

Rapidly increasing macroalgal cover not related to herbivorous fishes on Mesoamerican reefs

Adam Suchley, Melanie D McField, Lorenzo Alvarez-Filip

Long-term phase shifts from coral to macroalgal dominated reef systems are well-documented in the Caribbean. Although the impact of coral diseases, climate change and other factors is acknowledged, major herbivore loss through disease and overfishing is often assigned a primary role. However, direct evidence for the link between herbivore abundance, macroalgal and coral cover is sparse, particularly over broad spatial scales. In this study we use a database of coral reef surveys performed at 85 sites along the Mesoamerican Reef of Mexico, Belize, Guatemala and Honduras, to examine potential ecological links by tracking site trajectories over the period 2005-2014. Despite the long-term reduction of herbivory capacity reported across the Caribbean, the Mesoamerican reef region displayed relatively low macroalgal cover at the onset of the study. Subsequently, increasing fleshy macroalgal cover was pervasive. Herbivorous fish populations were not responsible for this trend as fleshy macroalgal cover change was not correlated with initial herbivorous fish biomass or change, and the majority of sites experienced increases in macroalgae browser biomass. This contrasts the coral reef top-down herbivore control paradigm and suggests the role of external factors in making environmental conditions more favourable for algae. Increasing macroalgal cover typically suppresses ecosystem services and leads to degraded reef systems. Consequently, policy makers and local coral reef managers should reassess the focus on herbivorous fish protection and consider complimentary measures such as watershed management in order to arrest this trend.

17 Abstract

18 Long-term phase shifts from coral to macroalgal dominated reef systems are well-
19 documented in the Caribbean. Although the impact of coral diseases, climate change
20 and other factors is acknowledged, major herbivore loss through disease and
21 overfishing is often assigned a primary role. However, direct evidence for the link
22 between herbivore abundance, macroalgal and coral cover is sparse, particularly over
23 broad spatial scales. In this study we use a database of coral reef surveys performed at
24 85 sites along the Mesoamerican Reef of Mexico, Belize, Guatemala and Honduras, to
25 examine potential ecological links by tracking site trajectories over the period 2005-
26 2014. Despite the long-term reduction of herbivory capacity reported across the
27 Caribbean, the Mesoamerican reef region displayed relatively low macroalgal cover at
28 the onset of the study. Subsequently, increasing fleshy macroalgal cover was pervasive.
29 Herbivorous fish populations were not responsible for this trend as fleshy macroalgal
30 cover change was not correlated with initial herbivorous fish biomass or change, and
31 the majority of sites experienced increases in macroalgae browser biomass. This
32 contrasts the coral reef top-down herbivore control paradigm and suggests the role of
33 external factors in making environmental conditions more favourable for algae.
34 Increasing macroalgal cover typically suppresses ecosystem services and leads to
35 degraded reef systems. Consequently, policy makers and local coral reef managers
36 should reassess the focus on herbivorous fish protection and consider complimentary
37 measures such as watershed management in order to arrest this trend.

38

39 Introduction

40 Caribbean coral reefs have experienced major declines over recent decades, with
41 substantial reductions in live coral cover accompanied by concomitant losses in reef
42 accretion and structural complexity (Schutte, Selig & Bruno, 2010; Alvarez-Filip et al.,
43 2011; Perry et al., 2015). Although a wide array of factors have contributed to reef
44 deterioration including coral diseases, coastal development and climate change, the
45 loss of key herbivores is thought to be a leading driver of ecosystem transition towards
46 macroalgal domination at many reef sites in the region (Hughes, 1994; Jackson et al.,
47 2014). Macroalgae compete with corals, reducing coral fecundity, recruitment and
48 survival via various mechanisms including overgrowth, shading and allelopathy
49 (McCook, Jompa & Diaz-Pulido, 2001; Hughes et al., 2007; Bruno et al., 2009; Rasher
50 et al., 2011). Today, populations of key herbivore taxa are diminished on many
51 Caribbean reefs. The sea urchin *Diadema antillarum* was previously an important grazer
52 in the Caribbean (Jackson et al., 2001). In 1983/4 *Diadema* suffered mass mortality
53 across the Caribbean due to putative disease and populations have subsequently
54 shown only limited recovery (Lessios, Robertson & Cubit, 1984; Kramer, 2003; Hughes
55 et al., 2010). Furthermore, long-term overfishing has resulted in marked reductions in
56 herbivorous fish populations at many sites across the region (Jackson et al., 2001;
57 Paddack et al., 2009).

58 Given the pivotal role of herbivores in controlling macroalgal growth (Mumby et al.,
59 2006), it is widely accepted that restoring populations of key herbivores enhances reef
60 resilience by controlling algal communities and facilitating coral recovery by freeing
61 space for coral recruits (Nyström, Folke & Moberg, 2000; McCook, Jompa & Diaz-

62 Pulido, 2001; McManus & Polsenberg, 2004; Bruno et al., 2009). Consequently, coral
63 reefs with high herbivore abundance are expected to have lower macroalgal cover and
64 greater coral cover (Jackson et al., 2014; Kramer et al., 2015). This paradigm has
65 encouraged global awareness campaigns promoting conservation and fisheries
66 management strategies to protect and restore populations of key herbivorous fishes,
67 particularly parrotfishes (Jackson et al., 2014). In the Mesoamerican region, for
68 example, Belize and Guatemala have banned the capture and possession of
69 herbivorous fishes (Kramer et al., 2015).

70 Direct evidence of herbivores' ability to facilitate the maintenance and recovery of
71 resilient coral reefs is limited. Experimental herbivore exclusion studies demonstrate the
72 action of *Diadema* and herbivorous fish grazing on macroalgal cover, although evidence
73 for the impact on corals is limited by the short-term nature and restricted spatial extent
74 of the experiments (Lirman, 2001; Burkepile & Hay, 2006, 2009; Hughes et al., 2007).
75 Observational studies tend to focus on inter-site comparisons without an explicit
76 temporal dimension, rather than tracking long-term reef change trajectories to provide a
77 more in-depth understanding of drivers of ecosystem dynamics (Karr et al., 2015). Little
78 consensus exists between studies, which exhibit contrasting patterns between
79 herbivorous fish populations and macroalgal cover. In a Caribbean-wide point-in-time
80 study, Newman et al. (2006) found a significant negative correlation between
81 herbivorous fish biomass and fleshy algal biomass, whereas Loh et al. (2015) observed
82 that overfished Caribbean sites had lower macroalgal cover than protected sites. For
83 the Northern Mesoamerican Reef of Mexico, Bozec et al. (2008) did not observe a
84 relationship between herbivore biomass and macroalgal cover. In a long-term study,

85 Ilves et al. (2011) observed increases in both herbivorous fish abundance and algal
86 cover in the Bahamas. On the Northern Florida Reef Tract, Lirman & Biber (2000)
87 observed no correlation between algal biomass and cover and fish grazer abundance
88 and consumption rates. Jackson et al. (2014) found a significant negative correlation
89 between parrotfish biomass and macroalgal cover in 16 Caribbean locations, however
90 no such relationship was observed for a broader data set covering 46 locations. The
91 lack of relationship between herbivorous fish and macroalgal cover is evident for other
92 regions: Carassou et al. (2013), for example, found that macroalgal cover was not
93 correlated with the biomass, density and diversity of macroalgae feeders in the South
94 Pacific.

95 To further understand the relationship between herbivory pressure and changes in
96 macroalgal cover we propose a simple conceptual framework (Fig. 1). Here, reefs may
97 experience one of four scenarios of temporal changes in fleshy macroalgal cover and
98 herbivorous fish biomass, a widely used proxy for herbivory intensity (Graham et al.,
99 2015). Principal ecological drivers are presented for each idealised scenario, although
100 in reality a number of drivers act in conjunction to varying extents. A phase shift from
101 coral to algae domination due to herbivore loss is represented by the scenario in the
102 upper-left quadrant. Here, decreasing herbivory leads to increasing macroalgal cover.
103 Conversely, in the bottom-right quadrant, *increases* in herbivorous fishes result in
104 reduced macroalgal cover. This quadrant represents the scenario sought by
105 management measures and fisheries regulations restricting extraction, particularly of
106 herbivorous fishes (Halpern, 2003; Lester et al., 2009; Selig & Bruno, 2010; Guarderas,
107 Hacker & Lubchenco, 2011).

108 Alternatively, a *positive* relationship may exist between macroalgal cover and
109 herbivorous fish biomass, as represented by the scenarios of the upper-right and
110 bottom-left quadrants of Fig. 1. This may occur when herbivores are food limited, as
111 evidenced by increases in herbivore abundance and biomass following algal growth and
112 by resource competition between *Diadema* and herbivorous fishes (Hay & Taylor, 1985;
113 Carpenter, 1990; Adam et al., 2011). In these scenarios, predominantly external drivers
114 such as nutrient availability, temperature and solar irradiance determine macroalgal
115 cover and herbivorous fish biomass responds according to food availability (Burkepile &
116 Hay, 2006; Ferrari et al., 2012). Numerous experimental manipulation studies have
117 reported the significant positive impact of nutrient enhancement on primary producer
118 abundance, although herbivory has generally been found to play a greater role
119 (Burkepile & Hay, 2006). Contrastingly, few studies have addressed the importance of
120 macroalgal productivity potential relating to environmental factors such as light
121 availability and temperature (Steneck & Dethier, 1994; Ferrari et al., 2012).

122 Herbivore and algal community composition also play an important role in herbivore-
123 algal dynamics. Subsequent to the *Diadema* mass mortality event of the early 1980's,
124 herbivorous fishes of the Scaridae and Acanthuridae families are recognised as the
125 primary herbivores on many Caribbean reefs (Jackson et al., 2014; Adam et al., 2015a).
126 While common *Acanthurus* surgeonfishes have a broad diet feeding on a combination
127 of turf algae, macroalgae and detritus, *Sparisoma* and *Scarus* parrotfishes are more
128 selective (Burkepile & Hay, 2011; Adam et al., 2015a). *Sparisoma* parrotfishes, with the
129 exception of the excavating *S. viride*, are macroalgae browsers, while *Scarus* spp.
130 primarily graze algal turfs (Bonaldo, Hoey & Bellwood, 2014; Adam et al., 2015b).

131 Consequently, a suitable mix of herbivores are required in order to both graze turf algae
132 to facilitate coral recruitment and to crop down macroalgal stands to reduce competition
133 with adult coral colonies (McCook, Jompa & Diaz-Pulido, 2001; Hughes et al., 2007;
134 Burkepile & Hay, 2008). However, herbivores' ability to effectively moderate macroalgal
135 cover is mediated by macroalgal predation defences (Rasher, Hoey & Hay, 2013). Such
136 defences are species specific and include morphological, structural, mineral and
137 chemical traits that deter herbivores, with several genera (e.g. *Lobophora*, *Peyssonnelia*
138 and *Codium*) being unpalatable (Hay, 1997; Smith, Hunter & Smith, 2010). These
139 defences likely influence herbivore feeding preferences and conversely algal community
140 structure is often influenced by herbivore mix, resulting in a complex interaction
141 between the two communities (Adam et al., 2015a).

142 Here, by following individual site trajectories, we examine the prevalence of the four
143 herbivorous fish and macroalgae change scenarios across 85 sites surveyed from 2005
144 to 2014 along the Mesoamerican Reef. We also consider herbivore functional group
145 composition and trajectories, and compare these with overall trends. Subsequently, we
146 evaluate the potential effects of herbivorous fish biomass, fleshy macroalgal cover and
147 other factors such as degree of protection, on changes in coral cover during the same
148 timeframe. Our hypothesis is that for sites where herbivory increased, fleshy macroalgal
149 cover decreased, and that herbivore biomass and the decline in macroalgal cover are
150 among the main factors explaining coral cover on today's reefs.

151

152 **Materials & Methods**

153 We used data produced by the Healthy Reefs Initiative (HRI) and the Atlantic and Gulf
154 Rapid Reef Assessment (AGRRA) programs, which include ecological censuses for 398
155 sites along the Mesoamerican Reef in Mexico, Belize, Guatemala and Honduras from
156 2005 to 2014. Site selection was based on benthic habitat maps produced by the
157 Millennium Reef Mapping Program, with 200 m × 200 m sites randomly selected
158 following stratification by geomorphological characteristics and depth (Andréfouët et al.,
159 2003; Kramer, 2003). The database contains 85 long-term monitoring sites that were
160 surveyed in 2005/2006 and 2013/2014 over a 7, 8 or 9-year period, a timeframe
161 sufficient to observe ecologically meaningful changes (Babcock et al., 2010). Of these
162 sites, 43 were repeatedly surveyed in four time periods (2005/2006, 2009/2010,
163 2011/2012 and 2013/2014). Sites were located primarily on the fore reef and reef crest
164 at a mean (\pm Standard Error s.e.m.) depth of 6.9 ± 0.2 m.

165 Benthic cover and reef fish surveys were performed according to AGRRA protocol, with
166 transects located haphazardly, parallel to the coast (Lang et al., 2010). The majority of
167 sites were surveyed at similar times during the summer year-on-year in order to
168 minimise seasonal effects. At each site an average of five to six 10 m-transects were
169 surveyed using point intercept methodology to determine benthic cover including hard
170 coral percentage cover and fleshy macroalgal percentage cover. The abundance and
171 total length (TL) of 81 key reef fish species, including herbivorous fishes of the Scaridae
172 and Acanthuridae families, was recorded in ten 30 m-long, 2 m-wide transects. Reef fish
173 abundance was subsequently converted to biomass density using standard allometric
174 length-weight conversions.

175 The data analyses focussed on the relation between three ecological indicators for each
176 reef site: herbivorous fish (Scaridae and Acanthuridae) biomass, fleshy macroalgal
177 (excluding turf and calcareous algae) cover and hard coral (scleractinians and *Millepora*
178 spp.) cover. Very few *Diadema* spp. were observed and therefore we focussed on reef
179 fishes as the principal herbivores. For all three ecological indicators, a number of
180 metrics were calculated to evaluate and examine temporal trends: absolute annual
181 change, annual relative rate of change and geometric rate of change. The metrics for
182 each ecological indicator (I) were determined as follows:

$$183 \quad I_{\text{Absolute Annual Change}} = \frac{(I_{t_f} - I_{t_0})}{\Delta t} \quad (1)$$

$$184 \quad I_{\text{Annual Relative Rate of Change}} = \frac{(I_{t_f} - I_{t_0})}{I_{t_0} \times \Delta t} \quad (2)$$

$$185 \quad I_{\text{Annual Geometric Rate of Change}} = \left(\frac{I_{t_f}}{I_{t_0}} \right)^{\frac{1}{\Delta t}} - 1 \quad (3)$$

186 where I_{t_f} is the value of the ecological indicator at the end of the period, I_{t_0} is the initial
187 value and Δt is the length of the period (in years). The former two metrics provide
188 complementary information, for example: if an ecological indicator such as coral cover
189 increases from 10 % to 15 %, the absolute change (equation (1)) is 5 %, while the
190 relative rate of change (equation (2)) indicates that coral cover has increased by 50 %
191 relative to its initial value. Geometric rate of change (equation (3)) was utilised in order
192 to assess and compensate for non-linearity in the relative rate of change, while still
193 providing an interpretable value (Côté et al., 2005).

194 Univariate comparison of ecological indicators was performed using ANOVA, t-tests or
195 non-parametric equivalents (Mann-Whitney U or Wilcoxon Signed Rank tests), based
196 on an assessment of normality and homogeneity of variance using Shapiro-Wilk and
197 Levene tests. To test our first hypothesis, herbivorous fish biomass was compared with
198 fleshy macroalgal cover using Spearman rank-order correlation due to non-normality.
199 Herbivorous fishes were further categorised according to feeding preferences as
200 macroalgae browsers (*Sparisoma* spp., with the exception of *S. viride*), turf grazers /
201 scrapers (*Scarus* spp. and *Acanthurus* spp.) or bioeroders (*Sparisoma viride*) (Bellwood
202 et al., 2004; Burkepile & Hay, 2011; Bonaldo, Hoey & Bellwood, 2014; Adam et al.,
203 2015a,b). Change in functional group biomass was compared with overall change in
204 herbivorous fish biomass using Spearman rank-order correlation. Furthermore, change
205 in macroalgal cover was compared with absolute levels of overall herbivorous fish and
206 macroalgae browser biomass both graphically by categorising sites by initial fish
207 biomass (based on deciles) and by using Spearman rank-order correlation.

208 To test our second hypothesis, change in absolute coral cover from 2005/6 to 2013/4 for
209 long-term monitoring sites was modelled using multiple linear regressions as model
210 assumptions were satisfied. To address the common problem of spatial autocorrelation
211 in multi-site studies we performed a Moran's I test on coral cover change by site
212 location which reported no spatial autocorrelation present (Moran's I = 0.070, P = 0.08).
213 The optimum regression model was selected based on Akaike Information Criterion
214 (AIC). Candidate independent variables were selected based on ecological relevance
215 and data availability (Table S1). Potential collinearity among predictor variables was
216 examined using Pearson correlations and variance inflation factors, and outliers were

217 removed on the basis of Cook's D. All statistical analyses were performed using R (R
218 Core Team, 2014).

219

220 **Results**

221 Here we present herbivorous fish biomass and fleshy macroalgal cover average trends
222 for repeatedly surveyed sites and assess changes in these variables for long-term
223 monitoring sites. Subsequently we examine herbivorous fish feeding guilds and
224 geographic trends for long-term monitoring sites, and assess the effect of protection on
225 site trajectories. Finally we present the ecological drivers of long-term coral cover
226 change.

227 *Herbivorous fish biomass and macroalgal cover trends*

228 During the time period 2005 to 2014, regional averages showed a clear trend of
229 increasing fleshy macroalgal cover on the Mesoamerican Reef, while herbivorous fish
230 biomass remained relatively constant. Across 43 sites surveyed repeatedly in four time
231 periods (Fig. 2), mean herbivorous fish biomass did not change significantly (Wilcoxon
232 Signed Rank, $Z = 0$, $P = 1$), while mean macroalgal cover doubled during the same
233 period (Wilcoxon Signed Rank, $Z = -5.02$, $P < 0.001$). Between 2005/2006 and
234 2009/2010 mean herbivorous fish biomass decreased and mean fleshy macroalgal
235 cover increased significantly (Wilcoxon Signed Rank, $Z = 3.36$, $P < 0.001$ and $Z = -3.86$,
236 $P < 0.001$, respectively). From 2009/10 to 2011/12 the trend appeared to be reversed,
237 although the changes were not significant for macroalgae (Wilcoxon Signed Rank, $Z = -$

238 2.95, $P = 0.003$ and $Z = 0.59$, $P = 0.55$, respectively; Fig. 2). From 2011/2012 to
239 2013/2014 macroalgal cover increased significantly, while herbivorous fish biomass
240 remained unchanged (Wilcoxon Signed Rank, $Z = -3.81$, $P < 0.001$ and $Z = -0.35$, $P =$
241 0.73 , respectively; Fig. 2).

242 Tracking individual trajectories of the 85 long-term monitoring sites surveyed over a 7, 8
243 or 9-year period permitted a more detailed investigation of the relation between the
244 temporal changes in herbivorous fish biomass and fleshy macroalgal cover.

245 Herbivorous fish biomass ranged from approximately 50 to 14,000 g/100m² and fleshy
246 macroalgal cover ranged from 0 to 57.5 %. There was no correlation between the
247 changes in herbivorous fish biomass and fleshy macroalgal cover for long-term
248 monitoring sites (Spearman, $r_s = -0.11$, $P = 0.35$). Only 7 % of sites exhibited increased
249 herbivorous fish biomass and decreased macroalgal cover; 35 % of sites displayed
250 decreases in fish biomass and increases in macroalgal cover; almost half of the sites
251 (48 %) exhibited increases in both herbivorous fish biomass and macroalgal cover; and
252 10 % displayed decreased fish biomass and macroalgal cover (Fig. 3). Across all sites
253 macroalgal cover increased irrespective of initial conditions of herbivorous fish biomass
254 (Spearman, $r_s = -0.12$, $P = 0.3$; Fig. 4A) and macroalgae browser biomass (Spearman,
255 $r_s = -0.21$, $P = 0.3$; Fig. 4B).

256 Considering herbivorous fish feeding preferences based on Bellwood et al. (2004),
257 communities of the Mesoamerican Reef present a mixture of guilds with 24.3 %
258 macroalgae browsers by biomass in 2013/14 (19.4 % in 2005/6), 48.4 % (57.3 %) turf
259 grazers / scrapers and 27.3 % (23.3 %) bioeroders. Herbivorous fish biomass and
260 macroalgal cover change were broadly similar between macroalgae browsers and

261 overall results (Fig. 3). Macroalgae browser biomass displayed a slightly greater
262 tendency for increase than overall herbivorous fish biomass, as observed for 61 % of
263 sites compared with 55 %, and site-level changes in these were correlated (Spearman,
264 $r_s = 0.70$, $P < 0.001$).

265 Geographically, the principal trend was for increasing fleshy macroalgal cover and
266 herbivorous fish biomass in Mexico and northern Belize, including the atolls of Turneffe
267 and Lighthouse Reef, but for increasing fleshy macroalgal cover and decreasing
268 herbivorous fish biomass to the south in south-central and southern Belize, Glover's
269 Reef, Guatemala and Cayos Cochinos, Honduras (Fig. 3). However, the Bay Islands of
270 Honduras were exceptions to this broad north-to-south trend with Guanaja island
271 displaying the highest proportion of sites with increasing herbivorous fish biomass and
272 decreasing macroalgal cover. The only other three sites that experienced increasing
273 herbivorous fish biomass and decreasing macroalgal cover were located at Isla Mujeres
274 and Puerto Morelos in Mexico, and San Pedro in Belize.

275 Of the 85 long-term monitoring sites, 12 sites were located within No Take Zones
276 (NTZs) where all extractive practices are prohibited, 47 were within Marine Protected
277 Areas but not NTZs (MPAs) where reefs benefit from regulation but some extractive
278 practices are permitted, and the remaining 26 were unprotected. The level of protection
279 was observed to affect the initial levels of fleshy macroalgal cover and herbivorous fish
280 biomass, in addition to changes in these over time. In 2005/6, sites within NTZs
281 exhibited similar herbivorous fish biomass and fleshy macroalgal cover to sites located
282 elsewhere within Marine Protected Areas (Mann-Whitney, $U = 197$, $Z = -1.60$, $P = 0.11$;
283 and $U = 297$, $Z = 0.28$, $P = 0.78$ respectively; Fig. 5). Protected sites (both MPAs and

284 NTZs) displayed significantly higher initial macroalgal cover than unprotected sites
285 (Mann-Whitney, both $U \geq 247$, $Z \geq 2.85$, $P \leq 0.003$; Fig. 5), but only protected sites
286 outside of NTZs exhibited significantly higher initial herbivorous fish biomass than
287 unprotected sites (Mann-Whitney, MPA vs unprotected, $U = 819$, $Z = 2.40$, $P = 0.016$;
288 NTZ vs unprotected, $U = 161$, $Z = 0.16$, $P = 0.89$; Fig. 5). Along the protection gradient
289 (from unprotected, through MPA to no-take protection), sites appeared to experience a
290 greater increase in herbivorous fish biomass and a lesser increase in macroalgal cover,
291 although the differences were not statistically significant (ANOVA, annual geometric rate
292 of change in fish biomass, $F_{2,82} = 0.04$, $P = 0.97$; annual geometric rate of change in
293 macroalgal cover, $F_{2,80} = 1.01$, $P = 0.37$).

294 *Predicting coral cover change*

295 Across all 85 long-term monitoring sites, mean (\pm s.e.m.) hard coral cover increased
296 significantly from 12.2 ± 0.8 % in 2005/6 to 15.0 ± 0.8 % in 2013/14 (Wilcoxon Signed
297 Rank, $Z = -3.81$, $P < 0.001$). Individual sites displayed varying trajectories with annual
298 changes in coral cover ranging from -3.1 % to $+2.7$ %. The optimum linear regression
299 model for the annual absolute change in hard coral cover displayed a modest but
300 significant fit (Adjusted $R^2 = 0.18$, $F_{7,74} = 3.57$, $P = 0.002$). The model included seven
301 predictor variables (Table S1), of which four were significant: MPA, country (Honduras),
302 annual logarithmic change in herbivorous fish biomass and initial hard coral cover (Fig.
303 6). Interpreting these significant variables, sites within Marine Protected Areas
304 experienced greater increases in coral cover than unprotected sites; Honduran sites
305 experienced lesser increases in coral cover than other countries; and increases in
306 herbivorous fish biomass corresponded with increases in coral cover. Initial coral cover

307 was the most significant predictor of coral cover change and therefore in order to further
308 understand its impact, sites were categorised as low (<10 %), medium (10-20 %) or
309 high ($\geq 20\%$) initial coral cover. For the 12 long-term monitoring sites with high initial
310 coral cover, mean coral cover decreased over time (mean \pm s.e.m. annual change in
311 coral cover of -0.6 ± 0.4 %), while coral cover increased for sites with lower levels of
312 initial cover (low initial coral cover, $+0.6 \pm 0.1$ %; medium initial coral cover, $+0.4 \pm 0.2$
313 %).

314 Despite not being selected in the optimum regression model, we further explored the
315 relationship between coral and macroalgal cover due to the long-term ecological shifts
316 reported on many Caribbean reefs. Across all 85 long-term monitoring sites, mean (\pm
317 s.e.m.) macroalgal cover increased significantly from 12.0 ± 1.1 % in 2005/6 to $24.1 \pm$
318 1.5 % in 2013/14 (Wilcoxon Signed Rank, $Z = -7.07$, $P < 0.001$). We observed little or
319 no relationship between coral and macroalgal cover since macroalgal cover consistently
320 increased irrespective of changes in coral cover (Fig. S3). All initial coral cover
321 categories (low (< 10 %), medium (10-20 %), and high (≥ 20 %)) experienced increases
322 in fleshy macroalgal cover, and initial macroalgal cover, similarly categorised, did not
323 impact coral cover changes over time (ANOVA, $F_{2,82} = 1.10$, $P = 0.34$).

324

325 Discussion

326 Substantial changes in the ecological composition of the Mesoamerican Reef were
327 evident in a time span of only nine years. The principal trend is for increasing fleshy
328 macroalgal cover, as observed at 83 % of long-term monitoring sites (Fig. 3). Mean

329 absolute cover of fleshy macroalgal cover increased by approximately 12 % in the
330 region between 2005 and 2014 (Fig. 2). Mean herbivorous fish biomass remained
331 relatively stable (Fig. 2), although displaying substantial site variation, with 55 % of sites
332 showing an increase in herbivorous fish biomass between 2005 and 2014 (Fig. 3). The
333 scenario of both increasing fleshy macroalgal cover and herbivorous fish biomass was
334 observed at 48 % of the 85 sites while the ‘desirable’ scenario of increasing herbivorous
335 fish biomass and decreasing macroalgal cover was the least frequent of all four
336 scenarios (Fig. 3). Similar trends were observed for the macroalgae-browsing fish guild
337 (Fig. 3), with site-level macroalgae browser biomass change correlating with overall
338 herbivorous fish biomass change. This suggests that fish herbivory was not a major
339 driver of fleshy macroalgal cover change on the majority of surveyed sites across the
340 Mesoamerican Reef (Fig. 3).

341 The clear pattern of increasing macroalgal cover and stable herbivorous fish biomass
342 on Mesoamerican reefs contrasts with the widely accepted coral reef top-down
343 herbivore control paradigm and management recommendations that advocate
344 increasing herbivory to control fleshy macroalgal cover (Nyström, Folke & Moberg,
345 2000; McCook, Jompa & Diaz-Pulido, 2001). This result is consistent with a multi-
346 decadal study reporting that macroalgal cover was not related to long-term parrotfish
347 losses due to fishing in the Philippines (Russ et al., 2015). Furthermore, we found that
348 coral cover on the Mesoamerican Reef was low and unrelated to macroalgal cover.
349 Since both coral cover and reduced herbivory were not responsible for increasing
350 macroalgal cover, external factors may have played a role. For the Mesoamerican Reef
351 region a growing body of evidence shows that rising nutrient levels is a worsening

352 problem that may be accelerating macroalgal increase. In the Mexican Caribbean
353 previous studies have observed elevated nutrient input to coral reefs due to coastal
354 development (Baker, Rodríguez-Martínez & Fogel, 2013; Hernández-Terrones et al.,
355 2015) and the subsequent degradation of reef systems (Bozec et al., 2008). In southern
356 Belize and Honduras riverine discharge and escalating reef sediment and nutrient loads
357 associated with urban and agricultural run-off may have played a role in increasing
358 macroalgal cover (Burke & Sugg, 2006; Carilli et al., 2009; Soto et al., 2009). Our
359 finding that fish herbivory is not responsible for macroalgal cover trends contrasts the
360 results of herbivore exclusion studies, which emphasize the relative importance of
361 herbivory over nutrient availability (McClanahan, Cokos & Sala, 2002; Burkepile & Hay,
362 2006, 2009; Sotka & Hay, 2009). However, contrary to the present study, such
363 experiments tend to be conducted on restricted spatial and temporal scales.
364 Unfortunately, site nutrient data are not widely available for the Mesoamerican Reef,
365 impeding a quantitative exploration of this effect in our analyses.

366 One alternative that could partially explain the rapid increases in fleshy macroalgae
367 across the Mesoamerican Reef is that reef ecosystems passed critical thresholds
368 beyond which herbivorous fishes are unable to control macroalgae due to either
369 excessive algal production and/or insufficient herbivory (Mumby, Hastings & Edwards,
370 2007). This is particularly relevant given that Caribbean reefs may suffer from
371 insufficient herbivory due to both the limited population recovery of *Diadema antillarum*
372 subsequent to previous mass mortality and the inability of herbivorous fish to
373 adequately compensate for this loss (McClenachan, 2009; Paddack et al., 2009;
374 Hughes et al., 2010). However, excessive algal production is unlikely on the

375 Mesoamerican Reef as regional average macroalgal cover increased from only 10 % in
376 2005/6 to 22 % in 2013/14 (Fig. 2), values that are likely considerably below ecosystem
377 thresholds for Caribbean reefs (Bruno et al., 2009). Furthermore, an examination of
378 macroalgal change by absolute levels of herbivorous fish biomass revealed increasing
379 fleshy macroalgal cover even for those sites with the highest initial fish biomass (the
380 uppermost deciles possessed average overall herbivorous fish biomass and
381 macroalgae-browsing fish biomass of 9,065 g/100m² and 1,762 g/100m² respectively;
382 Fig. 4). Although there is little consensus on Caribbean reef herbivorous fish thresholds,
383 a global assessment of the status of coral reef herbivorous fishes identified only 9 of
384 132 localities as having herbivorous fish biomass greater than 9,000 g/100m²,
385 suggesting this to be a high benchmark (Mumby, Hastings & Edwards, 2007; Edwards
386 et al., 2014). In addition, a negative correlation between Caribbean reef herbivorous fish
387 biomass and fleshy algal biomass has been previously observed with a site maximum of
388 only 7,000 g/100m² approximately (Newman et al., 2006).

389 The threshold hypothesis would be particularly relevant if the decline in average
390 herbivorous fish biomass between 2005/6 and 2009/10 resulted in changes in the
391 relative proportion of key functional groups, favouring non-macroalgae-browsing
392 species (Adam et al., 2015b; Fig. 2). However, the relative proportions of the three main
393 herbivorous fish functional groups remained stable during the study period (Fig. S4).
394 Additionally, a close examination of those sites that suffered the greatest herbivorous
395 fish biomass losses between 2005 and 2009 revealed that these sites experienced
396 similar macroalgal growth from 2009 to 2014 compared with other sites (Fig. S5). This
397 suggests that the observed rapid increases in fleshy macroalgae are not due to

398 Mesoamerican reefs passing critical thresholds of excessive algal production and/or
399 insufficient herbivory.

400 Fish populations may impact benthic communities indirectly through mediation of
401 benthic competition. Sponges are a major component of Caribbean coral reef benthos
402 that compete for space with corals and macroalgae (Loh et al., 2015). Sponges'
403 competitive superiority over corals is well documented and likely due to a number of
404 mechanisms including shading, smothering and allelopathy (Porter & Targett, 1988; Loh
405 et al., 2015). Overfishing of spongivorous parrotfishes and angelfishes has been shown
406 to alter ecosystem dynamics through the alleviation of predation pressure on sponges
407 (Loh & Pawlik, 2014; Loh et al., 2015). Therefore, it is likely that at sites with high
408 parrotfish biomass, spongivory will control benthic sponge cover, indirectly benefiting
409 macroalgal and coral communities via reduced benthic competition. Unfortunately we
410 could not further explore the role of sponges in shaping benthic interactions as the
411 survey protocol does not focus on producing reliable sponge cover information (Lang et
412 al 2010).

413 Coral recovery on the Mesoamerican Reef was related to MPA protection and
414 increasing biomass of herbivorous fish, but not via the expected mechanism of
415 macroalgal declines through fish herbivory. Alternative mechanisms for the effect of
416 protection on reef corals are less well studied, but may include reduced disease
417 prevalence, and diminished physical reef damage through regulation of fishing and
418 recreational diving practices (Hasler & Ott, 2008; Lamb et al., 2015). Replenished fish
419 communities inside marine reserves can also drive coral recovery through ecological
420 processes not necessarily linked with herbivory. For example, trophically diverse fish

421 communities inside marine reserves have been shown to ameliorate coral disease
422 prevalence, although the pathways through which this takes place remain unclear
423 (Raymundo et al., 2009). Alternatively, coral cover and complexity may influence
424 herbivorous fish populations, rather than vice-versa, or the relationship may be purely
425 correlative with both indicators being driven by marine protection (Halpern, 2003; Selig
426 & Bruno, 2010; Alvarez-Filip, Gill & Dulvy, 2011).

427 Reef protection has a positive impact on herbivorous fish biomass and coral cover,
428 although fleshy macroalgal cover continued to increase at most sites. Although
429 protection impacted herbivorous fish biomass and macroalgal cover trajectories (Fig. 5),
430 initial differences between protected and unprotected sites tend to persist, with
431 unprotected sites continuing to display lower macroalgal cover. This may be attributable
432 to reserve age, as protected sites were located within reserves designated in 2003 (± 1
433 year) on average, and studies have shown that protection influence may be subject to a
434 lag effect (Selig & Bruno, 2010; Babcock et al., 2010). Furthermore, the use of
435 protection categories (No Take Zones (NTZs), Marine Protected Areas but not NTZs,
436 and unprotected) is a coarse measure of the actual range of protection and fishing
437 pressure experienced at sites. Additionally, local conditions and reserve regulations
438 often obfuscate protection impact due to variability of internal factors such as reef
439 community structure and enforcement level, and external impacts including local
440 stressors and global climate change (Mora et al., 2006; McClanahan et al., 2006; Selig,
441 Casey & Bruno, 2012). Finally, trophic effects may play a role since trophic cascades
442 are expected when populations of large predators are enhanced due to protection
443 (Estes et al., 2011). The protection of piscivores, for example, may result in herbivore

444 reduction and consequently elevated macroalgal growth inside marine reserves.
445 However, studies that explored this question have found that changes in predator
446 populations do not discernibly influence, or are even positively correlated with the
447 density, size, and biomass of herbivorous fishes, suggesting that top-down forces may
448 not play a strong role in regulating large-bodied herbivorous fish on coral reefs (Mumby
449 et al., 2006; Houk & Musburger, 2013; Rizzari, Bergseth & Frisch, 2015).

450

451 **Conclusions**

452 Despite the long-term reduction of herbivory capacity reported across the Caribbean,
453 the Mesoamerican Reef displayed relatively low macroalgal cover at the onset of this
454 study. Subsequently, during the last decade, fleshy macroalgal cover increased rapidly
455 on Mesoamerican reefs. Herbivorous fish populations were not responsible for this
456 trend, contrasting the coral reef top-down herbivore control paradigm and implicating
457 the role of external factors in making environmental conditions more favourable for
458 algae. Increasing macroalgal cover typically suppresses ecosystem services and leads
459 to degraded reef systems. Consequently, policy makers and local managers should
460 consider complementary protection measures such as watershed management, in
461 addition to herbivorous fish protection, in order to arrest this trend.

462

463 **Acknowledgments**

464 The authors recognize the invaluable efforts of Healthy Reefs Initiative (HRI) partner
465 organizations and individual field researchers who collaborated over the years in
466 collecting the data. Data contributors are listed in HRI Report Cards and supplemental
467 reports, available at www.healthyreefs.org. In particular Ian Drysdale, Marisol Rueda,
468 Ana Giro and Roberto Pott are recognised for coordinating field surveys, training and
469 data entry. The HRI database is processed and managed in conjunction with Ken Marks
470 and Judith Lang. Our manuscript was significantly improved by insightful comments
471 from R. Iglesias-Prieto, J. Bruno and one anonymous reviewer.

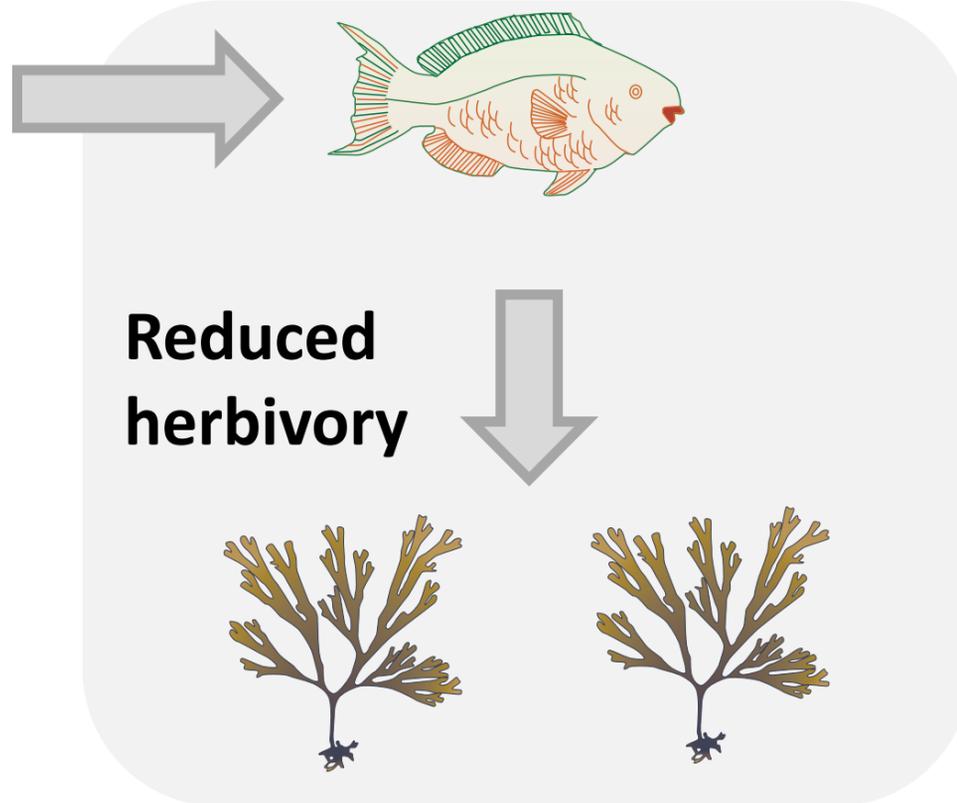

Figure 1(on next page)

Relationship between changes in herbivorous fish biomass and benthic fleshy macroalgal cover.

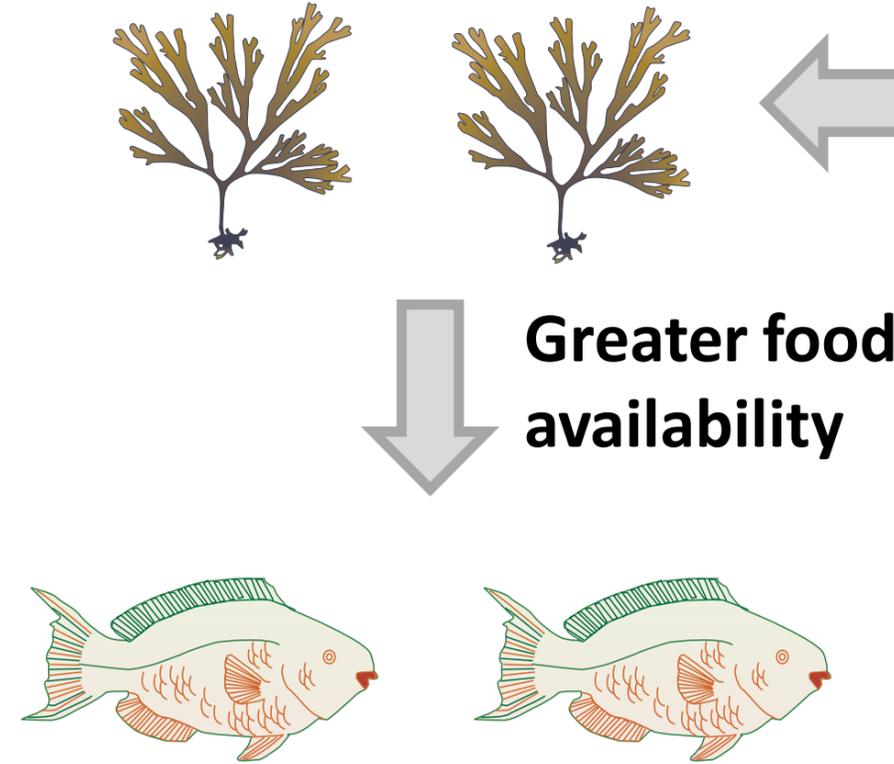

Possible cause-and-effect scenarios with external drivers are postulated for each quadrant. Fish and algae graphics by Diana Kleine and Tracey Saxby (IAN Image Library, Integration and Application Network, University of Maryland Center for Environmental Science, <http://ian.umces.edu/imagelibrary>).

Fleshy Macroalgal Cover Change

Extraction / habitat loss

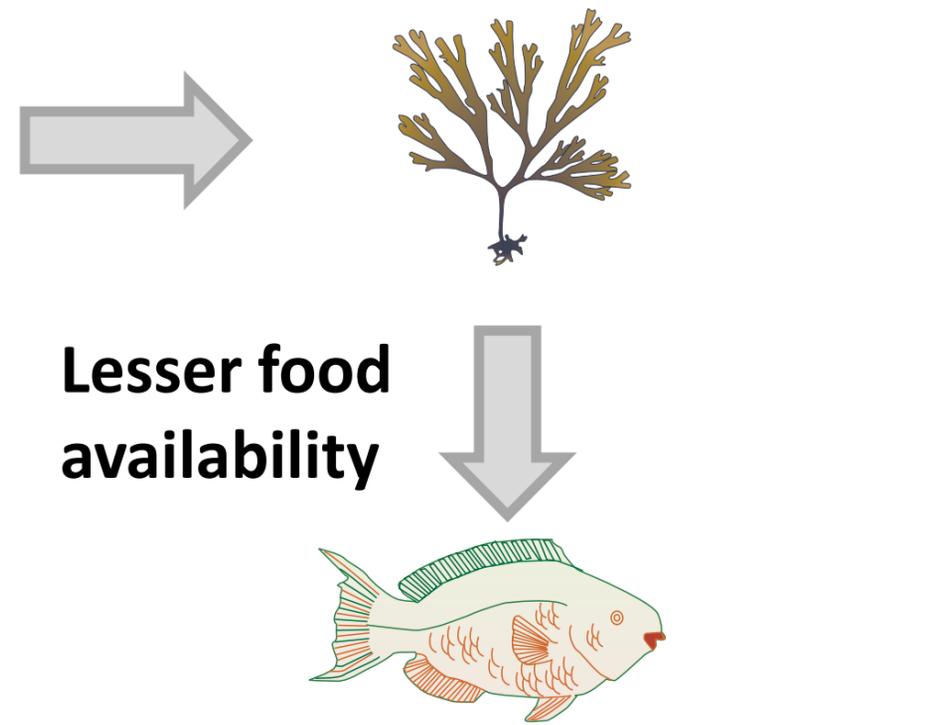

Algae-favourable conditions (e.g. nutrient enrichment)

Herbivorous Fish Biomass Change

Algae-adverse conditions

Protection / habitat availability

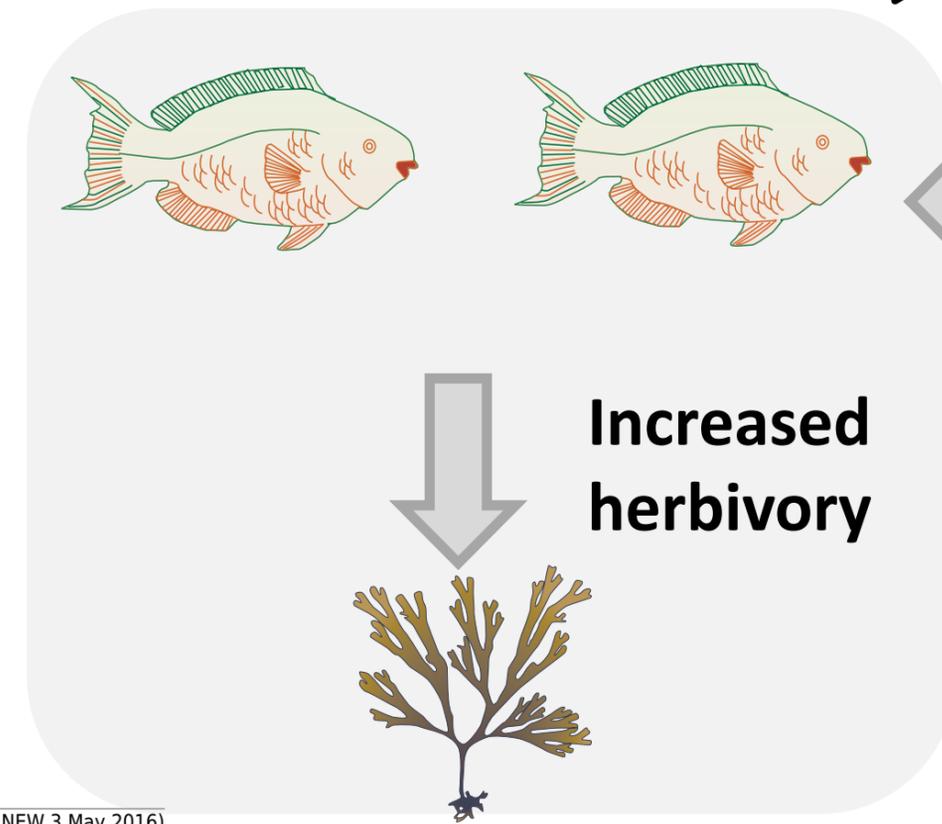

Figure 2 (on next page)

Temporal trend in mean herbivorous fish biomass and benthic fleshy macroalgal cover on the Mesoamerican Reef.

Mean (\pm s.e.m.) values are shown for all 43 sites surveyed repeatedly in each monitoring period (2005/2006, 2009/2010, 2011/2012 and 2013/2014). Similar trends were observed for all sites surveyed in consecutive monitoring periods (Fig. S1).

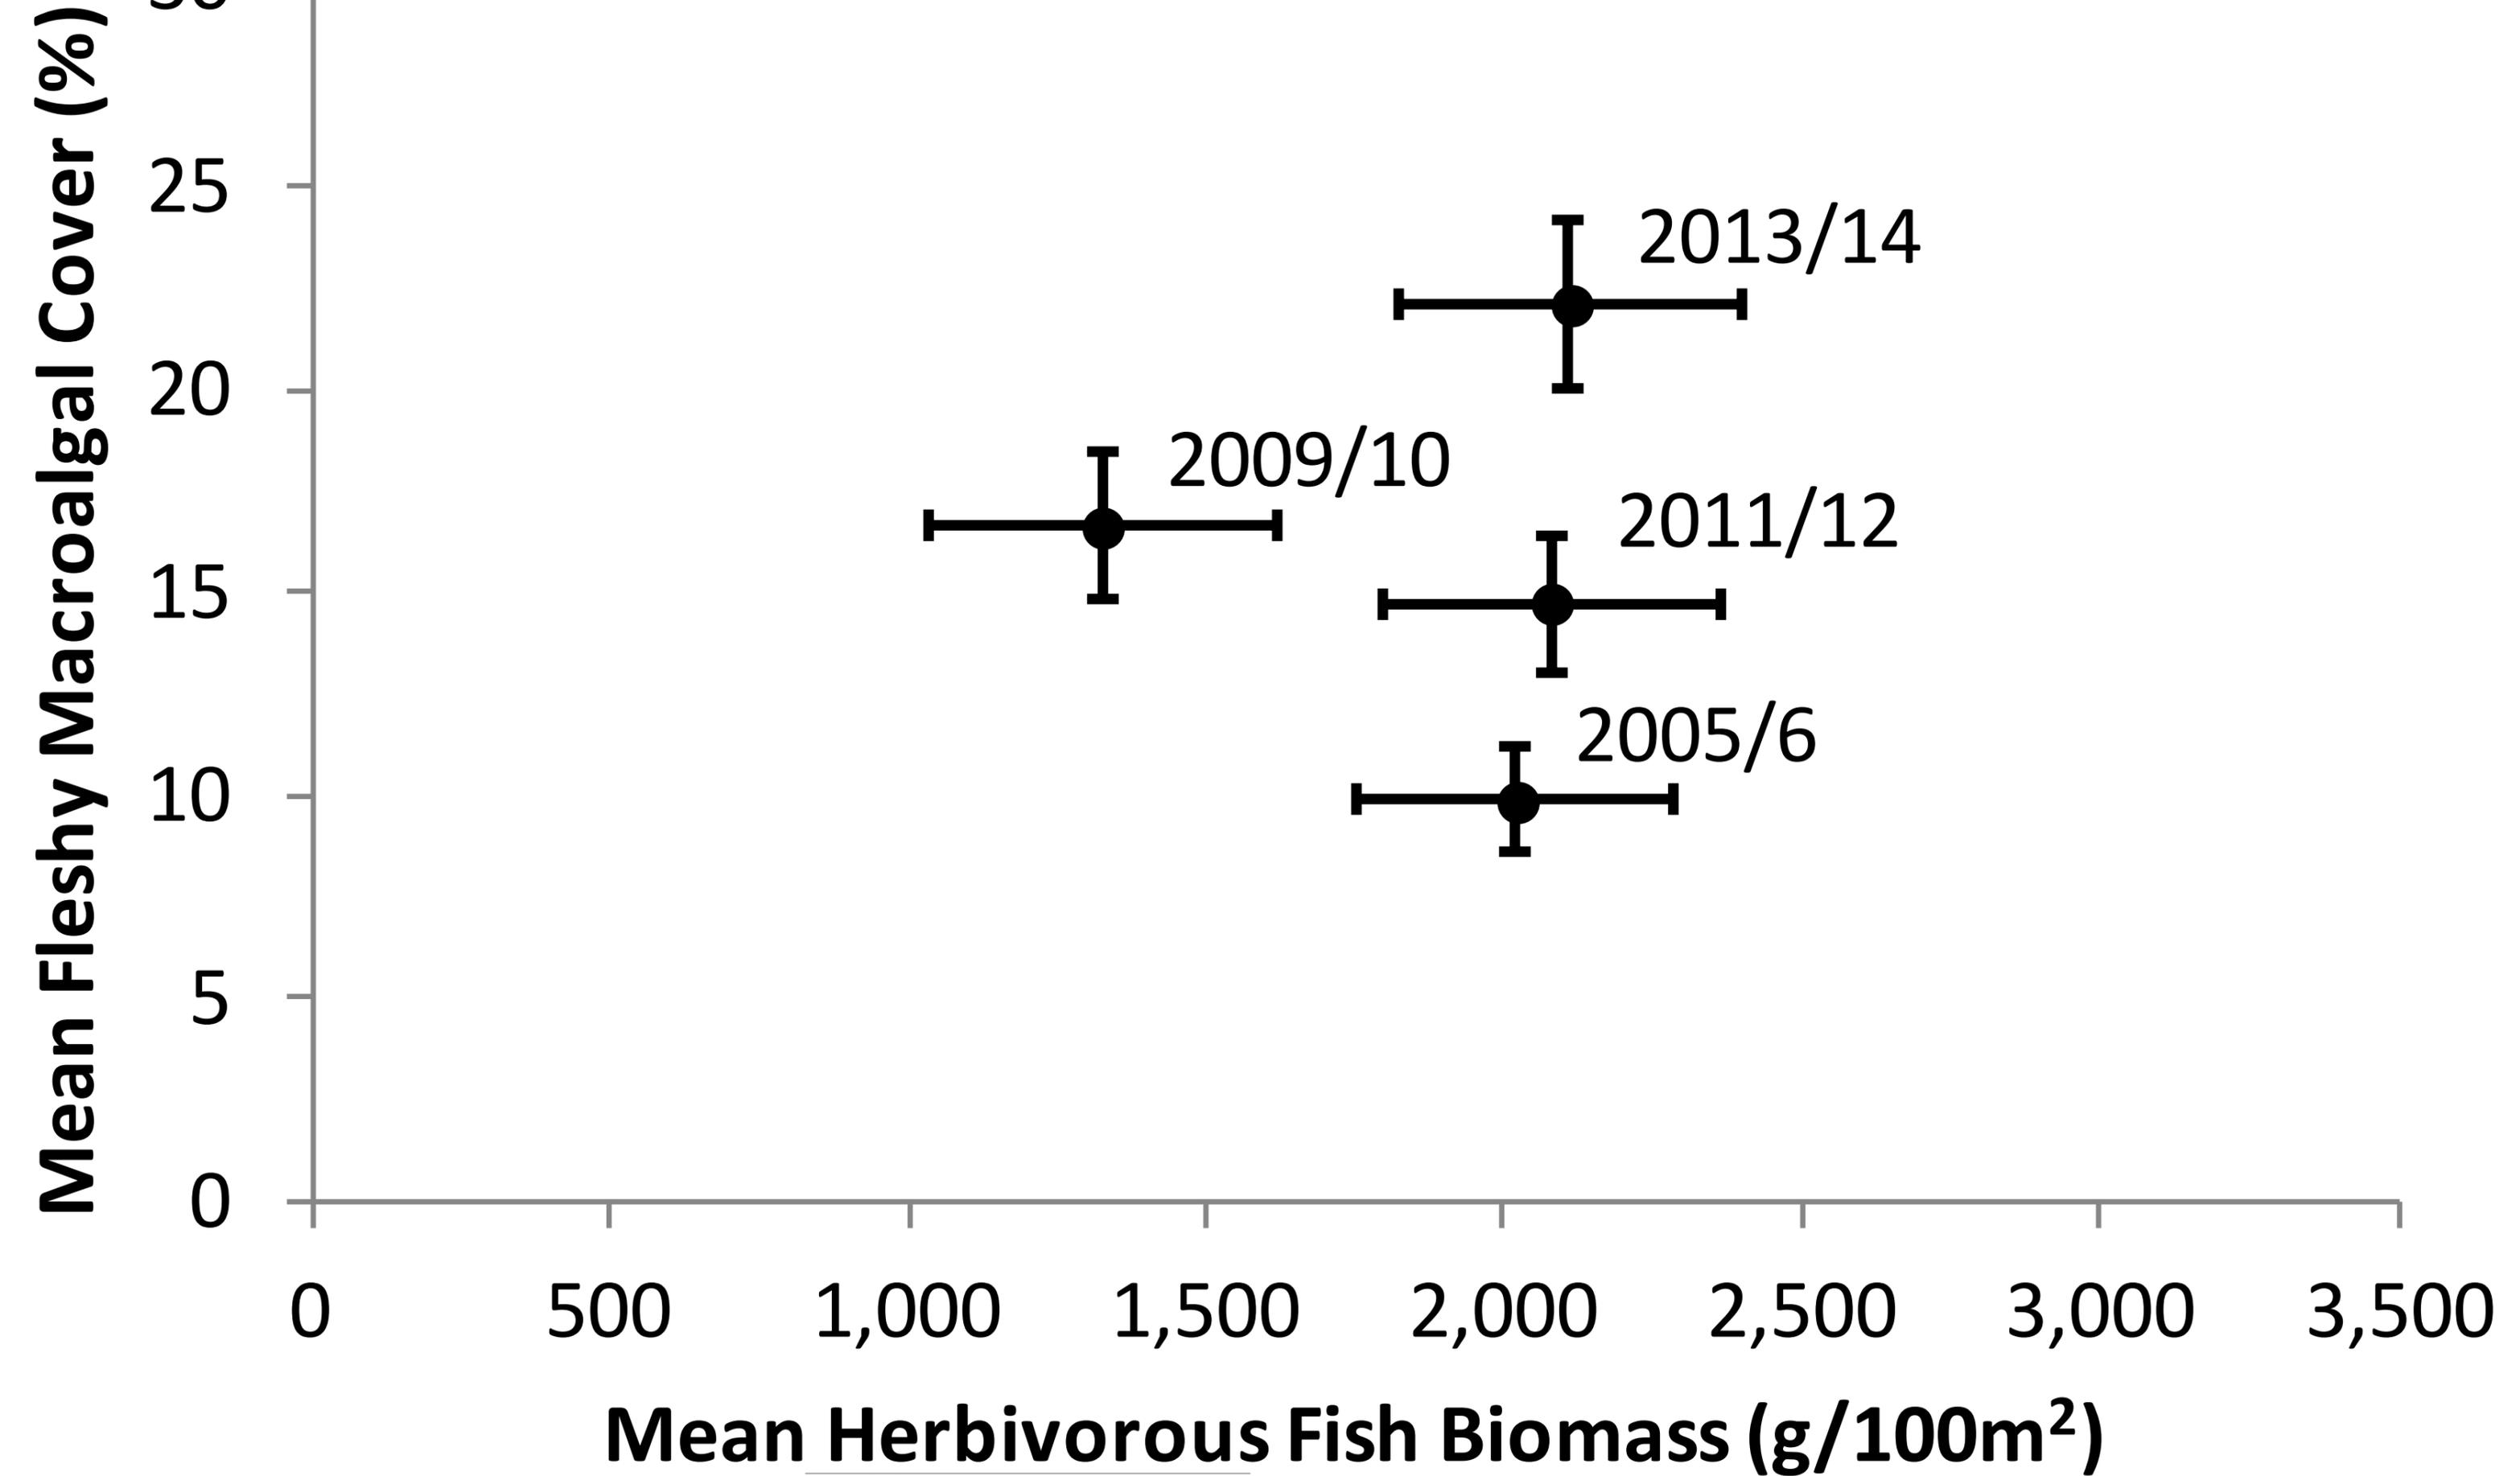

Figure 3(on next page)

Long-term herbivorous fish and benthic fleshy macroalgal cover trends on the Mesoamerican Reef.

Map and graphs indicating relationship between changes in overall and macroalgae-browsing herbivorous fish biomass and fleshy macroalgal cover from first (2005 or 2006) to last (2013 or 2014) year for all (85) long-term monitoring sites with ≥ 7 years' history. Map indicates Healthy Reef Initiative regions within countries and locates sites by the relationship between changes in herbivorous fish biomass and fleshy macroalgal cover (Kramer et al., 2015). Inset graphs separately indicate the relationship between changes in herbivorous fish biomass and fleshy macroalgal cover, and macroalgae-browsing herbivorous fish biomass and fleshy macroalgal cover. For inset graphs, each circle represents the sites for that quadrant and circle position reflects mean site-level annual geometric rates of change. Circle area represents proportion of sites in that quadrant (also labelled). All (85) sites with ≥ 7 years' of history are plotted in order to provide long-term trends, although the equivalent analysis for sites with ≥ 8 years' of history produced similar results (Fig. S2).

HRI Sites >=7 years history

- ★ Algae Increasing + Fish Increasing
- ★ Algae Increasing + Fish Decreasing
- ★ Algae Decreasing + Fish Increasing
- ★ Algae Decreasing + Fish Decreasing

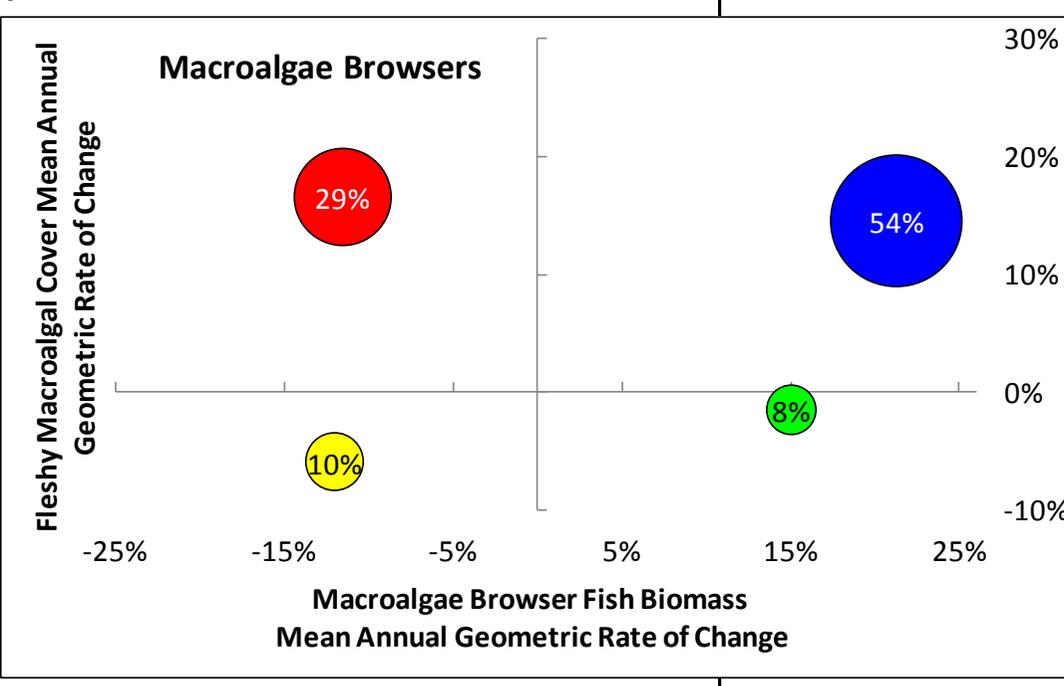

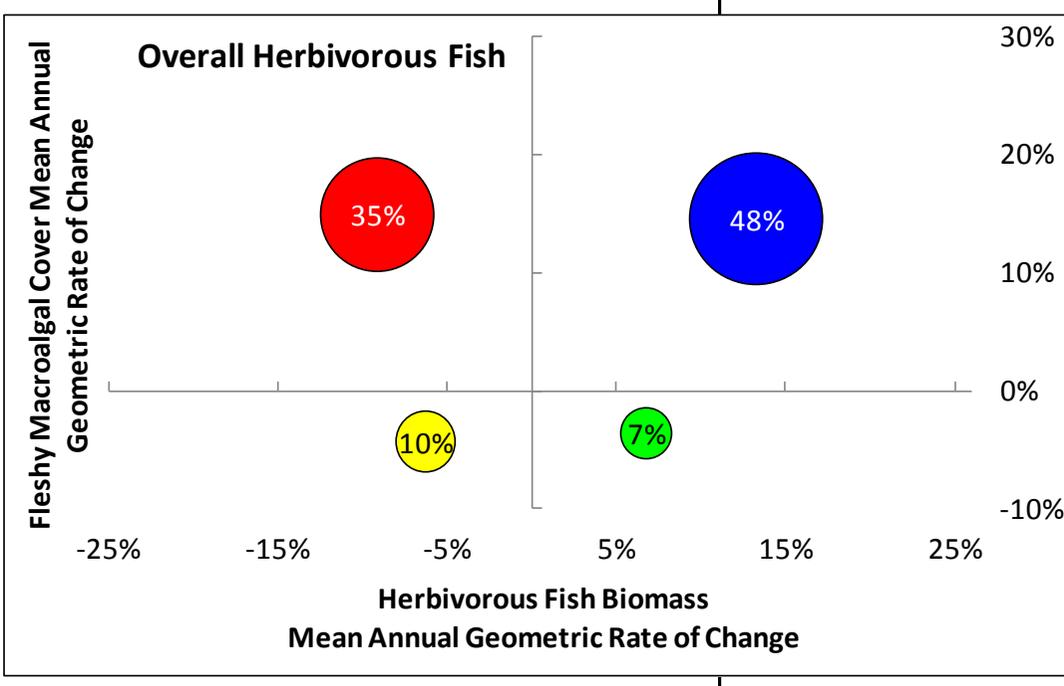

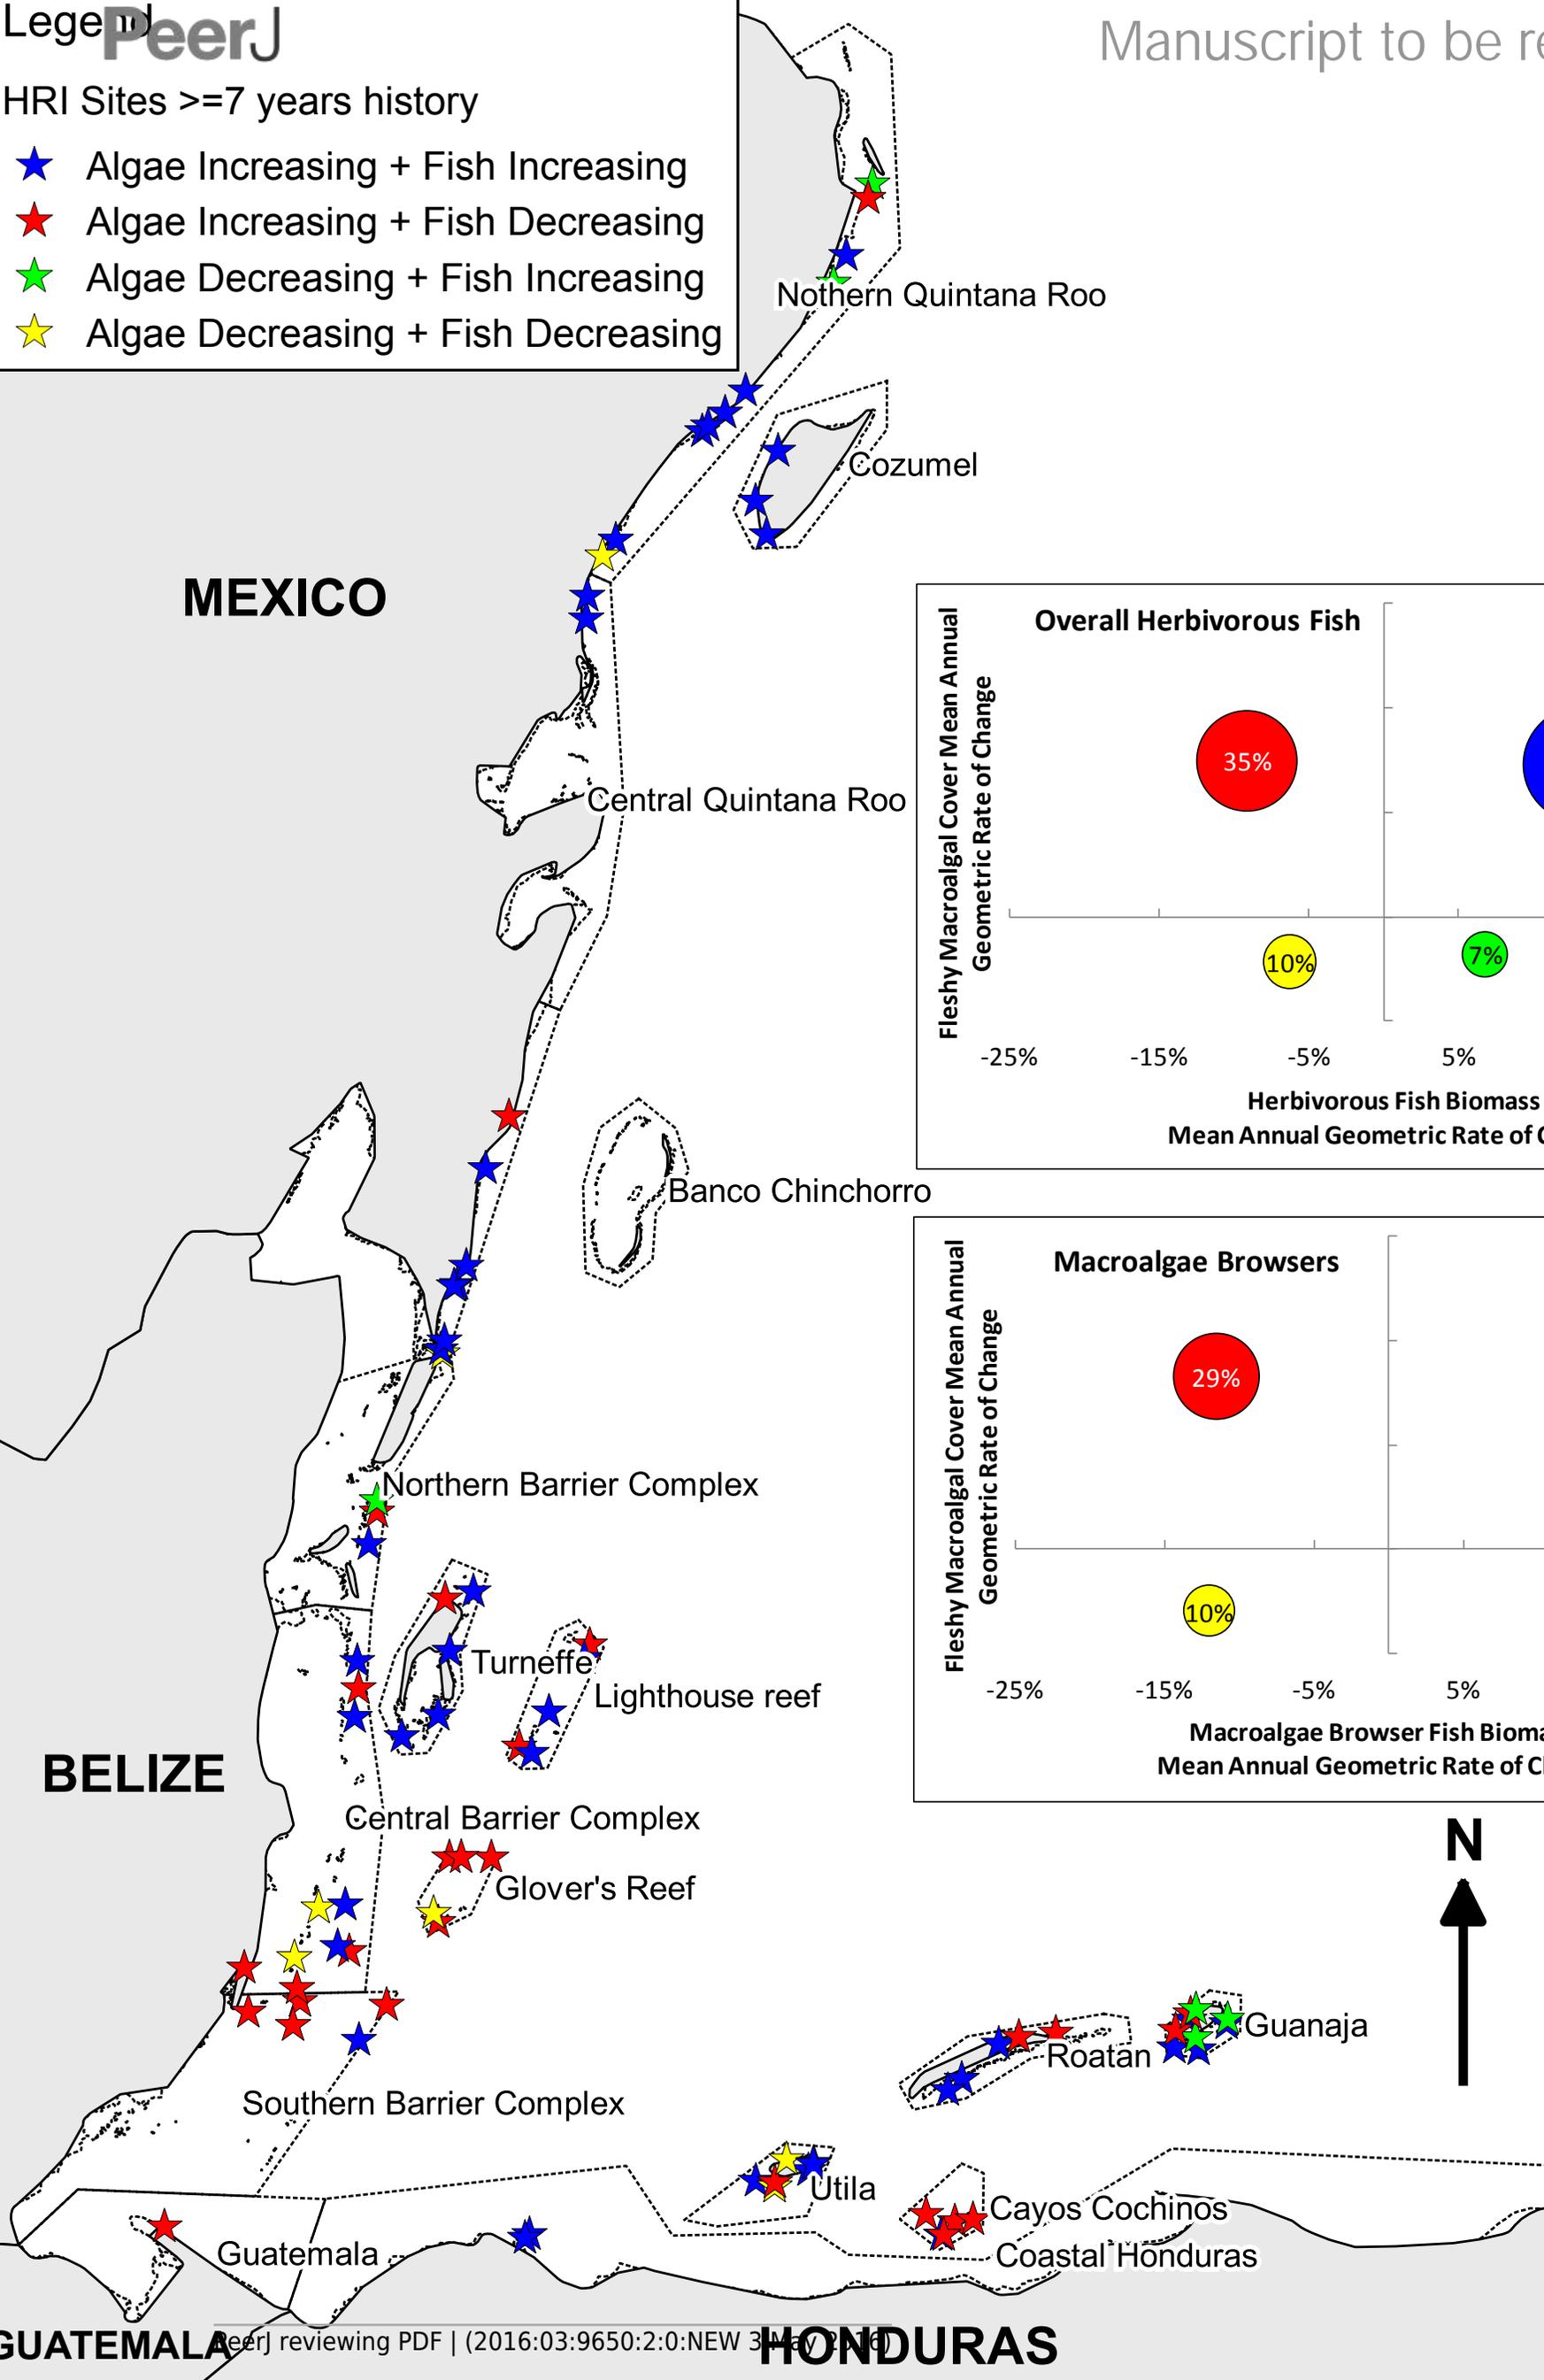

Figure 4(on next page)

Effect of initial herbivorous fish biomass on fleshy macroalgal cover on the Mesoamerican Reef.

A) Mean (\pm s.e.m.) benthic macroalgal cover in 2005/6 (green symbols) and 2013/14 (red symbols) by initial level of overall herbivorous fish biomass, for all (85) long-term monitoring sites. Sites divided into 10 categories based on initial overall herbivorous fish biomass deciles. B) Mean (\pm s.e.m.) benthic macroalgal cover in 2005/6 (green symbols) and 2013/14 (red symbols) by initial macroalgae browser biomass, for all (85) long-term monitoring sites. Sites divided into 10 categories based on initial macroalgae browser biomass deciles.

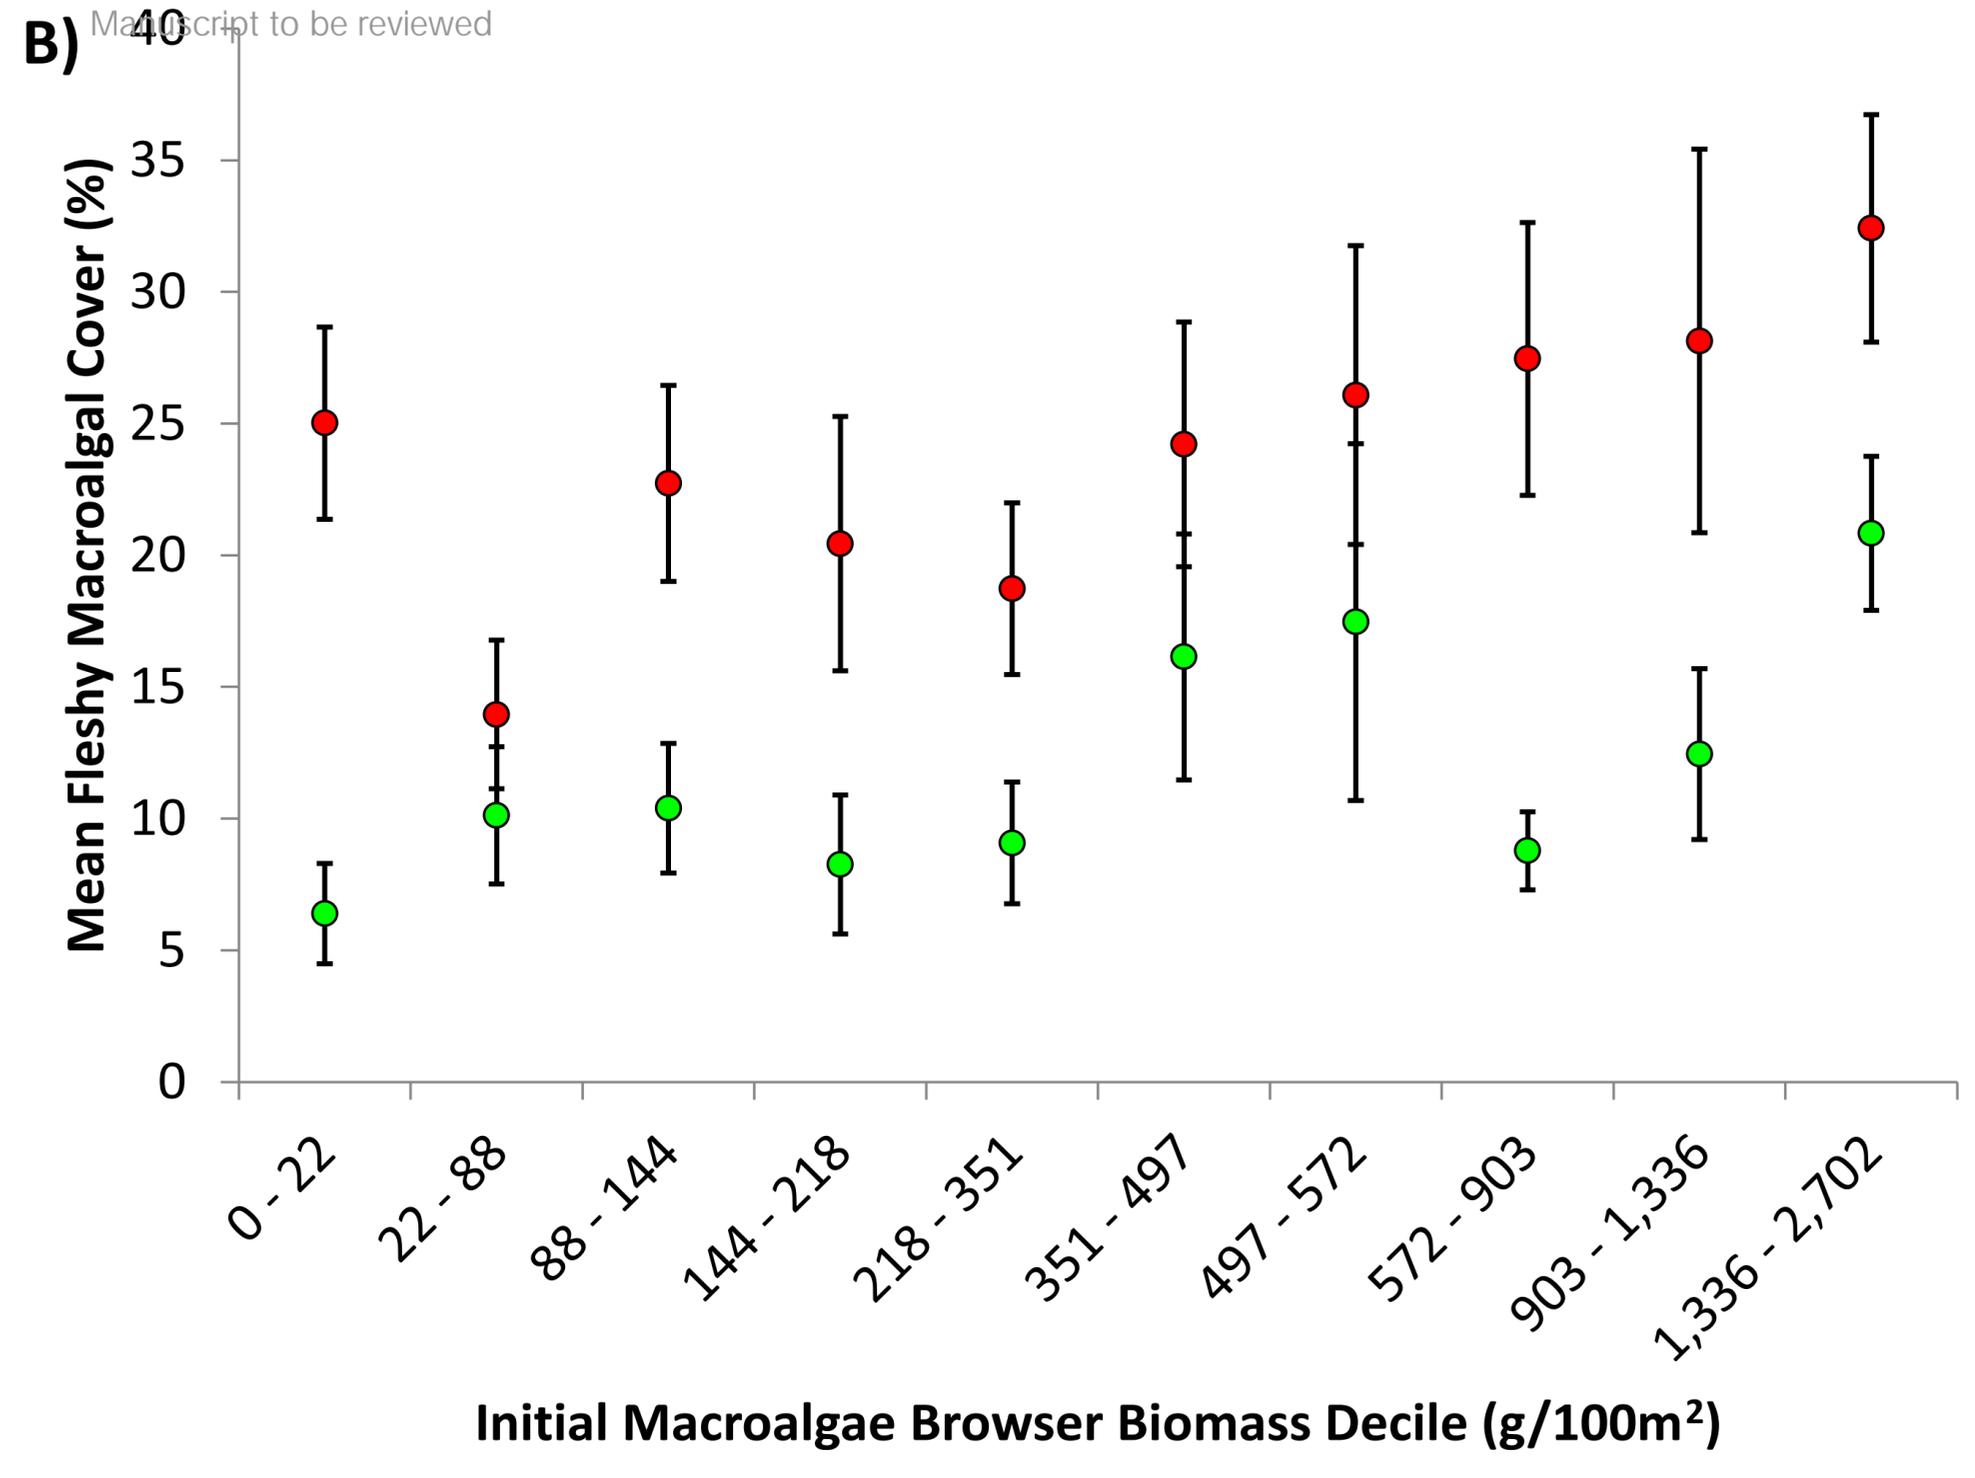

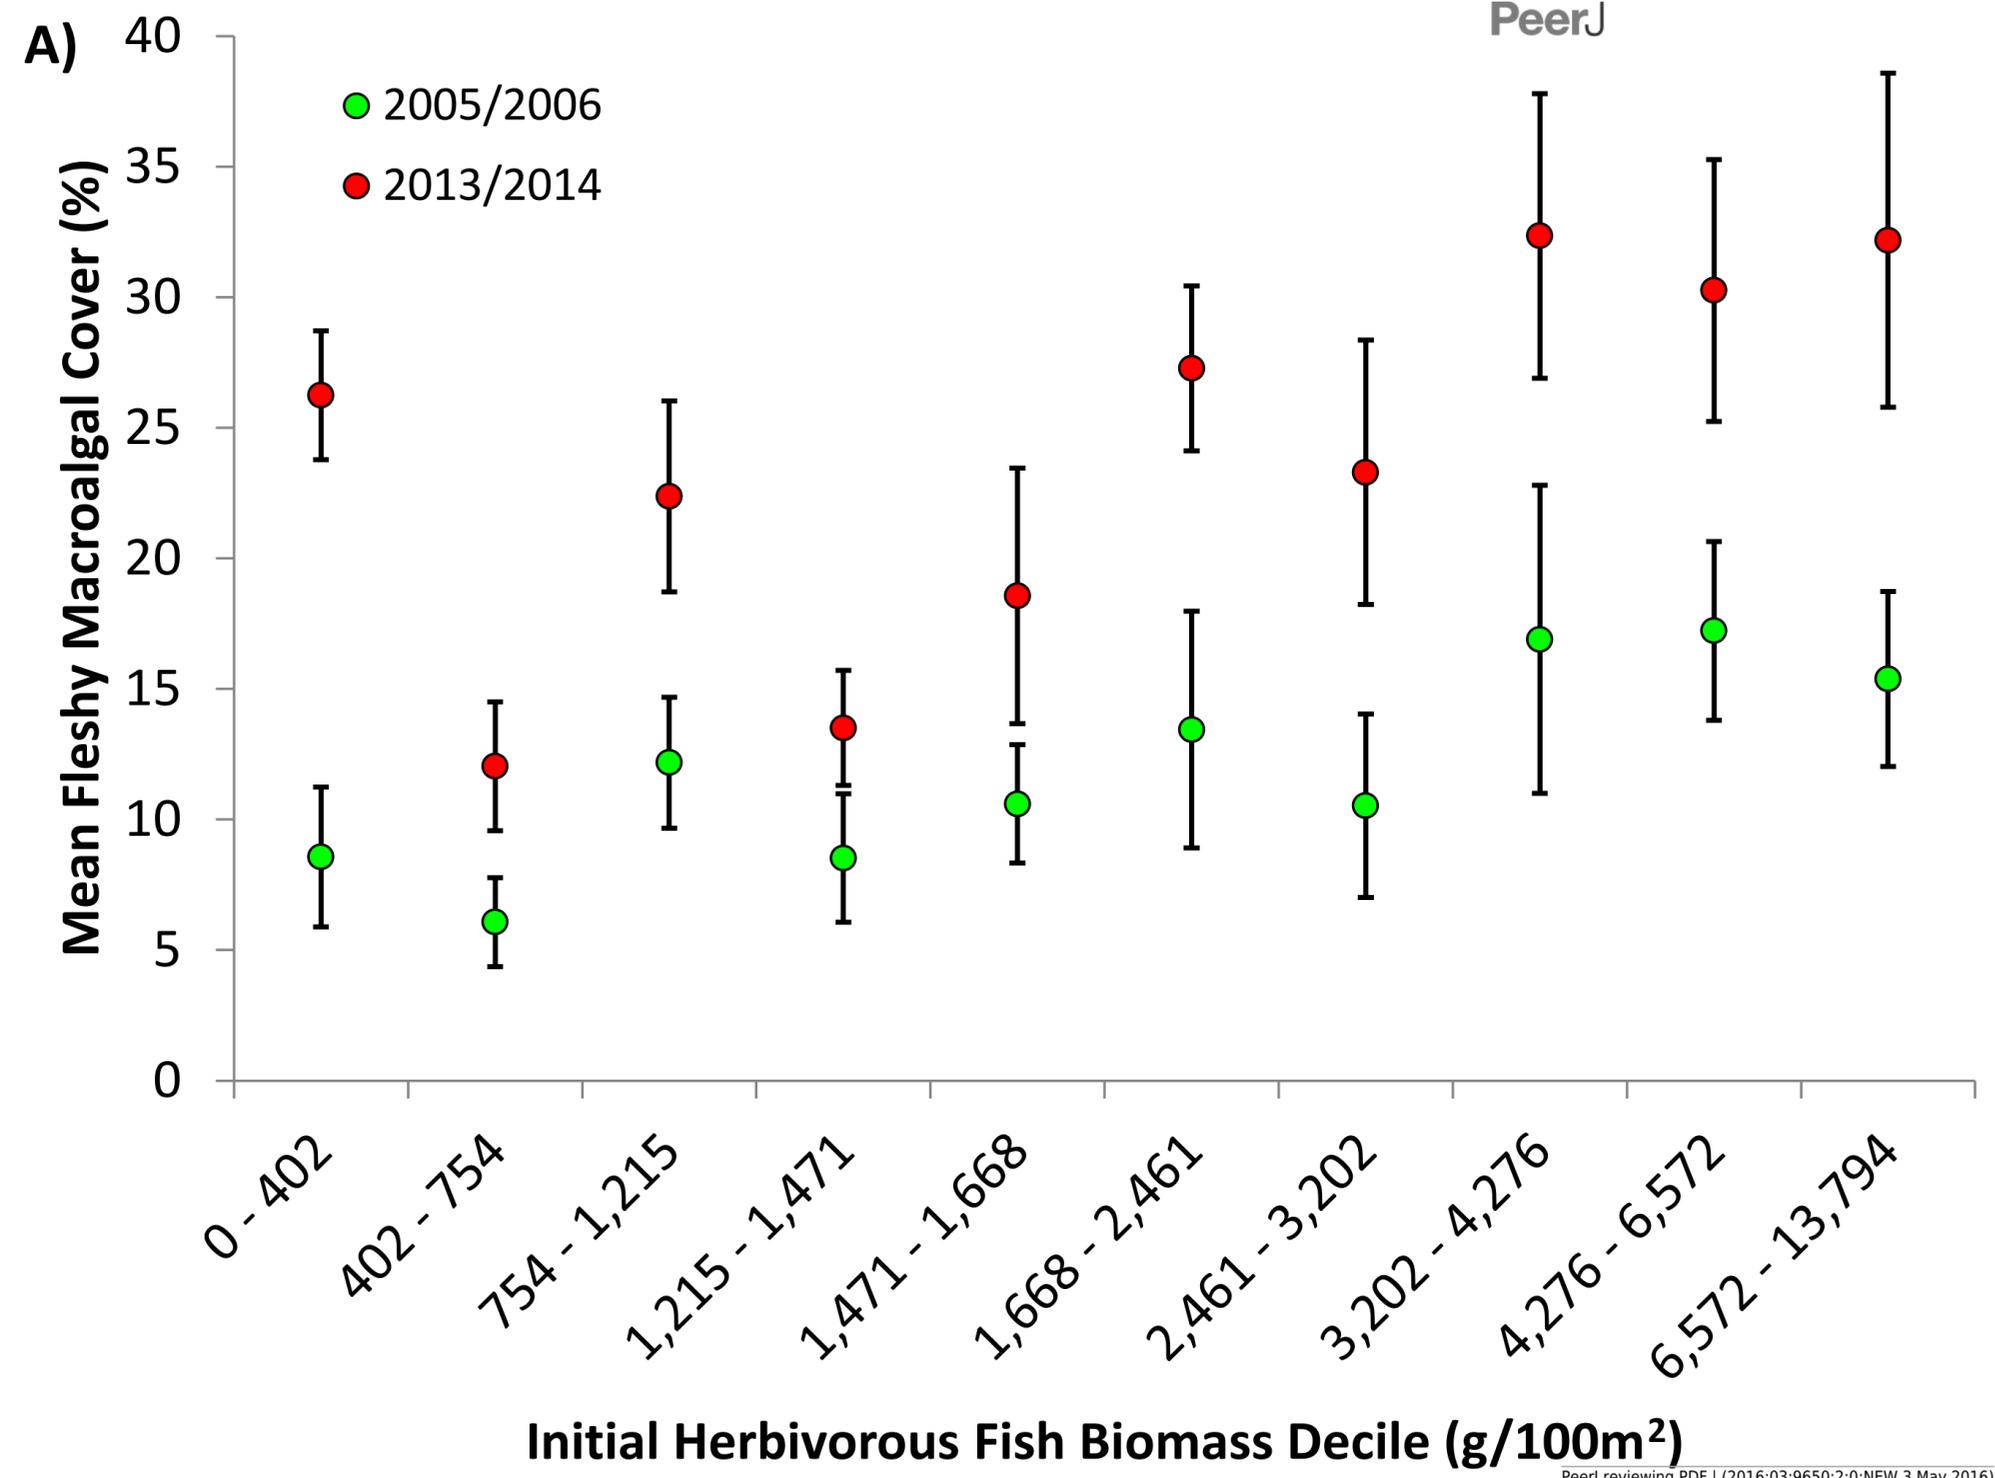

Figure 5 (on next page)

Effect of protection on herbivorous fish biomass and fleshy macroalgal cover on the Mesoamerican Reef.

Mean (\pm s.e.m.) herbivorous fish biomass and benthic macroalgal cover in 2005/6 (green symbols) and 2013/14 (red symbols) by level of protection, for all (85) long-term monitoring sites. Unprotected = sites outside Marine Protected Areas ($n = 26$), MPA = sites inside Marine Protected Areas but not within No Take Zones ($n = 47$), NTZ = sites within No Take Zones within Marine Protected Areas ($n = 12$).

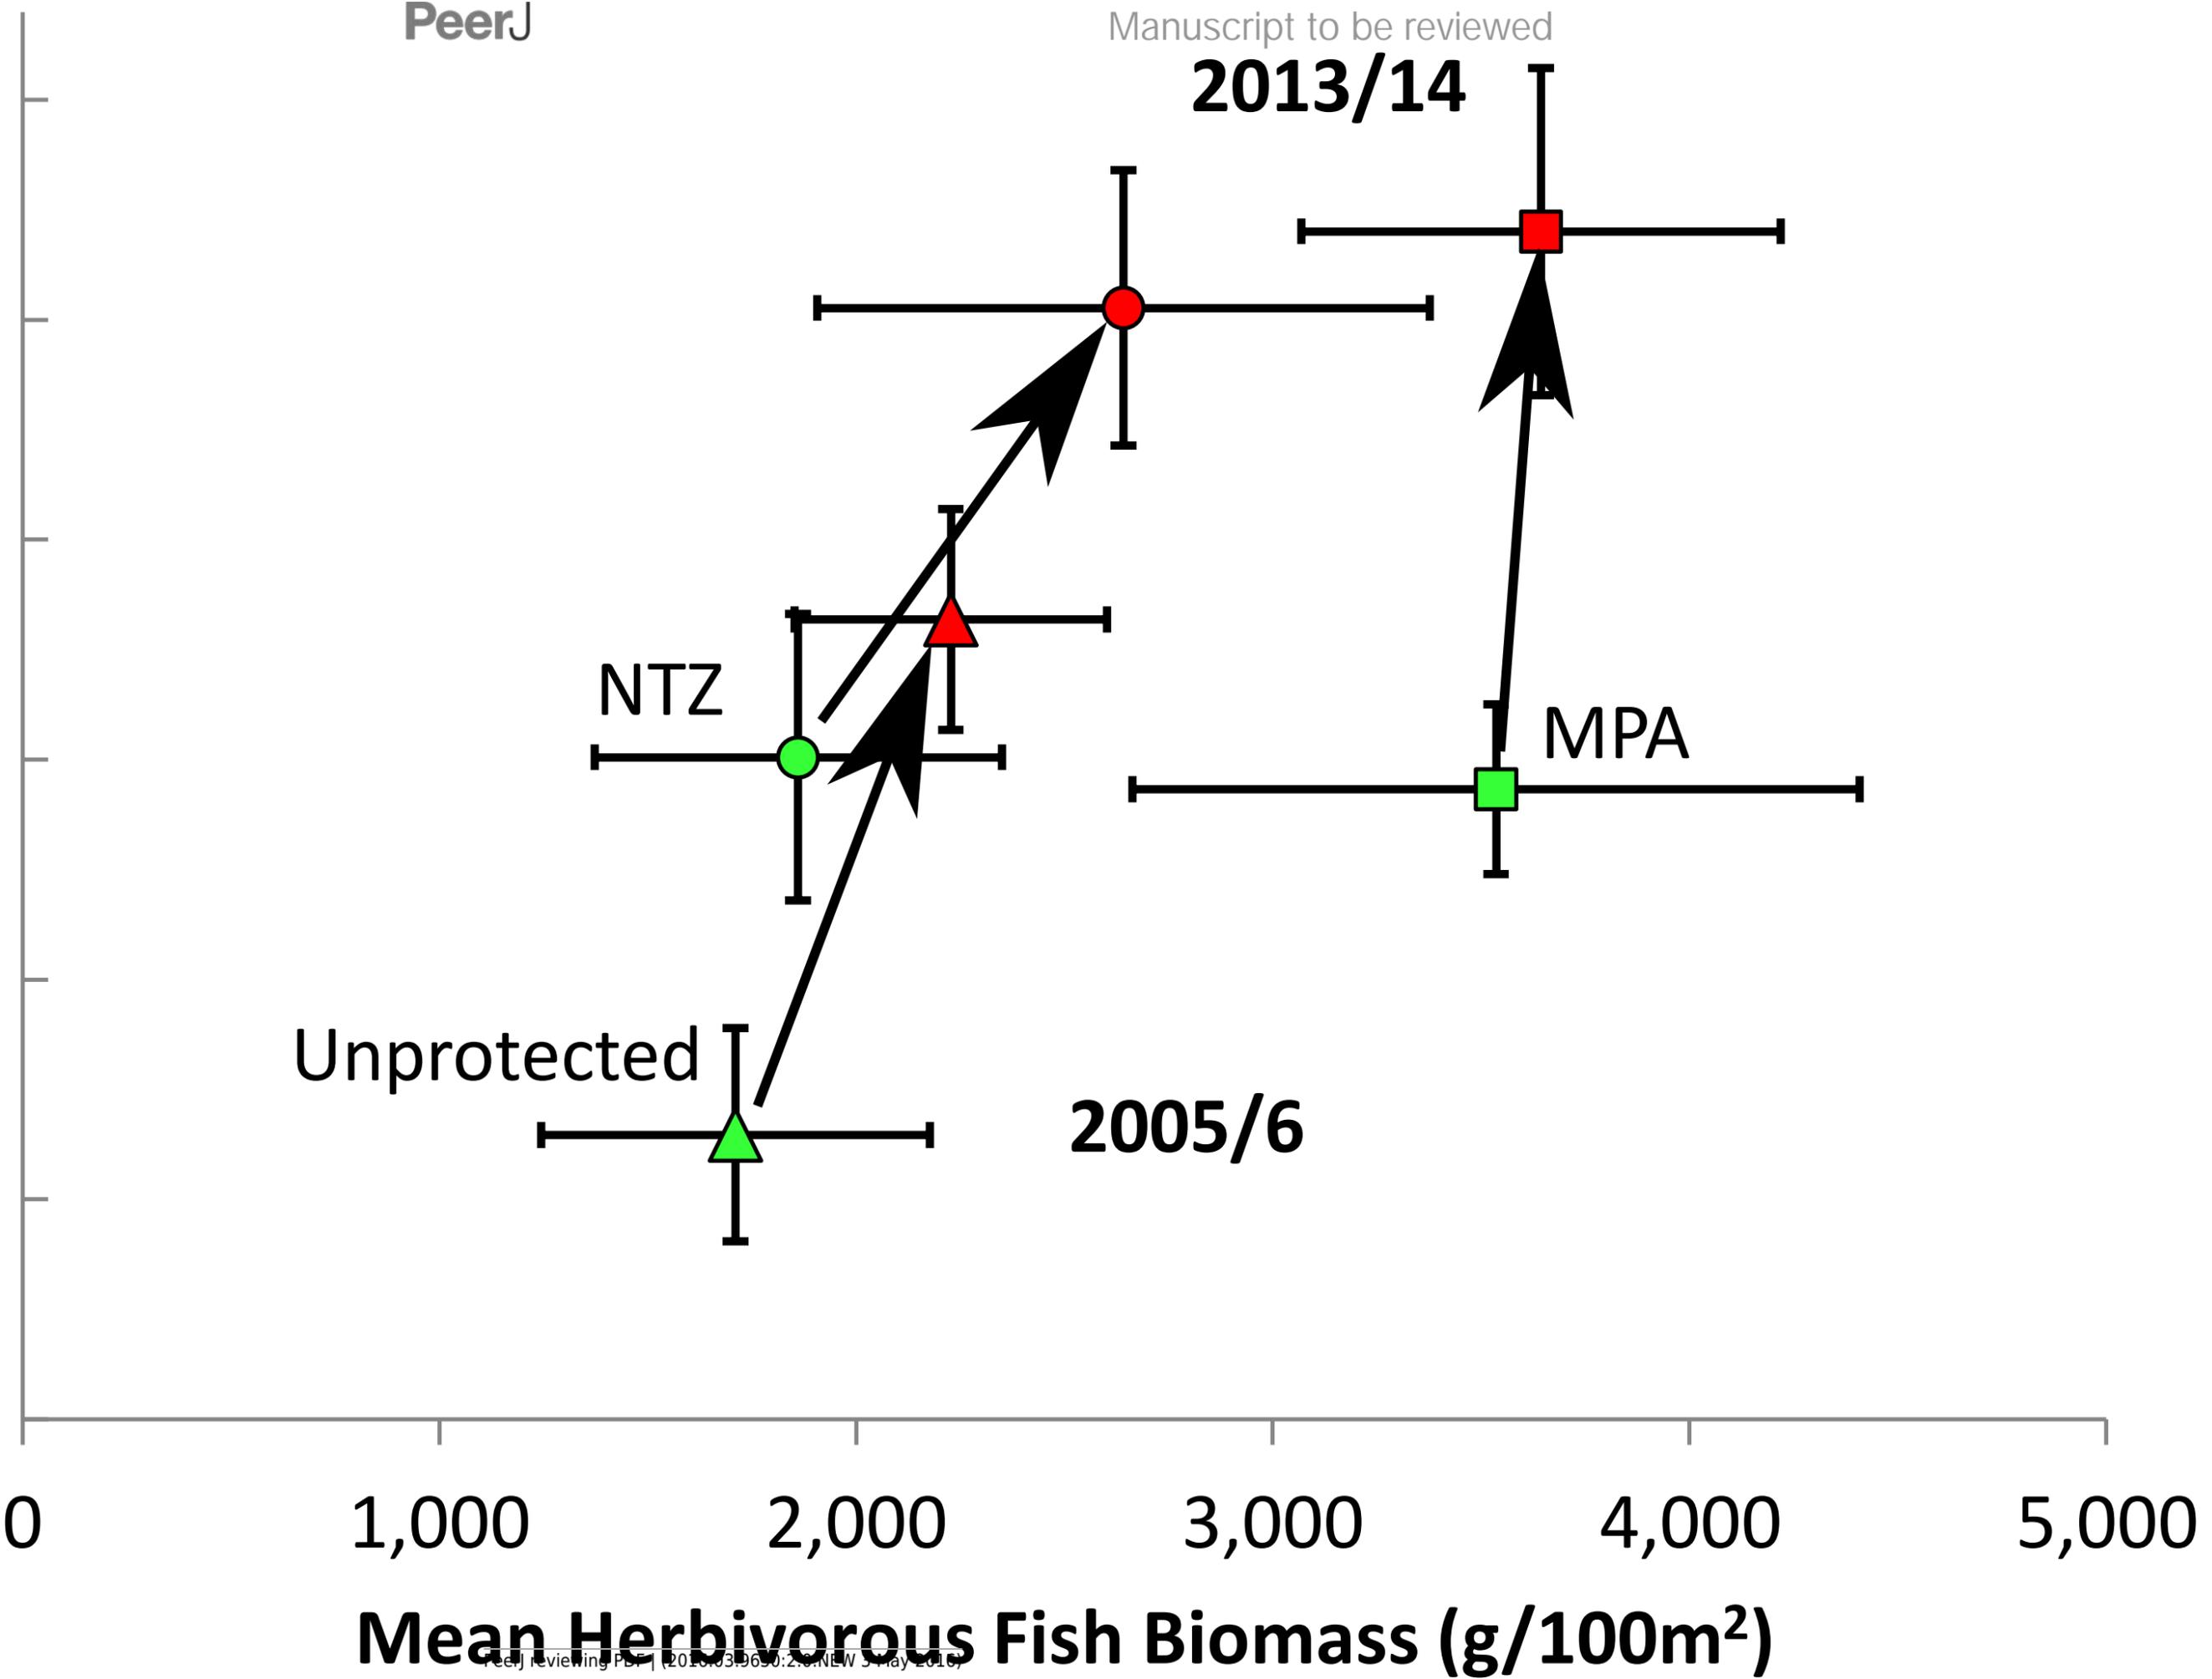

Figure 6(on next page)

Prediction of coral cover change on the Mesoamerican Reef.

Standardised regression coefficients for independent variables in AIC-selected optimum model of annual absolute change in hard coral cover from 2005/6 to 2013/14 for all long-term monitoring sites. MPA and NTZ are binary indicators of the location of sites within a Marine Protected Area or No Take Zone, respectively. Mexico and Honduras are binary indicators of the location of sites within those countries. Coefficients reflect the number of standard deviations change in the dependent variable for a one standard deviation increase in each independent variable, while controlling for all other independent variables. Error bars are coefficient standard errors. Significant variables (in non-standardised regression) are highlighted (***) 0.001 level, * 0.05 level).

Standardised Regression Coefficient
