
241 the surveys were not significantly higher at clear-cuts (mean  $\pm$  SE:  $19.2 \pm 2.1$ ) than mature ( $16.2$   
242  $\pm 0.5$ ) or middle-aged stands ( $18.5 \pm 2.0$ ) (ANOVA:  $F_{(2,9)} = 0.87$ ,  $p = 0.451$ ).

## 243 **Discussion**

244 *Resource harvesting*

245 A high percentage of ants walking down trees (approximately 70%) appeared to be carrying  
246 honeydew in their gasters, suggesting that this was their main task in climbing trees. This is as  
247 expected as honeydew constitutes 78-92 % of the diet of wood ants (Domisch et al. 2009). Of the

248 30% of ants for which no discernible stretching of the gaster was observed, it is possible that  
249 many were involved in other activities, such as guarding resources, or that they had collected  
250 much smaller volumes of honeydew. Smaller percentages of ants returning from trees collected  
251 arthropod prey and nest material. While it might appear opportune to collect arthropod prey if  
252 encountered in the canopy, the collection of nest material from such a height and in trees up to  
253 14 m from the nest was unexpected. Ants collecting needles from pine or spruce canopies in  
254 older forests travel considerably further than would appear necessary, given that needles are  
255 abundant on the forest floor. A possible explanation is that needle quality is better if needles are  
256 removed directly from the tree, perhaps because micro-organism activity is lower on such  
257 needles. The lower Carbon to Nitrogen ratio of needles found on ant mounds, relative to those  
258 found on the forest floor (Kilpeläinen et al. 2007), suggests that harvesting of needles from the  
259 canopy may be common practice for *F. aquilonia*. However, further sampling is required to  
260 properly address this supposition.

261 *Do ants adjust their foraging based on distance?*

262 In accordance with central place foraging theory (MacArthur & Pianka 1966; Orians & Pearson  
263 1979), the distance travelled positively affected the load collected by ants. In contrast to  
264 previous studies, which showed that larger ants travel greater distances to forage because they  
265 are able to carry a greater load relative to their body weight (e.g., Herbers & Cunningham 1983;  
266 McIver & Loomis 1993; Rosengren & Sundström 1987; Wright et al. 2000), size did not  
267 determine distance travelled: we found a significant relationship between mass and distance for  
268 ants walking down trees but not for ants walking up trees. This suggests that, within the range of  
269 distances examined in this study, there is no distinct division of labour depending on worker size,

270 but that individual workers recognize that they have travelled further and must therefore collect  
271 more honeydew.

272 An alternative explanation for the observed positive load-distance relationship is that high  
273 activity of ants on trees near mounds might lead to crowding and faster turnover of workers,  
274 resulting in smaller loads as a consequence of reduced time spent harvesting (Grüter et al. 2012;  
275 Wright et al. 2000). Such a density-dependent response could also explain our finding that,  
276 although ants were more active on large-diameter trees, they harvested less honeydew. This is  
277 consistent with the suggestion that greater recruitment may involve some defence of the resource  
278 (Sundström 1993). This proposition is further supported by the appearance of distance as an  
279 important predictor of the percentage of individuals with liquid loads among the best models  
280 (Table 1), indicating more workers engaged in tasks other than harvesting at trees closer to the  
281 nest.

282 *Do ants adjust their foraging based on resource quality?*

283 Optimal foraging theory suggests that animals allocate more effort to harvesting resources of  
284 higher quality (MacArthur & Pianka 1966). Individual honeydew load did not differ between  
285 tree species, despite differences in sugar composition (Johansson *unpublished*). In contrast, ants  
286 responded to trees differing in diameter as though they differed in quality. Differences between  
287 small- and large-diameter trees in the mature forest may reflect differences in the quality of  
288 honeydew as a result of changes in tree defence against aphid herbivory with age. Vigorous  
289 and/or fast growing plants usually have fewer secondary metabolites and are therefore often  
290 preferred by herbivores, including aphids (Price 1991; Price et al. 1987; Whitham 1978).  
291 However, Johansson & Gibb (2012) showed that spruce trees in mature forest, which tend to be  
292 of larger diameter, have a greater concentration of some sugars attractive to ants than young trees

293 regenerating in clear-cuts. This suggests that sugar quality may actually be higher in large-  
294 diameter trees, so resource quality is unlikely to be a driver of this difference.

295 Despite the smaller individual loads harvested from larger trees, colonies allocated more workers  
296 to large trees. Models showed that the net result of opposing allocation of worker activity and  
297 individual loads was that, close to the nest, a similar mass of honeydew was harvested from  
298 small and large trees (Figure 4). However, further from the nest, larger honeydew loads from  
299 smaller trees did not compensate for the greater activity on larger trees. Thus, the colony-level  
300 mass gain from large trees remained relatively constant with distance, while the mass gain from  
301 smaller trees declined rapidly.

302 At the colony level, a decline in selection of smaller trees with distance from the nest is  
303 consistent with optimal foraging as small trees can be considered to act as small resource  
304 patches. This is in agreement with previous studies that have shown greater recruitment to better  
305 quality (or larger) resource patches (Nonacs & Dill 1991; Taylor 1977). However, another  
306 possible explanation for the rapid decline in use of small trees with distance may be related to the  
307 limitations of ant navigation, which, for *Formica spp.*, is largely dependent on memorising the  
308 location of landmarks (Fukushi & Wehner 2004; Graham & Collett 2002). Larger trees may  
309 therefore present a clearer image for visual memory, although the panorama, rather than  
310 individual features, may be critical for navigation (Collett 2009). Alternatively, foraging paths  
311 can be costly to maintain in complex habitats (Shepherd 1982), so resources available from  
312 smaller trees may fall below the threshold under which maintenance is efficient.

313 *Is optimal foraging affected by stand age?*

314 Although the total quantity of honeydew harvested per hectare differs between stands of different  
315 ages (Gibb & Johansson 2010), we detected no change in the foraging responses of individual

316 ants. While the interaction between diameter and stand age appeared amongst the best models for  
317 mass gain, this relationship was of low importance. The basic rules that determine the behaviour  
318 of individuals were minimally altered by anthropogenic disturbance alone. However tree  
319 diameter and distance, which vary with stand age, were important predictors in the set of best  
320 models. This suggests that other factors that vary with stand age, such as time since disturbance,  
321 competition or predation are not important in modifying the optimal foraging relationship.  
322 Previous studies suggest foraging behaviours of ants and other species are often affected by  
323 anthropogenic disturbances (Goverde et al. 2002; Mahan & Yahner 1999; Sorvari &  
324 Hakkarainen 2004). However, changes in behaviour may reflect attempts by individuals to  
325 optimise foraging in the new environment, so may not alter this fundamental relationship.

### 326 *Conclusions*

327 Our findings suggest that most *F. aquilonia* workers observed on trees are engaged in honeydew  
328 harvesting. The clear effect of distance on worker loads is consistent with predictions from  
329 optimal foraging theory. However, for both distance and diameter, activity declined as loads  
330 increased, indicating a role for crowding in reducing colony-level efficiency (Dreisig 1988;  
331 Grüter et al. 2012). Load-distance relationships were consistent across stands of different ages,  
332 suggesting no effect of stand age on this fundamental response, despite effects of stand age on  
333 activity and honeydew quality (Gibb & Johansson 2010; Johansson & Gibb 2012). This is in  
334 contrast to findings suggesting effects of anthropogenic disturbances on a range of behavioural  
335 responses. However, changes in behaviour may often occur to optimise foraging or nesting  
336 success. Behavioural changes in response to disturbance may thus tend to be consistent with  
337 optimal foraging if they are within the evolutionary experience of a species.

338 **Supporting information**

339 **Table S1:** Available background data on the study sites, including head width, nest volume and  
340 activity of *Formica aquilonia* (Gibb & Johansson 2010), temperature on days of sampling for  
341 experiment 2, numbers of aphids on three branches taken from five spruce trees and aphids per  
342 needle collected in arboreal surveys (Gibb & Johansson 2010), and sucrose levels in honeydew  
343 collected from the crops of *F. aquilonia* workers (Johansson & Gibb 2012).

344 **Acknowledgements:**

345 We would like to thank Åke Nordström and Ylva Nordström for invaluable assistance in the  
346 field.
