

# **Motor deficits in reading disability and language impairment: same or different?**

Several studies have found evidence of motor deficits in poor readers. There is no obvious reason for motor and literacy skills to go together, and it has been suggested that both deficits could be indicative of an underlying problem with cerebellar function and/or procedural learning. However, the picture is complicated by the fact that reading problems often co-occur with oral language impairments, which have also been linked with motor deficits. This raises the question of whether motor deficits characterise poor readers when language impairment has been accounted for – and vice versa. We considered these questions by assessing motor deficits associated with RD and LI. A large community sample provided a subset of 9- to 10-year-olds, selected to oversample children with reading and/or language difficulties, to give 48 children with comorbid LI+RD, 70 children with RD only, 34 children with LI only, and 170 typically-developing (TD) children with neither type of difficulty. These children were given four motor tasks that taxed speed, sequence, and imitation abilities to differing extents. A double dissociation emerged, such that RD was associated with poor performance on a fingertip sequencing task, whereas LI was not. In contrast, LI but not RD was associated with problems in imitating hand positions. Poor performance on a speeded peg-moving task that required a precision grip was found in both LI and RD, with the poorest performance on those with comorbid LI+RD. This study confirms that RD is associated with poor motor skills, even when LI has been accounted for, but the deficits are specific to particular tasks that involve a combination of speed and precision. The associations were reliable, but the effect sizes were relatively small, consistent with the idea that there may be overlapping risk factors for motor deficits and poor reading.

# 1 Introduction

2 It has been noted for many years that children who are poor readers may also show  
3 signs of clumsiness and poor fine motor control. In an early epidemiological study, Rutter and  
4 Yule (1970) found an excess of motor impairments in children who were poor readers relative  
5 to their IQ ('specific reading retardation'), regardless of whether this was assessed by parental  
6 report, clinical observation or direct assessment. This kind of observation has been used as  
7 evidence that reading disability is not just the result of poor teaching, but has a neurological  
8 basis (Ramus, 2004). However, the link between motor impairment and literacy problems  
9 remains poorly understood.

10 One complication is that it remains unclear whether motor impairments are a genuine  
11 correlate of reading disability, or whether they are linked more closely to other problems that  
12 co-occur with poor reading. Many children diagnosed with reading disability (or  
13 'developmental dyslexia') also have oral language problems, but these may be overlooked if  
14 language is not formally assessed (Bishop & Snowling, 2004). Studies of children with  
15 language impairments provide ample evidence that motor deficits are common in this  
16 population. These observations raise two related questions. Will we find evidence of motor  
17 impairment if we focus only on poor readers who do not have oral language problems? And if  
18 motor deficits are seen in children with combined reading and language impairments, are they  
19 the same as those in children who read well despite oral language problems?

20 Another issue concerns the variation in how motor skills are measured. Previous  
21 studies have included both fine and gross motor skills, tasks that stress speed vs. those  
22 stressing precision, and tasks that involve learning vs. those that do not. We need to clarify  
23 whether reading disability and language impairment are associated with distinct types of

motor difficulty. The answer to this question has implications for our understanding of possible neurological underpinnings of children's language and literacy problems.

In the current study we used the term "reading disability" (RD) rather than developmental dyslexia, defining RD in terms of low scores on a quantitative measure of reading accuracy in the context of normal range nonverbal IQ. A group defined this way overlaps substantially with those typically studied as cases of developmental dyslexia, but the nomenclature emphasises that this is not a clear-cut syndrome with sharp diagnostic boundaries. Furthermore, in line with most current practice, we do not distinguish between children with a substantial discrepancy between nonverbal IQ and reading or language and those with more even cognitive profiles (Stanovich, 1991). Our approach to language impairment (LI) is similar. Here too, several lines of research indicate that the nature and causes of language impairment are similar, regardless of whether there is a large discrepancy with nonverbal IQ, provided IQ is broadly within normal limits (Bishop, 1994). We focus on children scoring at the low end of reading and language ability, because these are children who attract professional concern, but this does not mean that we regard RD and LI as disorders that are distinct from normal variation.

Our first question is whether motor deficits are associated with both RD and LI. Because many children have both reading and language difficulties, the existing literatures on dyslexia and LI cannot answer this question: we need a study of children who have been explicitly assessed for both oral and written language abilities. Second, we can ask what kinds of motor impairment are most closely linked with reading and/or language problems. Various possible explanations need to be considered. It could be that the motor deficit co-occurs with other disorders because the causal factors that lead to RD and/or LI are correlated with causal factors that lead to motor problems. For instance, genetic variants that affect the risk for RD

may affect development of motor systems as well. Or the link may go beyond common causes to involve shared underlying cognitive processes – for instance, difficulties in speed of processing or sequencing. In terms of this second type of explanation, different theoretical accounts of developmental disorders predict specific problems with different aspects of movement, such as speed, sequencing or motor imitation. Thus, by pinpointing the nature of motor deficits that co-occur with reading or language difficulties, we may cast light on cognitive underpinnings of these disorders, clarifying whether they have similar origins.

We will first review what is known about different motor abilities in relation to reading and language impairments and then present new data on a large sample of children assessed for both language and literacy skills.

### *Speed*

Slow motor movements have been reported in individuals with reading difficulties, on tasks such as peg-moving and bead-threading (Fawcett & Nicolson, 1995; Stoodley & Stein, 2006), and foot-tapping (Fawcett & Nicolson, 1999). Fawcett & Nicolson (1999) saw these findings as consistent with their theory of cerebellar impairment in dyslexia, as cerebellar patients show similar deficits in these tasks. Morris et al. (1998) reported deficits in finger-tapping and finger dexterity in children with reading disability, especially in children who were poor at a task of rapid serial naming. However, Gaysina, Maughan and Richards (2010) found no association between speed on a simple finger-tapping task and poor reading in a population cohort of 15-year-olds.

In a review of motor skills in SLI, Hill (2001) noted that deficits were usually found on speeded motor tasks. An early demonstration of this was by Bishop and Edmundson (1987), who suggested that motor speed might be a marker of neurodevelopmental maturity.

They found that on a peg-moving task many 4-year-olds with language impairments improved from the impaired to the normal range over an 18-month follow-up period, with a close parallel between improvement in language skills and motor speed. They suggested a possible maturational lag in language impaired children, where the duration of the lag is related to the severity of language impairment. Bishop (2002) replicated the finding of slower peg-moving in an older group of language-impaired children, and also demonstrated deficits on a simple task that involved tapping a tally counter with the thumb as quickly as possible. Hill (2001) suggested that slow motor performance might be part of a more general slowing of cognitive processing, which has been proposed to affect SLI across several modalities (Kail, 1994).

### *Sequencing*

Advocates of the cerebellar theory of dyslexia have noted impairments of sequencing in individuals with dyslexia (Nicolson & Fawcett, 2007). Consistent with this, Stoodley, Harrison and Stein (2006) found that implicit motor learning was poor in adults with dyslexia: on a serial reaction time task, their speed did not improve when the sequence of stimuli was repeated, whereas controls showed implicit learning. In a similar vein, an underlying deficit in the learning of serial-order information has been described in developmental dyslexia, on the basis of impaired Hebbian learning (Szmalec et al., 2011). The Hebb tasks involved implicit learning of the sequence of perceived stimuli, rather than motor sequencing. However, if this kind of learning was impaired in SLI or dyslexia, it could lead to problems in automatizing the sequence of movements involved in motor tasks.

The ability to perform a sequence of actions has also been studied in children with language impairments. Bishop and Edmundson (1987) noted that children with SLI made more sequence errors in peg-moving than controls; picking up pegs in the wrong order, or

placing them in the wrong hole. Hill, Bishop, and Nimmo-Smith (1998) interpreted the greater errors in representational gesture production as an inability to implement the precise sequence of movements in children with SLI. More recently, several studies have demonstrated impairments of implicit motor learning on the serial reaction time task in children with SLI (Tomblin, Mainela-Arnold, & Zhang, 2007; Lum et al., 2010, 2012; Mayor-Dubois et al., 2012; Gabriel et al., 2013; H J Hsu & D V M Bishop, unpublished data). These studies were prompted by the procedural deficit hypothesis of Ullman and Pierpont (2005) who suggested that children with SLI have abnormalities in the procedural memory system, affecting the ability to learn both linguistic and non-linguistic sequences. Nicolson and Fawcett (2007) took this idea further, suggesting that dyslexia and SLI might be caused by impairments in different parts of the procedural learning system, with the cortico-cerebellar system implicated in dyslexia, and the cortico-striatal system in SLI. However, no studies have directly compared children with these two disorders on the same task.

### *Imitation*

Problems with motor imitation are usually thought of as characterising autistic disorder, where they are seen as part of a more general problem in social cognition (Williams, Whiten, Suddendorf, & Perrett, 2001). However, given that imitation is a key ingredient in language learning, it is worth considering whether children with SLI might also have problems with imitating, even in nonverbal contexts. A study by Vukovic, Vukovic, and Stojanovic (2010) suggested this may be the case. They asked children to imitate simple and complex movements, with fingers, hands, and arms. Children with SLI were able to imitate significantly fewer movements than typically developing children, showing a marked impairment even for simple movements, whereas control children performed at ceiling levels.

Consistent with this was a study by Dohmen, Chiat and Roy (in press), who found deficits in imitation of non-instrumental movements by much younger language-delayed children aged from 2 to 3 years.

These findings of deficits in imitation contrast with earlier findings by Hill (1998), who compared various tasks of motor praxis in children with SLI and those with Developmental Co-ordination Disorder (DCD). She found that when asked to copy meaningless hand postures and sequences, children with DCD or SLI performed as well as peers, though interpretation of this result was complicated by ceiling effects. Other results from Hill (1998), however, seem to contradict the idea of an imitation deficit in SLI. When producing representational gestures of familiar motor acts, children with SLI and children with DCD made more errors than age-matched children, and performed at a similar level to typically-developing children who were 4 years younger; importantly, this was found regardless of whether the child had to imitate the gesture, or generate it from verbal command. Hill concluded that when performing familiar actions, kinaesthetic information may be especially important, and she suggested that the praxic difficulties of children with SLI and those with DCD may have kinaesthetic origins.

#### *Current Study*

The current study compared children with RD and those with LI to typically-developing (TD) children on motor tests that varied in the demands they placed on speed, imitation and sequential order. No other study has looked closely at the motor abilities of these two groups on the same tasks. As well as considering differences between children scoring in the impaired range on reading and oral language measures, we examined correlations between quantitative measures of speech, language and reading skills.

## 141 Method

### 142 *Participants*

143 The initial sample included 388 same-sex twins recruited through the Twins Early  
 144 Development Study (TEDS), a community sample of twins born in England and Wales  
 145 (Trouton, Spinath, & Plomin, 1994). The selection and categorisation of this particular  
 146 subsample has been described in detail by Bishop, McDonald, Bird, and Hayiou-Thomas  
 147 (2009). As previously described, this sample was enriched with cases of language and literacy  
 148 problems by oversampling children who had been identified as having difficulties in these  
 149 areas on previous waves of testing. Children with nonverbal IQs less than 80 or greater than  
 150 120 were excluded. In addition, potential participants were excluded if they had evidence of  
 151 hearing loss, autism, physical handicap, or a language spoken at home other than English. A  
 152 further 16 were excluded from the current study due to incomplete data on motor measures.  
 153 This left 322 participants who were aged 9 or 10 years at the time of testing ( $M = 9.54$ ,  $SD = .$   
 154 37).

155 Children were first grouped according to reading ability. Children were classified as  
 156 having reading disability (RD) if their average score on two Test of Word Reading Efficiency  
 157 (TOWRE; Torgesen, Wagner, & Rashotte, 1999) subtests was below the 13th percentile.  
 158 Children were also categorised according to language ability, either as language typical or  
 159 language impaired (LI). Where a child had at least two scores more than 1.33  $SD$  below the  
 160 normative mean on five core language measures (see below for details), they were categorised  
 161 as LI.

162 The final sample consisted of 48 children (18 girls and 30 boys) with comorbid  
 163 LI+RD, 34 children (16 girls and 18 boys) with LI only, 70 children (34 girls and 36 boys)

with RD only, and 170 children (99 girls and 71 boys) who met criteria for neither disorder (typically developing, TD).

Data collection conformed to the Declaration of Helsinki, and ethics approval was obtained from Oxford University's Experimental Psychology Research Ethics Committee. Parents of participating children gave informed consent, and children gave verbal assent, as agreed by the Ethics Committee.

### *Language and reading tasks*

Core diagnostic tests. The battery of five core language tests, used to define LI, included expressive and receptive tests of vocabulary and sentence processing: (1) Vocabulary subtest from the Wechsler Abbreviated Scale of Intelligence (WASI: Wechsler, 1999); (2) Understanding Directions subtest from the Woodcock-Johnson III (Woodcock, McGrew, & Mather, 2001); (3) Comprehension subtest from Expressive, Receptive and Recall of Narrative Instrument (ERRNI; Bishop, 2004); (4) Mean Length of Utterance from the ERRNI; (5) NEPSY Sentence repetition (Korkman, Kirk, & Kemp, 1998). Reading was assessed using the TOWRE Phonological decoding efficiency and Word reading efficiency subtests (Torgesen et al., 1999). These assess speeded reading of real words and nonwords. Scores on the two reading subtests are highly correlated, and were averaged.

Supplementary language and literacy tests. Two additional subtests from the NEPSY, oromotor skills and nonword repetition were used to assess speech production and phonological memory respectively (Korkman et al., 1998). An average score was obtained from the Pictures and Digits Rapid Serial Naming subtests of the Phonological Assessment Battery (Frederickson, Frith, & Reason, 1997). Scores for reading accuracy, comprehension

and rate were obtained from a shortened version of the Neale Analysis of Reading Ability (Neale, 1997), which assesses reading of meaningful texts.

Nonverbal ability. The Block Design subtest from the WASI was administered as a measure of nonverbal ability (Wechsler, 1999).

All tests are standardized, but scores were restandardized relative to a normative set of twins who were representative of the whole population, to ensure comparability of norms across tests (see Bishop et al., 2009 for further details and for information on reliability of measures).

### *Motor tasks*

Motor tasks were interleaved within the battery of language and reading ability tests, in a session lasting no longer than 2 hours.

NEPSY Repetitive Fingertip Tapping (Korkman et al., 1998) is a task designed to assess finger dexterity and motor speed. Children were required to tap their index finger to their thumb on the same hand, making a circular shape. The experimenter demonstrated, and children were instructed to repeat this action as fast as possible. The time was noted for 32 correct taps. This procedure was administered using the child's preferred hand, and then repeated with the non-preferred hand. The mean time for 32 taps was inverted to give taps per second, so that proficient performance corresponded to a high score.

NEPSY Sequential Fingertip Tapping (Korkman et al., 1998) is aimed at assessing finger dexterity and motor speed, and includes sequential movement. Children sequentially tapped their thumb to each finger of the same hand, from index to little finger. Participants were asked to repeat this sequence as fast as possible, and timed for 8 correct sequences. They first completed the sequences with their preferred hand, and then their non-preferred hand.

The mean time for eight sequences was inverted to give sequences per second, so that proficient performance corresponded to a high score.

The Purdue Pegboard tests manipulative dexterity, and was administered according to the procedure described by Tiffin (1968). This task was selected to assess precision grip, which is known to depend on cerebellar activity (Monzée, Drew, & Smith, 2004). The task also includes a speed element, as children were given 30 seconds to move as many small pegs into individual peg holes (in a top-to-bottom line) as possible. Participants completed the task twice with their preferred hand, then their non-preferred hand, giving a total of 4 trials.

NEPSY Imitating Hand Positions (Korkman et al., 1998) assesses the ability to imitate hand and finger positions. Children were instructed to copy hand positions administered by the experimenter. A maximum of 20 seconds was allowed for each of the 12 hand positions. One point was awarded for each correct hand position within the time limit. Again children first completed the task with their preferred hand, and then with their non-preferred hand.

### *Analytic approach*

Previous research has not found reliable effects of language or literacy on relative hand skill (Bishop, 1990, 2001), and so scores for preferred and non-preferred hands were combined to form a composite score for each motor task. Scores were inspected and transformations applied if necessary to correct for non-normality. A natural log transform was used for the two NEPSY Fingertip Tapping tasks, and a rank transform for NEPSY Imitating Hand Positions.

Our primary goal was to consider how language and reading status affected motor performance on the different tasks, and so we included the binary categories of RD and LI as factors in SPSS multilevel linear models for each motor task. The interaction between LI and

RD was also tested to see whether the combination of both conditions had a greater impact than would be predicted from their separate effects. Sex was included as a covariate in the model. Because our participants were twins, the individual observations were not independent. This was taken into account by including family membership as a random effect in the multilevel models. Effect sizes for significant main effects are reported as Cohen's  $d$ , based on difference in estimated marginal means divided by the pooled standard deviation.

Analysis of RD and LI effects allows us to relate results to the prior literature on dyslexia and SLI, but these categories involve arbitrary subdivisions of continuous scales of language and reading ability. To explore the data in a more quantitative fashion, two-tailed Pearson correlations were computed for language and reading task standard scores with transformed motor scores, for supplementary as well as core diagnostic tests. Because of the large number of correlations computed, there is a risk of finding spurious associations, but the twin design of our study allowed for a natural replication study. Twins from each family were assigned randomly into twin group 1 or twin group 2 and correlations were run separately for each twin group, so we could establish how replicable significant correlations were.

## Results

### *Multilevel modelling*

Figure 1 shows mean raw scores on the four motor tests in relation to language and reading impairment. Log- or rank-transformed scores, as described above, were used in the analysis where appropriate to improve normality. F-ratios for the multilevel linear models are shown in Table 1.

Different patterns of results were found for the four motor tasks. On the NEPSY Repetitive Fingertip Tapping task, there was no significant effect of language impairment or reading disability, and no interaction between these factors. For NEPSY Sequential Fingertip Tapping, there was a significant effect of reading disability, but no effect of language impairment, and no interaction between these factors. In contrast, on the Purdue Pegboard, there was a substantial effect of language impairment, and a smaller but significant effect of reading disability. As can be seen in Figure 1, the lowest scores were obtained by those with a dual deficit of LI with RD, but this could be explained as an additive influence of the two conditions, as the interaction between them was not significant. This pattern of results was maintained when sex-corrected scores were used in the analysis. On the NEPSY Imitation of Hand Positions test, there was a significant effect of language impairment. The effect of reading disability was not significant and there was no interaction between the two conditions.

#### *Correlations*

Figure 2 shows the correlations between cognitive tests and motor tests in the two subsamples of twins (each containing one member of a twin pair, selected at random). For a sample of this size, a correlation of .16 is significant at .05 level, a correlation of .20 is significant at .01 level, and a correlation of .26 is significant at .001 level. None of the correlations with finger-tapping were consistently found in both samples at the .05 level.

The NEPSY Sequential Fingertip Tapping task had consistent, though modest, correlations with many of the literacy tasks, but was not reliably correlated with three of the core language measures: MLU, story comprehension or vocabulary. For this task, the highest correlation in both subsamples was with NEPSY Oromotor Sequences, suggesting that there may be a common core involvement of motor systems in sequencing speech and finger

movements. On the other hand, it is also noteworthy that all three of the indices from the Neale Analysis of Reading Ability were significantly correlated with finger sequencing, even though this task is not speeded and has limited motor demands.

The Purdue Pegboard task was reliably correlated with most of the tasks in the test battery, whereas NEPSY Imitation of Hand Positions showed an inconsistent pattern of correlations in the two subsamples of twins. Only nonverbal ability and WASI Vocabulary were consistently significantly correlated with this test in both subsamples. The correlational analysis casts some doubt on the reliability of the association of this subtest with language impairment, because associations with Woodcock-Johnson Comprehension, NEPSY Sentence Repetition and ERRNI MLU were seen in only one of the two subgroups of twins.

## Discussion

This study confirmed that motor impairments are associated with RD, even when it occurs without LI; however, there were different patterns of association for the two disorders suggesting that the underlying reasons for motor deficits are not the same.

### *Speed*

Three of the motor tasks stressed speed: NEPSY Repetitive Fingertip Tapping, NEPSY Sequential Fingertip Tapping and the Purdue Pegboard. The simplest of these tasks, Repetitive Fingertip Tapping, did not discriminate groups: children with reading disability or language impairment were as fast as typically-developing children on this measure. This contrasts with a previous study by Bishop (2002), who found reduced speed on a thumb-tapping task in language-impaired children. However, that task involved repeatedly depressing the switch on a tally counter, a novel movement which some children found

difficult to do with one hand. Our current data show that if the task demands are reduced to the bare minimum, children with developmental disorders of language and reading can perform as fast as other children.

When the child had to sustain a repetitive sequence of finger movements, however, a small deficit was seen in children with RD, and when the task was to quickly pick up and place small metal components with a precision grip, there were significant deficits associated with both LI and RD, with particularly poor performance by children who had comorbid LI+RD. These findings are compatible with previous research that has found that peg-moving tasks are sensitive indicators of motor deficits in both SLI (Bishop & Edmundson, 1987) and dyslexia (Fawcett & Nicolson, 1995).

### *Sequencing*

Problems in sequencing motor movements have been observed in children with SLI doing peg-moving (Bishop & Edmundson, 1987) and gesture production (Hill et al., 1998), and impaired sequence learning has been observed in serial reaction time tasks in both dyslexia (Stoodley et al., 2006) and SLI (e.g. Tomblin et al., 2007). In the current study, the one task that involved explicitly producing a sequence of motor movements, NEPSY Sequential Fingertip Tapping, showed a deficit for RD but not for LI. Note, however, that the NEPSY Sequential Fingertip Tapping task is very simple, and the sequence of movements is predictable. Furthermore, the correlational analysis revealed that this motor task was associated with a measure of oromotor skills (repeating tongue-twisters). This task had not been included in the diagnostic battery for LI, because it stresses articulation rather than language ability.

### *Imitation*

Imitation tasks have shown that language impaired children successfully imitate fewer movements than peers (Vukovic et al., 2010), though for one study this was only true for familiar gestures (Hill, 1998). The current study confirmed that language impaired children correctly imitated fewer hand positions, despite the fact that most of these were novel gestures. The correlational analyses revealed that this effect appears to be driven by vocabulary.

We are aware of no previous research on imitation abilities of children with reading disability, which was not associated with impaired imitation in the current study. The interesting question raised by the imitation task is whether there is some supramodal imitation ability that affects children's ability to learn language as well as their ability to imitate gestures. Imitation involves perceiving a signal produced by another person and then translating that observed percept into a motor programme for producing the same movement. Without imitation ability, language could not be learned. Insofar as imitation has been an explicit focus of research attention, this has mainly concerned children with autism, rather than SLI. Deficits in imitation are a hallmark of autism, and are thought to be a barrier to learning to communicate. Our results suggest that milder imitative difficulties may underlie slow learning in some children with LI. Nevertheless, we need to be cautious in interpreting this result. The size of the deficit seen in imitation in the LI group was relatively large (Table 1.), but the correlational analysis suggested that nevertheless this result may not be robust. When we considered correlations on individual tests across the full range of ability, the only language test to reliably relate to imitation was WASI Vocabulary. Other measures, such as MLU, Sentence Comprehension and Story Comprehension showed inconsistent correlations with the imitation tasks in the two subsets of twins. Three of the measures, NEPSY Oromotor Sequences, Nonword Repetition and Sentence Repetition, involved explicit imitation of

speech, yet these subtests were associated with the motor imitation task in only one of the two subsets of twins.

Some neurological data supports the link between language and imitation. Repetitive transcranial magnetic stimulation (rTMS) to Broca's area, well known for its role in speech production, interfered with imitation of action (Heiser et al., 2003). The stimulation did not significantly impair production of the same action when the cue to perform was spatial. This specific deficit in action imitation during rTMS suggests that certain parts of Broca's area have a role in action imitation. MRI has shown functional and structural abnormality in children with SLI. Badcock et al. (2012) found reduced activation in Broca's area in children with SLI during an inner speech task, and increased grey matter in this area compared to unaffected siblings and controls. Broca's area could be a shared area involved in both language and imitation ability. Furthermore, fMRI data showed that action observation caused activation in Broca's area (Fadiga et al., 2006). Heiser et al. (2003) described Broca's area as an area of shared neural mechanisms for communication; through language, action imitation, and action recognition.

### *General Discussion*

It is important to note that all of these tasks, even those not considered speeded, included a speed element. The sequence task was scored according to the speed with which children completed 8 sequences. This measure alone cannot tell us whether some children got lower scores because they made sequence errors, or because they were simply slower but accurate. However, as children with reading disability were no slower at repetitive fingertip tapping, it suggests that there was something specific to the sequence tapping beyond speed that caused the increased time score. Similarly, the deficit seen in the peg-moving task may be

one of dexterity or sequencing as opposed to speed. Time pressure did not appear to be a major factor affecting performance in the test of imitating hand positions, but nevertheless there was a time limit for each trial, and in future studies it would be worth noting whether some children continued to attempt the posture after the limit expired. We used existing standardized tests, which are not designed to tease apart the individual skills which may be contributing to lower performance. In future work it would be useful to devise tasks which are designed to separate the requirements for imitation, sequence and speed, and to look more directly at motor learning as well as performance.

Overall, these results provide further evidence that language and reading impairments co-occur with other deficits, seen here in poor fine motor ability compared to peers. We have also confirmed that children with RD have motor deficits affecting the sequencing of movements even when their oral language skills are intact. In contrast, deficits in imitation of hand positions were selectively associated with oral language difficulties. Our results support the view that RD and LI do not just vary in severity; although they commonly overlap. The distinctive patterns of associated motor impairment suggest we will obtain more coherent results if we assess both oral language and literacy skills when looking for neurobiological bases of these developmental disorders.

## Acknowledgements

We thank the twins and their families and teachers who participated in this research. This study would not have been possible without generous assistance of Robert Plomin, Bonamy Oliver, Alexandra Trouton, and other staff from the Twins Early Development Study.

# Figure 1

Mean scores on motor tests by group

TD = typically developing; RD = reading disability; LI = language impairment; Error bars show standard errors.

# Table 1(on next page)

F-ratios, p-values and effect sizes for main effects from multilevel model analysis for four motor tasks

Effect	Statistic	Finger tapping	Finger sequences	Purdue pegboard	Imitation of hand positions
LI	F	0.03	0.16	6.94*	8.87*
	p	.860	.688	.009	.003
	Cohen's d	.02	.05	.31	.34
RD	F	0.45	4.01*	3.98*	1.30
	p	.502	.046	.047	.255
	Cohen's d	.07	.21	.21	.12
LI x RD	F	1.70	0.15	0.77	0.94
	p	.193	.694	.381	.332
sex	F	5.45*	1.03	3.16	2.09
	p	.021	.311	.077	.150

## Figure 2

Pearson correlations between cognitive measures and motor test scores, separately for twin 1 and twin 2

A correlation of .16 is significant at .05 level; a correlation of .20 is significant at .01 level; a correlation of .26 is significant at .001 level.
