Genetic markers of inflammation may not contribute to metabolic traits in Mexican children.

Neeti Vashi, Carolina Stryjecki, Jesus Peralta-Romero, Fernando Suarez, Jaime Gomez-Zamudio, Ana I. Burguete-Garcia, Miguel Cruz, David Meyre

Background. Low-grade chronic inflammation is a common feature of obesity and its cardio-metabolic complications. However, little is known about a possible causal role of inflammation in metabolic disorders. Mexico is among the countries with the highest obesity rates in the world and the admixed Mexican population is a relevant sample due to high levels of genetic diversity. **Method.** Here, we studied 1462 Mexican children recruited from Mexico City. Six genetic variants in 5 inflammation-related genes were genotyped: rs1137101 (*LEPR)*, rs7305618 (*HNF1A)*, rs1800629 (*TNFA*), rs1800896, rs1800871 (*IL-10)*, rs1862513 (*RETN)*. Ten continuous and eight binary traits were assessed. Linear and logistic regression models were used adjusting for age, sex, and recruitment centre. **Results.** We found that one SNP displayed a nominal evidence of association with a continuous trait: rs1800871 (*IL-10*) with LDL (beta = -0.068 ± 1.006, P = 0.01). Subsequently, we found one nominal association with a binary trait: rs7305618 (*HNF1A*) with family history of hypertension (odds-ratio = 1.389 [1.054-1.829], P = 0.02). However, no P-value passed the Bonferroni correction for multiple testing. **Discussion.** Our data in a Mexican children population are consistent with previous reports in European adults in failing to demonstrate an association between inflammation-associated SNPs and metabolic traits.

24   **Abstract**

25   **Background.** Low-grade chronic inflammation is a common feature of obesity and its cardio-

26   metabolic complications. However, little is known about a possible causal role of inflammation

27   in metabolic disorders. Mexico is among the countries with the highest obesity rates in the world

28   and the admixed Mexican population is a relevant sample due to high levels of genetic diversity.

29   **Method.** Here, we studied 1462 Mexican children recruited from Mexico City. Six genetic

30   variants in 5 inflammation-related genes were genotyped: rs1137101 (*LEPR*), rs7305618

31   (*HNF1A*), rs1800629 (*TNFA*), rs1800896, rs1800871 (*IL-10*), rs1862513 (*RETN*). Ten

32   continuous and eight binary traits were assessed. Linear and logistic regression models were used

33   adjusting for age, sex, and recruitment centre.

34   **Results.** We found that one SNP displayed a nominal evidence of association with a continuous

35   trait: rs1800871 (*IL-10*) with LDL (beta = -0.068 ± 1.006, P = 0.01). Subsequently, we found one

36   nominal association with a binary trait: rs7305618 (*HNF1A*) with family history of hypertension

37   (odds-ratio = 1.389 [1.054-1.829], P = 0.02). However, no P-value passed the Bonferroni

38   correction for multiple testing.

39   **Discussion.** Our data in a Mexican children population are consistent with previous reports in

40   European adults in failing to demonstrate an association between inflammation-associated SNPs

41   and metabolic traits.

46

47 **Introduction**

48   Obesity has increased rapidly in prevalence over the last 30 years causing a growing

49 public health burden at the worldwide level(Ogden et al. 2010). Obesity is no longer only a

50 concern for high income countries, but is escalating in developing countries as well(Hossain et

51 al. 2007). Even more concerning are the increasing rates of childhood obesity which have tripled

52 over the last 30 years(Ogden et al. 2010). In 2011-2012, the age-adjusted prevalence of obesity

53 in adults from the United States of America was 47.8%, 42.5%, 32.6% and 10.8% in non-

54 Hispanic Blacks, Hispanics, non-Hispanic White Americans, and non-Hispanic Asians,

55 respectively(Ogden et al. 2014). These discrepancies may be due to differences in diet, lifestyle,

56 socioeconomic status and access to health care across ethnic groups. However they may also

57 reflect differences in the genetic susceptibility to obesity and metabolic disorders as evidenced

58 by admixture studies(Norden-Krichmar et al. 2014). Twin studies have reported heritability

59 estimates between 47-90% for body mass index (BMI)(Elks et al. 2012). Eleven monogenic

60 genes and more than 140 polygenic loci have been identified to date, accounting for a modest

61 fraction of the heritability of obesity(Locke et al. 2015b; Yazdi et al. 2015). Obesity is associated

62 with cardio-metabolic complications (insulin resistance, type 2 diabetes, hypertension,

63 dyslipidemia, cardiovascular disease) that cluster into the so-called metabolic syndrome(Walker

64 et al. 2012). However, the relationship between obesity and associated complications is complex

65 as obesity does not always convert into a metabolic syndrome (Karelis et al. 2004; Kramer et al.

66 2013). Consistent with the phenotypic correlations seen in observational epidemiology, shared

67 genetic contributions between the components of the metabolic syndrome suggest that shared

68 molecular roots may be involved in the development of the metabolic syndrome(Avery et al.

69 2011; van Vliet-Ostaptchouk et al. 2013; Vattikuti et al. 2012).

70   Inflammation has recently been advocated as one of the pathophysiological mechanisms

71   linking obesity to other metabolic complications(Hotamisligil 2006). Inflammation can be

72   defined as a protective response of an organism to infection and injury. This operates through

73   initiating a healing process of pathogen killing and tissue repair to restore homeostasis at the

74   infected and/or damaged sites(Hotamisligil 2006). Normally, the inflammatory response to

75   harmful stimuli is short-lived and once the damage is removed or neutralized, the inflammation

76   is resolved through negative feedback mechanisms(Hotamisligil 2006). However, inflammatory

77   response that fails to regulate itself becomes chronic and is believed to set the stage for a broad

78   range of diseases(Hotamisligil 2006). Obesity and its cardio-metabolic complications are

79   associated with low-grade chronic inflammation, characterized by abnormal cytokine production,

80   activation of a network of inflammatory signal pathways, and new connective tissue

81   formation(Wellen & Hotamisligil 2005).

82   Genome-wide association and in a lesser extent candidate gene studies identified around

83   fifty common genetic variants associated with serum inflammatory biomarker levels (e.g. C-

84   reactive protein (CRP), soluble Intercellular Adhesion Molecule 1 (sICAM-1), interleukin-6 (IL-

85   6) or soluble P-selectin)(Raman et al. 2013). Researchers then used these recently discovered

86   genetic variants to determine whether this chronic inflammation is a cause of obesity and other

87   metabolic disorders, or a consequence of it. Overall, Mendelian randomization experiments

88   including gene variants in inflammation pathways did not evidence a causal role of inflammation

89   in obesity or type 2 diabetes(Brunner et al. 2008; Rafiq et al. 2008; Welsh et al. 2010) and

90   conflicting results about a causal link between inflammation and cardiovascular disease have

91   been reported(Brunner et al. 2008; Consortium 2012; Raman et al. 2013; Varbo et al. 2013). At

92   this stage, more research is needed to understand the role of inflammation in the development of

93   obesity and cardio-metabolic complications, particularly in non-European populations.

94   Metabolic syndrome is observed in childhood obesity, but can also develop in lean

95   children, suggesting that obesity is a marker for the syndrome, not a cause(Elliott et al. 2009).

96   Since obesity and its complications are associated with atherogenesis starting in childhood and

97   early adulthood(Tounian et al. 2001; Weiss et al. 2013), a better understanding of the molecular

98   mechanisms involved in the clustering of cardio-metabolic factors early in life may help to

99   develop more efficient programs to prevent the development of metabolic syndrome.

100   The Mexican population is characterized by a high prevalence of obesity and metabolic

101   complications. The 2012 National Health and Nutrition Survey indicates that 34.4% and 71.2%

102   of the Mexican children and adults respectively are overweight or obese(León-Mimila et al.

103   2013; Tounian et al. 2001). This ranks Mexico among the countries with the highest obesity rates

104   in the world(Barquera et al. 2009; León-Mimila et al. 2013). The prevalence of metabolic

105   syndrome (ATP III criteria) in children and adolescents living in Mexico was estimated to be

106   20% in 2006(Barquera et al. 2009; Castillo et al. 2007). Depending on the definitions used

107   (American Heart Association/ National Heart, Lung, and Blood Institute or the International

108   Diabetes Federation), the prevalence of metabolic syndrome among Mexican adults ranges from

109   59.7 to 68.7%(Castillo et al. 2007). This exceptionally high burden of obesity and metabolic

110   syndrome in the Mexican population is largely due to the rapid transition towards an

111   'obesogenic' environment characterized by a sedentary lifestyle, an increase in the consumption

112   of sugar-sweetened beverages coupled with the recent proliferation of fast food

113   restaurants(Isordia-Salas et al. 2011). However, the tremendous genetic variety and unique

114   genetic architecture of the admixed Mexican population may partly account for a higher

115 susceptibility to obesity and metabolic disturbances than in other populations(Rivera et al. 2002).

116 Mexican populations consist of Native individuals as well as individuals of European or African

117 descent(Rivera et al. 2002). The distributions and proportions of these three groups vary with

118 the region studied however evidence shows very few true Natives remain as virtually all native

119 groups show some degree of admixture, mainly with Europeans(Consortium 2014). Thus

120 studying the Mexican population gives insight into the disease mechanisms of a variety of races

121 due to the genetic diversity present in the population(Consortium 2014; Lisker 1996).

122 In this study, we assessed the association of 6 common genetic single nucleotide

123 polymorphisms (SNPs) in 5 inflammation-related genes with 10 continuous and 8 binary

124 metabolic traits in 1462 children from the Mexican population. Our data do not favor an

125 association between inflammatory processes and the development of metabolic complications.

126 **Methods**

127 **Study Participants**

128 A total of 1462 unrelated children aged 6-14 having both genetic and phenotypic data available

129 were included in this study. Children were randomly selected to participate in a cross-sectional

130 study from four schools in Mexico City between July 2011 and July 2012. Anthropometric traits

131 were assessed by a trained pediatrician. Blood samples were collected for biochemical

132 measurements and DNA extraction. Information regarding family history of type 2 diabetes,

133 obesity and hypertension was obtained via questionnaires. The study protocol was approved by

134 the Mexican Social Security Institute National Committee and the Ethical Committee Board and

135 all experiments were performed in accordance with relevant guidelines and regulations. Informed

136 consent was obtained from both parents and the child.

137 **Genotyping**

138   Genomic DNA was extracted from peripheral blood using the FLEX STAR Autogen platform

139   (Holliston, Massachusetts US). The genotyping was performed using the TaqMan OpenArray

140   Real-Time PCR System (Life Technologies, Carlsbad, US), following the manufacturer's

141   instructions. We selected 6 SNPs in or near 5 genes that displayed redundant associations with

142   inflammation-related traits in literature: rs1137101 (leptin receptor (*LEPR)*), rs7305618

143   (hepatocyte nuclear factor 1 alpha (*HNF1A)*), rs1800629 (tumor necrosis factor alpha (*TNFA)*),

144   rs1800896, rs1800871 (interleukin-10 (*IL-10)*), rs1862513 (resistin (*RETN)*) (Kilpelainen et al.

145   2010; Ortega et al. 2014; Raman et al. 2013; Wang et al. 2011). The 6 SNPs showed no deviation

146   from Hardy-Weinberg Equilibrium ($0.22 \leq P \leq 0.76$). The call rate for each of the 6 SNPs was

147   comprised between 94.6 and 100 % (Supplementary Table 1). The two SNPs rs1800896 and

148   rs1800871 in *IL-10* display modest linkage disequilibrium in the Mexican children study sample

149   (r2 value = 0.239).

150   **Phenotyping**

151   All participants were weighed using a digital scale (Seca, Hamburg, Germany). Height was

152   measured with a portable stadiometer (Seca 225, Hamburg, Germany). Body mass index was

153   calculated as weight (kg) / (height $(m)^2$) and classified as underweight, normal weight,

154   overweight, obese according to the Centers for Disease Control and Prevention CDC 2000

155   references. Waist circumference (WC) and hip circumference (HC) were measured at the

156   midpoint between the lowest rib and the iliac crest at the top of the iliac crest respectively, after a

157   normal exhalation with children in the standing position. Systolic and diastolic blood pressure

158   (SBP and DBP) were measured using a mercurial sphygmomanometer (ALPK2, Tokyo, Japan).

159   Blood pressure readings were taken for each participant twice on the right arm in a sitting

160   position with a 5 minute rest between each measurement and the mean of the two readings was

161   determined. Hypertension was defined as average measured blood pressure above the American

162   Heart Association's recommendations (systolic ≥ 140 mmHg or diastolic ≥ 90 mmHg). Blood

163   samples were obtained following a 12 hour fast and were analyzed for fasting glucose, total

164   cholesterol (TC), HDL-cholesterol (HDL), LDL-cholesterol (LDL) and triglycerides (TG) using

165   the ILab 350 Clinical Chemistry System (Instrumentation Laboratory IL. Barcelona Spain).

166   Insulin (IU) was measured by chemiluminescence (IMMULITE, Siemens, USA). The 2003

167   ADA criteria for fasting plasma glucose (FPG) were used to classify children as normal (FPG <

168   5.6 mmol/L), as having impaired fasting glucose (IFG; FPG 5.6- 6.9 mmol/L), or as having T2D

169   (FPG > 7.0 mmol/L)(Lisker et al. 1996). Subjects with IFG or T2D were considered as having

170   hyperglycemia. Dyslipidemia was defined as fasting triglycerides ≥ 100 mg/dL (0-9 years of age)

171   or triglycerides ≥ 130 mg/dL (10-19 years of age) and/or HDL-C < 35 mg/dL and/or LDL-C ≥

172   130 mg/dL, according to current recommendations(Kalra et al. 2009). Information regarding

173   family history of type 2 diabetes, overweight / obesity, and hypertension was obtained via

174   questionnaires.

175   **Statistical Analyses**

176   Statistical analyses were performed using SPSS (version 20). We assessed the power of

177   our sample using QUANTO software version 1.2.4 (University of Southern California, Los

178   Angeles, CA, USA). Non-biological outlier data were discarded. Due to the risk of blood

179   hemolysis, fasting insulin values < 1 mIU/l were discarded from the study. The normal

180   distribution of continuous variables was tested using the Kolmogorov-Smirnov test. All traits of

181   interest deviated significantly from normality. Logarithmic transformations corrected the lack of

182   normality for fasting insulin, improved the distribution of six traits (BMI, waist and hip

183   circumference, waist to hip ratio, total cholesterol, triglycerides,) despite still deviating from

184   normality, and did not improve the distribution of fasting glucose, HDL and LDL cholesterol.

185   Linear regression models were used to examine the association between the SNPs and metabolic

186   traits. These tests were adjusted for sex, age and the recruitment centre. Genetic association

187   studies were performed under an additive mode of inheritance for 5 out of 6 SNPs and the effect

188   allele was the minor allele. Because only one AA homozygous carrier was identified for

189   rs1800629 (*TNFA*), we used a dominant model instead. Two-sided P <0.05 before Bonferroni

190   correction were considered as nominally significant. After applying a Bonferroni's correction for

191   multiple testing (18 binary / continuous traits x 6 SNPs), P-values < 4.6×10^{-4} (0.05/108) was

192   considered as significant.

193   **Results**

194   **Characteristics of the Mexican children population**

195   The main anthropometric and biological characteristics of the 1462 Mexican children are

196   summarized in Table 1. Fifty-three percent of the population were males. Children exhibited an

197   average age and BMI of 9.24 ± 2.07 years and 19.65 ± 4.20 kg/m^2, respectively. Using the

198   Centers for Disease Control and Prevention 2000 references, 1.4% of the children were

199   underweight, 49.4% were normal weight, 21.3% were overweight and 27.9% were obese.

200   Additionally, 1.5, 3.1 and 34.9% of children displayed hypertension, hyperglycemia, and

201   dyslipidemia, respectively. A family history of overweight / obesity, type 2 diabetes or

202   hypertension was reported for 53.0, 12.0 and 16.3 % of children, respectively (Table 1). The

203   sample size was similar for all traits except fasting insulin (data available in 78.5% of subjects)

204   due to the phenomenon of blood hemolysis.

205   **Association between genetic markers of inflammation and continuous metabolic traits**

206 The associations between the 6 genetic variants of inflammation and 10 continuous metabolic

207 traits are reported in Table 2. Only one SNP displayed a nominal evidence of association:

208 rs1800871 (*IL-10*) with LDL (beta = -0.068 ± 1.006, P = 0.010).

209 **Association between genetic markers of inflammation and binary metabolic traits**

210 The associations between the 6 genetic markers of inflammation and 8 binary metabolic traits are

211 reported in Table 3. One nominally significant association was found: rs7305618 (*HNF1A*) with

212 family history of hypertension (1.389 [1.054-1.829] p=0.020). No P-value was significant after

213 Bonferroni correction for multiple testing.

214 **Discussion**

215 In the present study, we assessed the association of 6 common genetic variants in 5

216 inflammation-related genes with 10 continuous and 8 binary metabolic traits in 1462 children

217 from the Mexican population. We found one nominal associations between a genetic variant and

218 the continuous traits. Subsequently, we only found two nominal associations between genetic

219 variants and continuous / binary metabolic traits. No P-value resisted to a Bonferroni correction

220 for multiple testing (P < 4.6 x 10^{-4}). The number of significant P-values obtained in this

221 experiment at the 0.05 alpha level was less than the number of associations expected by chance

222 (~ 5). Overall, our negative results do not suggest an association between inflammation-

223 associated SNPs and metabolic traits in Mexican children. This is in line with previous reports

224 from literature, that at best suggest a possible association between inflammation and

225 cardiovascular events(Elliott et al. 2009; Fall et al. 2015; Hingorani 2012; Rafiq et al. 2008;

226 Raman et al. 2013; Varbo et al. 2013; Welsh et al. 2010). Our findings are also supported by the

227 discoveries of hypothesis-free genome-wide association studies for metabolic traits that show a

228 limited overlap with genetic markers of inflammation to date(Ehret et al. 2011; Locke et al.

229 2015a; Mahajan et al. 2014; Raman et al. 2013; Willer et al. 2013).

230 Power calculations on the standard trait BMI indicate that we only have a fair likelihood to

231 identify associations at the nominal and Bonferroni corrected levels (Supplementary figure 1 and

232 2). Therefore, we cannot totally exclude that the nominal associations reported here are actually

233 true subtle positive results. For instance, we found that the rs7305618 SNP near *HNF1A* was

234 nominally associated with a family history of hypertension. The *HNF1A* gene encodes hepatic

235 nuclear factor 1 alpha (HNF1a), a transcription factor expressed in the liver, pancreas, gut and

236 kidney(Ban et al. 2002). Mutations in the *HNF1A* gene account for approximately 70% of cases

237 of maturity onset diabetes of the young (MODY)(VaxiHaire et al. 1995). *HNF1A* mutation

238 carriers display a distinct hypertension status(Owen et al. 2002). HNF-1a is an essential

239 transcription factor in nephron development and rare coding loss-of-function mutations in

240 *HNF1A* lead to renal malformations and renal dysfunction in mice and humans(Bingham et al.

241 2000; Malecki et al. 2005; Pontoglio et al. 1996). Testing the associations of the *HNF1A*

242 rs7305618 SNP with adult hypertension in independent studies may therefore be relevant.

243 Similarly, the association of rs1800871 (*IL-10*) with LDL is indirectly supported by previous

244 reports in literature. While the adenovirus-mediated gene transfer of interleukin-10 in an

245 hyperlipidemic LDLr knock-out mouse model results in lowering of cholesterol levels and

246 attenuation of atherogenesis, interleukin-10 deficiency in a distinct hyperlipidemic

247 apolipoprotein E knock-out mouse model leads to an increase of LDL and

248 atherosclerosis(Caligiuri et al. 2003; Von Der Thusen et al. 2001). However, further studies in

249 independent Mexican children populations are needed to confirm these nominal associations. No

250 study in children has assessed the association of genetic markers of inflammation with metabolic

251 traits, making any comparisons to our data difficult.

252 Our study has several strengths. It is the first to explore the associations of a representative list of

253 genetic variants related to inflammation with metabolic traits in children and in the Mexican

254 population. Additionally, we assessed diverse metabolic traits including both continuous and

255 binary variables. Limitations of the study include an under-optimal statistical power to identify

256 even substantial genetic effects, especially after corrections for multiple tests (Supplementary

257 Figure 1 and 2). Additionally, the list of SNPs related to inflammation that we assessed did not

258 include the more recent GWAS discoveries for inflammation traits(Raman et al. 2013). We did

259 not assess the association of these SNPs with intermediate inflammatory serum markers (e.g.

260 CRP, sICAM-1, IL-6, soluble P-selectin). Finally, using ancestry informative markers to adjust

261 for potential population stratification was not performed in this study.

262 In conclusion, the association study of 6 SNPs in 5 inflammation-related genes with 10

263 continuous and 8 binary cardio-metabolic traits in 1462 Mexican children does not suggest an

264 association between inflammation-associated SNPs, obesity and its metabolic complications.

265 Additional studies with larger sample sizes, a more exhaustive panel of SNPs and the availability

266 of both inflammatory serum biomarkers and clinical traits in Mexican and other populations will

267 provide a more definitive answer to this important research topic.

615   **Table 1. Characteristics of the Mexican children population.**

Trait	Mean ± Standard Deviation	Sample Size
Sex (% Male/Female)	53.0/47.0	775/687
Age (Years)	9.24 ± 2.07	1462
BMI (Kg/m2)	19.65 ± 4.20	1461
Waist to hip ratio	0.85 ± 0.06	1417
Systolic blood pressure (mmHg)	98.58 ± 10.88	1457
Diastolic blood pressure (mmHg)	66.25 ± 8.80	1458
Low density lipoprotein-cholesterol (mg/dl)	102.43 ± 26.43	1462
High density lipoprotein-cholesterol (mg/dl)	50.58 ± 12.82	1462
Total cholesterol (mg/dl)	157.27 ± 33.53	1462
Triglycerides (mg/dl)	93.67 ± 49.69	1462
Fasting glucose (mmol/l)	4.57 ± 0.53	1461
Fasting insulin (mIU/l)	9.10 ± 7.05	1148
Underweight (%)	1.40	1462
Normal weight (%)	49.40	1462
Overweight (%)	21.30	1462
Obese (%)	27.90	1462
Hypertension (%)	1.50	1452
Hyperglycemia (%)	3.10	1456
Dyslipidemia (%)	34.90	1457
Type 2 diabetes family history (%)	11.98	1461
Hypertension family history (%)	16.29	1461
Overweight / obesity family history (%)	53.05	1461
